Coagulopathy is a significant risk factor and a common abnormality noted in patients with refractory HF. An abnormal international normalized ratio (INR) in the absence of warfarin use is of added concern, because it may reflect chronically high RA pressures, leading to hepatic congestion and, ultimately, to hepatic fibrosis and cirrhosis. Prolonged abnormal INR and low platelet count combined with use of anticoagulation or antiplatelet therapy are associated with significant perioperative bleeding, requiring multiple transfusions, leading to increased PVR, RV failure, decline in renal function, hemodynamic instability, and multiple-organ failure. In addition, patients with severe HF typically have a nutritional basis for abnormal coagulation because of depletion of several specific coagulation factors, such as factor VII. The minimum preoperative screen for coagulation abnormalities should include prothrombin time (PT), partial thromboplastin time (PTT), INR, platelet count, and in view of the high likelihood of previous heparin exposure, a heparin-induced thrombocytopenia (HIT) assay. The presence or development of HIT is associated with a high risk of bleeding, as well as thrombosis of MCS devices.

Other Medical Considerations

Other important medical considerations in instituting MCS include the presence or absence of significant aortic, mitral, or tricuspid valve disease, coronary artery disease, and atrial and ventricular arrhythmias, as well as intracardiac shunts. Additional content on this topic is presented in the online supplement for this chapter (Important Medical Conditions in Instituting Mechanical Circulatory Support).

Patient Outcomes

Temporary Mechanical Circulatory Support

Temporary MCS is indicated in patients with cardiogenic shock refractory to medical therapy when *rapidly achieved* augmentation of cardiac output and reduction of ventricular filling pressures are required to sustain life.[20] When used in the setting of medically refractory myocarditis or takotsubo cardiomyopathy, temporary MCS may provide time for spontaneous recovery and discontinuation of MCS. When cardiogenic shock complicates longstanding HF, temporary MCS can provide the time needed for patients, family members, and physicians to make critical decisions about long-term MCS and heart transplantation. Patients with HF severe enough to warrant long-term MCS but with reversible clinical characteristics (e.g., coagulopathy from hepatic congestion, acute renal failure from low cardiac output and high RA pressure, hypoalbuminemia resulting from cardiac cachexia and bowel edema) that put them at high risk for perioperative death with a long-term device may benefit from temporary MCS, if their risk profile could be substantially improved with temporary MCS to the extent that they would become good candidates for a durable MCS device. The clinical evaluation of temporary MCS devices for treatment of cardiogenic shock generally has not involved randomized clinical trials but rather has relied on the use of prospective, single-arm observation studies to validate device design, safety, and efficacy. **Table 29.2** summarizes extracorporeal assist devices and their characteristics.

TABLE 29.2

Temporary Mechanical Circulatory Support (MCS) Devices*

DEVICE	PUMP MECHANISM	PUMP ENERGY SOURCE	METHOD OF PLACEMENT	VENTRICLE SUPPORTED	DEGREE OF SUPPORT†
Intra-aortic balloon pump (IABP) (several manufacturers)	Counterpulsation	Pneumatic	Percutaneous placement via femoral artery or operative placement in ascending aorta or axillary artery	Principal effect: reduction of LV afterload and increase in coronary perfusion	Partial-support device
Extracorporeal life support (ECLS) (several manufacturers depending on pump selected)	Continuous-flow rotary pump with centrifugal design	Variable; depends on pump used for ECLS circuit (most frequently a continuous-flow rotary pump with centrifugal design)	Percutaneous or operative placement	Venous-arterial configuration Partial unloading of right and left ventricles by reduction in preload with oxygenation of blood	Full-support device (4-6 L/min)
CentriMag VAD (St. Jude Medical, Minneapolis)	Continuous-flow rotary pump with centrifugal design (magnetic levitation; no bearing)	Electric motor	Operative placement	Right, left, or biventricular support	Full-support device (4-6 L/min)
TandemHeart pVAD (CardiacAssist, Pittsburgh)	Continuous-flow rotary pump with centrifugal design (hydrodynamic support of impeller)	Electric motor	Percutaneous placement Requires transseptal placement of cannula for left atrial drainage Arterial return to femoral artery	LV support‡	Partial-support device (2-4 L/min)
Impella 2.5, CP, 5.0, or RP (Abiomed Corp., Danvers, Mass)	Continuous-flow rotary pump with microaxial design (bearing support of impeller)	Electric motor	Percutaneous via femoral artery (Impella 2.5, CP, or 5.0) or operative placement via aorta or axillary artery depending on device size (Impella 5.0, CP) Placement across aortic valve (Impella 5.0, CP) Inflow from left ventricle and outflow in ascending aorta	LV support or RV support (Impella RP)‡	Partial-support device 1-3 L/min for Impella 2.5 or full-support device 3.5-4 L/min for Impella CP 5 L/min for Impella 5.0

*The table includes representative MCS devices and is not meant to be an exhaustive listing of all devices currently available in the United States or internationally.

†Values of cardiac support represent approximate ranges and capabilities of the device.

‡Impella RP designed specifically for right ventricular support. Provides 4 liters or greater of flow.

Intra-Aortic Balloon Pump

The intra-aortic balloon pump remains the most commonly used MCS device (**see Fig. 29.1**). The IABP consists of a balloon catheter and a pump console to control the timing of balloon inflation and deflation. The catheter is a double-lumen, 7.5- to 8.0 French (F) catheter with a polyethylene balloon attached at its distal end, with one lumen of the catheter attached to the pump and used to inflate the balloon with gas. Helium is used because its low viscosity facilitates rapid transfer in and out of the balloon, and because it absorbs very rapidly in blood if the balloon ruptures. Timing of balloon inflation and deflation is based on electrocardiogram (ECG) or pressure triggers. The balloon inflates with the onset of diastole, which roughly corresponds with electrophysiologic repolarization or the middle of the T wave on the surface ECG, or just after the dicrotic notch on the aortic pressure tracing. Following diastole, the balloon rapidly deflates at the onset of LV systole, which is timed electrocardiographically to the peak of the R wave on the surface ECG. The IABP increases diastolic blood pressure, decreases afterload, decreases myocardial oxygen consumption, increases coronary artery perfusion, and modestly enhances cardiac output. The IABP provides modest ventricular unloading but does increase mean arterial pressure and

coronary blood flow. Patients must have some level of LV function and electrical stability for an IABP to be effective, because any increase in cardiac output depends on the work of the heart itself. Optimal hemodynamic effect from the IABP depends on several factors, including the balloon's position in the aorta, the blood displacement volume, the balloon diameter in relation to aortic diameter, the timing of balloon inflation in diastole and deflation in systole, and the patient's own heart rate, blood pressure, and vascular resistance.

The efficacy of IABP counterpulsation was recently evaluated in SHOCK II, a randomized, prospective, open-label, multicenter trial comparing IABP therapy with best available medical therapy for treatment of AMI complicated by cardiogenic shock.[21] All patients were expected to undergo early revascularization (by means of percutaneous coronary intervention or bypass surgery). At 30 days, 119 patients in the IABP group (39.7%) and 123 patients in the control group (41.3%) had died (RR with IABP, 0.96; 95% CI 0.79 to 1.17; $P = 0.69$). No significant differences were found in secondary endpoints or in process-of-care measures, including the time to hemodynamic stabilization, the length of stay in the intensive care unit, serum lactate levels, dose and duration of catecholamine therapy, and renal function. The use of IABP counterpulsation did not significantly reduce 30-day mortality in patients with AMI complicated by cardiogenic shock for whom an early revascularization strategy was planned. There have not been adequately powered randomized clinical trials of IABP to assess for a mortality benefit in cardiogenic shock occurring outside the context of an AMI.

Extracorporeal Life Support and Extracorporeal Membrane Oxygenation

Extracorporeal membrane oxygenation (ECMO) provides cardiopulmonary support for patients whose heart and/or lungs can no longer provide adequate physiologic support[22-24] (**Fig. 29.5**). ECMO can be either venovenous (VV) for oxygenation only or venoarterial (VA) for oxygenation and circulatory support. In cases of biventricular failure, VA ECMO is the MCS of choice for patients in cardiogenic shock and impaired oxygenation, since it provides full cardiopulmonary support. ECMO may be placed at the bedside without fluoroscopic guidance. ECMO is similar to a CPB circuit used in cardiac surgery. VA ECMO involves a circuit composed of a continuous-flow centrifugal pump for blood propulsion and a membrane oxygenator for gas exchange. A venous cannula drains deoxygenated blood into a membrane oxygenator for gas exchange, and oxygenated blood is subsequently infused into the patient through an arterial cannula. VA ECMO provides systemic circulatory support with flows sometimes exceeding 6 L/min depending on cannula size. Because of the increase in systemic afterload, however, VA ECMO alone may not significantly reduce ventricular wall stress and may result in LV distension in cases where residual LV function is inadequate to eject against the increase in systemic afterload. This may result in high myocardial oxygen demand (secondary to high filling pressures and volume). This may have negative consequences on myocardial recovery unless the left ventricle is unloaded by concomitant IABP, an LV vent, atrial septostomy, or use of a percutaneous LV-to-aorta VAD.

Numerous large clinical series have reported successful use of extracorporeal life support (ECLS) for cardiac and respiratory support in adult, pediatric, and neonatal patients.[22,24] In the largest series to date, Bartlett and colleagues[24] at the University of Michigan reported on outcomes for 1000 patients supported with ECLS from 1980 through 1998. Cardiac failure was the indication for support in 146 cases. Survival to hospital discharge occurred in 33% of adult patients (31 cases) and in 48% of pediatric patients (105 cases). Survival in adult patients was improved by using ECLS as a bridge to placement of longer-term implantable devices in patients who did not demonstrate early recovery of myocardial function. However, the availability of long-term implantable devices has extended the use of ECLS to situations where recovery of myocardial function is unlikely.

Left Atrium to Aorta Assist Device

The TandemHeart paracorporeal ventricular assist device (pVAD) is a percutaneously inserted extracorporeal left atrial–aorta assist device that pumps blood from the left atrium to the femoral artery through a transseptally placed LA cannula, thereby bypassing the left ventricle entirely (**see Fig. 29.4**). The TandemHeart system includes a 21F transseptal cannula, a centrifugal pump, a femoral arterial cannula, and a control console. The TandemHeart is approved by FDA to incorporate an oxygenator to the circuit, allowing for concomitant LV unloading and oxygenation. The centrifugal blood pump contains a hydrodynamic bearing that supports a spinning impeller. The impeller is powered by a brushless direct-current (DC) electromagnetic motor, rotating between 3000 and 7500 rpm. The external console controls the pump and provides battery backup in case of power failure. A continuous infusion of heparinized saline flows into the lower chamber of the pump, which provides lubrication and cooling, and prevents thrombus formation. The redirection of blood from the left atrium reduces LV preload, LV workload, filling pressures, wall stress, and myocardial oxygen demand. The increase in arterial blood pressure and cardiac output supports systemic perfusion. The flow through the TandemHeart is additive to LV output through the aortic valve (parallel circulation). However, the contribution from the native heart is typically reduced as MCS support is increased due to changes in LV loading conditions (i.e., decrease in preload and increase in afterload). Coronary flow is driven by the perfusion pressure (diastolic pressure − right atrial pressure). With a parallel circulation, the aorta is perfused and pressured by both the left ventricle and the TandemHeart. Not infrequently, LV contraction (native heart output) may be negligible, and systemic perfusion is pump dependent, with a flat mean arterial pressure curve. This situation can result in stasis of blood within the aortic root, resulting in thrombus formation and stroke.

In a randomized comparison of IABP with the TandemHeart, Thiele and colleagues[25] reported a more effective improvement in cardiac power index as well as other hemodynamic and metabolic variables with the TandemHeart pVAD compared with the IABP. Complications such as severe bleeding and limb ischemia, however, were encountered more frequently after VAD support. Thirty-day mortality rates were similar between the groups, but the study was underpowered to compare mortality between groups.

Left Ventricle to Aorta Assist Device

The Impella is a continuous flow micro-axial pump designed to pump blood from the LV into the ascending aorta, in series with the LV (**see Fig. 29.3**). Three versions are available for LV assist and include the 12F (Impella 2.5) and 21F (Impella 5.0), which provide maximal flow rates of 2.5 and 5.0 L/min, respectively, and the 14F device (Impella CP), with an intermediate level of support of 3.0 to 4.0 L/min. A device specifically designed for RV support, the Impella RP, is also available. The devices for LV assist are designed to be placed via the femoral artery, either percutaneously (Impella 2.5 and CP) or with a surgical cutdown (Impella 5.0). Alternate access sites such as the subclavian artery have been described but are not routinely used. The tip of the catheter is a flexible pigtail loop that stabilizes the device in the LV with a low likelihood of perforation. The pigtail connects to the cannula that contains the pump inlet and outlet areas, motor housing, and pump-pressure monitor. The 9F catheter shaft proximal to the pump houses the motor power leads and purge and pressure measurement lumens. The catheter's proximal end consists of a hub for attachment of a console cable and side arms for attachment of purge solution and pressure-measurement tubing. The Impella CP device has just recently become available in the United States, so the most experience to date has been with the Impella 2.5 device. The Impella pumps blood from the left ventricle into the ascending aorta, thereby unloading the LV and increasing forward flow. It reduces myocardial oxygen consumption, increases coronary perfusion, improves mean arterial

pressure, and reduces PCWP. The Impella 2.5 provides a greater increase in cardiac output than the IABP but less than the TandemHeart device. The more powerful Impella CP and 5.0 devices are comparable to the TandemHeart device in terms of support. Similar to the TandemHeart, adequate RV function or concomitant RVAD is necessary to maintain LV preload and hemodynamic support during biventricular failure or unstable ventricular arrhythmias.

In a prospective, randomized clinical trial comparing the Impella 2.5 to the IABP, cardiac index was significantly increased in patients with the Impella 2.5 compared with patients supported with an IABP.[26] Overall mortality rates at 30 days were similar in both groups, but the study was not adequately powered to assess for a mortality difference.

Despite the absence of suitably powered randomized clinical trials demonstrating a mortality benefit over IABP therapy (which itself has no proven mortality benefit), the use of temporary MCS devices in patients with cardiogenic shock is likely to continue. In comparison with an IABP, these devices provide a much larger increment in cardiac output and superior LV unloading.

Devices Intended for Long-Term Mechanical Circulatory Support

The introduction of continuous-flow technology into clinical practice was a milestone in the field of MCS therapy and led to significant improvements in survival and reduction of serious major adverse events, especially in the area of device malfunction. Compared with pulsatile-flow devices, continuous-flow technology provides functionally equivalent hemodynamic support improvement of kidney and liver function. Long-term survival with continuous-flow technology is significantly better with half the rate of stroke and infection and one-third the rate of device malfunction compared to pulsatile-flow technology. **Table 29.3** summarizes the characteristics of durable MCS devices intended for long-term use.

TABLE 29.3

Long-term Durable Mechanical Circulatory Support (MCS) Devices*

DEVICE	PUMP MECHANISM	PUMP ENERGY SOURCE	METHOD OF VENTRICLE PLACEMENT SUPPORTED		INDICATION
HeartMate 3† (St. Jude Medical, Minneapolis)	Continuous-flow rotary pump with centrifugal design and magnetic levitation of internal impeller	Electric motor Power to pump delivered via percutaneous lead with external power source and computer controller	Operative	Left ventricle Implantable pump with intrapericardial placement	Long-term support (intended for BTT and DT indication)

Durable Implantable Left Ventricular Assist Devices

HeartMate 3

The HM3 is intended for long-term support of patients with advanced HF (**see Fig. 29.5**). HM3 is currently in clinical evaluation for long-term support indication in the Multicenter Study of MagLev Technology in Patients Undergoing Mechanical Circulatory Support Therapy with HeartMate 3 (MOMENTUM) trial. MOMENTUM is a multicenter randomized clinical trial evaluating the HM3 to the HeartMate II pump. Initial results of a short-term cohort (6-month follow-up) have been reported.[9] Of 294 patients, 152 were assigned to the HM3 centrifugal-flow pump group and 142 to the HeartMate II axial-flow pump group. In the intention-to-treat population, the primary endpoint (disabling stroke-free survival at 6 months while supported on original device, or transplanted or explanted for myocardial recovery) occurred in 131 patients (86.2%) in the HM3 group and in 109 (76.8%) in the HeartMate II group (absolute difference, 9.4 percentage points; 95% lower confidence boundary, −2.1; $P < 0.001$ for *noninferiority*; hazard ratio [HR], 0.55; 95% CI 0.32 to 0.95; two-tailed P = 0.04 for superiority). There were no significant between-group differences in the rates of death or disabling stroke, but reoperation for pump malfunction occurred less in the HM3 than in the HeartMate II group (1 [0.7%] vs. 11 [7.7%]; HR, 0.08; 95% CI 0.01 to 0.60; $P = 0.002$). Suspected or confirmed pump thrombosis did not occur in the centrifugal-flow pump group but was experienced by 14 patients (10.1%) in the axial-flow pump group (**Table 29.4 and eTable 29.1**).

CAP, Continued access protocol; *HCVA,* hemorrhage cerebrovascular accident; *HF,* heart failure; *ICVA,* ischemic cerebrovascular accident; *RVAD,* right ventricular assist device.

HeartMate II

The HeartMate II (**see Fig. 29.7**) is intended for long-term support of patients with advanced HF and is the most evaluated MCS device to date, with more than 13,000 implantations worldwide. Patient outcomes after implantation of the HeartMate II have been extensively evaluated in five major scientific reports on its use for BTT and DT indications within the context of pre- and postapproval clinical trials[5,27-30] (**Table 29.4 and eTable 29.1**). Additional content on this topic is presented in the online supplement for this chapter (Clinical Trials with the HeartMate II Device).

HVAD

The HVAD has undergone clinical evaluation in the United States for BTT indication in a prospective, nonrandomized clinical trial, ADVANCE[31,32] (**Table 29.4 and eTable 29.1**). The unique feature of ADVANCE was the use of a contemporaneous, observational control arm derived from registrants entered into INTERMACS. The primary outcome in ADVANCE was success defined as survival on the originally

implanted device, transplantation, or explantation for ventricular recovery at 180 days and was evaluated for both noninferiority and superiority. A total of 140 patients received the investigational pump, and 499 patients received a commercially available pump (the HeartMate II in at least 95% of cases) implanted contemporaneously. Success was achieved in 90.7% of patients on the investigational pump and in 90.1% of controls, establishing the noninferiority of the investigational pump ($P < 0.001$; 15% noninferiority margin). At 6 months, median 6-minute walk distance increased by 128.5 meters, and both disease-specific and global quality-of-life scores improved significantly. The HVAD was approved for use in the United States for the BTT indication in 2012 and currently is completing clinical evaluation in the United States for the DT indication; the ENDURANCE and ENDURANCE Supplemental Trials are multicenter randomized clinical trials comparing the HVAD to the HeartMate II.

Total Artificial Heart

SynCardia Total Artificial Heart–Temporary (TAH-t)

Another option for MCS is the total artificial heart (TAH). The 70-mL stroke volume version of the SynCardia CardioWest Total Artificial Heart–Temporary (TAH-t; **Fig. 29.10**) was evaluated in a large, prospective, nonrandomized trial conducted in five centers for BTT indication in 81 patients at risk for imminent death from irreversible biventricular cardiac failure.[33] The study cohort was compared with a nonrandomized, observational control cohort of 35 patients. The primary study endpoints included the rates of survival to heart transplantation and survival after transplantation. The rate of survival to transplantation was 79% (95% CI 68% to 87%). Of the 35 patients in the control cohort who met the same entry criteria but did not receive the TAH-t, 16 (46%) survived to transplantation ($P < 0.001$). Overall, the 1-year survival rate among the patients who received the TAH was 70%, compared with 31% among the controls ($P < 0.001$). After transplantation, 1-year and 5-year survival rates among patients who had received the TAH were 86% and 64%.[33] The SynCardia TAH-t was approved by the FDA for BTT in 2007. The TAH-t is currently being evaluated in the United States for DT indication. A smaller version of the device (50-cc ventricle) is also being evaluated in U.S. clinical trials.

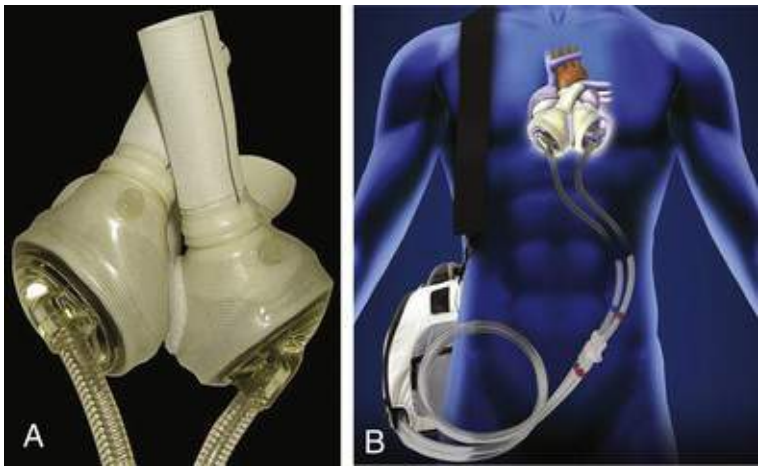

FIGURE 29.10 Syncardial Total Artificial Heart-Temporary (Syncardia Systems, Tucson, Arizona). **A,** The TAH-t consists of a right and left prosthetic ventricle. The prosthetic ventricles, made of biocompatible polyurethane, have a capacity of 70 mL. A 50-cc prosthetic ventricle is currently being evaluated in clinical studies in the United States to permit use in patients with small body habitus. The ventricles are pneumatically driven with four flexible polyurethane diaphragms positioned between the blood surface and the air sac. When compressed air is forced into the air sacs simultaneously, compression is effected onto the blood sac and ejection occurs in simulation of cardiac systole. Cardiac ejection in the TAH-t thus occurs in parallel from the left and right sides. As the air sac is deflated, the blood sac is filled passively from the atrial connection. Two mechanical valves are situated along the prosthetic ventricle to provide unidirectional inflow and outflow. The prosthetic ventricles are connected by quick-connect silicone cuffs to two atrial connectors on the cuffs (*not shown*), and two connectors on the end of the grafts are sewn to the aorta and pulmonary artery. The compressed air is delivered by an external console (*not shown*) through two separate air tubes connected to the right and left prosthetic ventricles. The console has two independent controllers that allow redundancy for emergency backup. Compressed air cylinders inside the console can be used to mobilize the patient. **B,** Portable drive unit to permit hospital discharge and improve patient mobility is also available.

Interagency Registry of Mechanically Assisted Circulatory Support

An important milestone in the advance of MCS therapy has been the development of the National, Heart, Lung and Blood Institute (NHLBI)–sponsored national registry, the Interagency Registry for Mechanically Assisted Circulatory Support (INTERMACS). INTERMACS is the largest available data repository for the study of durable MCS outcomes.[34] INTERMACS represents a collaboration between the NHLBI, the FDA, the CMS, device manufacturers, and the professional community and began prospective patient enrollment and data collection in June 2006. In March 2009, CMS and the U.S. Department of Health and Human Services mandated that all U.S. hospitals approved for use of MCS for DT enter MCS patient data into INTERMACS for all noninvestigative MCS devices approved by FDA. Although mandated data entry was discontinued by CMS in October 2013, the number of DT implants entered annually into INTERMACS has increased. Since the inception of INTERMACS, the ongoing evolution of strategies for device application and the types of available devices has continued to refine the landscape of MCS. The major limitation of INTERMACS is the inability to enter patient information on investigative devices currently in evaluation in the United States, as well as the need for informed consent, which represents a barrier for capture of all patients receiving MCS therapy. To date, data on more than 15,000 patients receiving durable MCS therapy have been reported to INTERMACS.[34] The overall survival rate for all patients undergoing primary implantation of a durable MCS device is approximately 80% at 1 year and 70% at 2 years[34] (**Fig. 29.11**). Survival for patients undergoing primary implantation with an LVAD was

superior to survival with bilateral VAD or TAH.

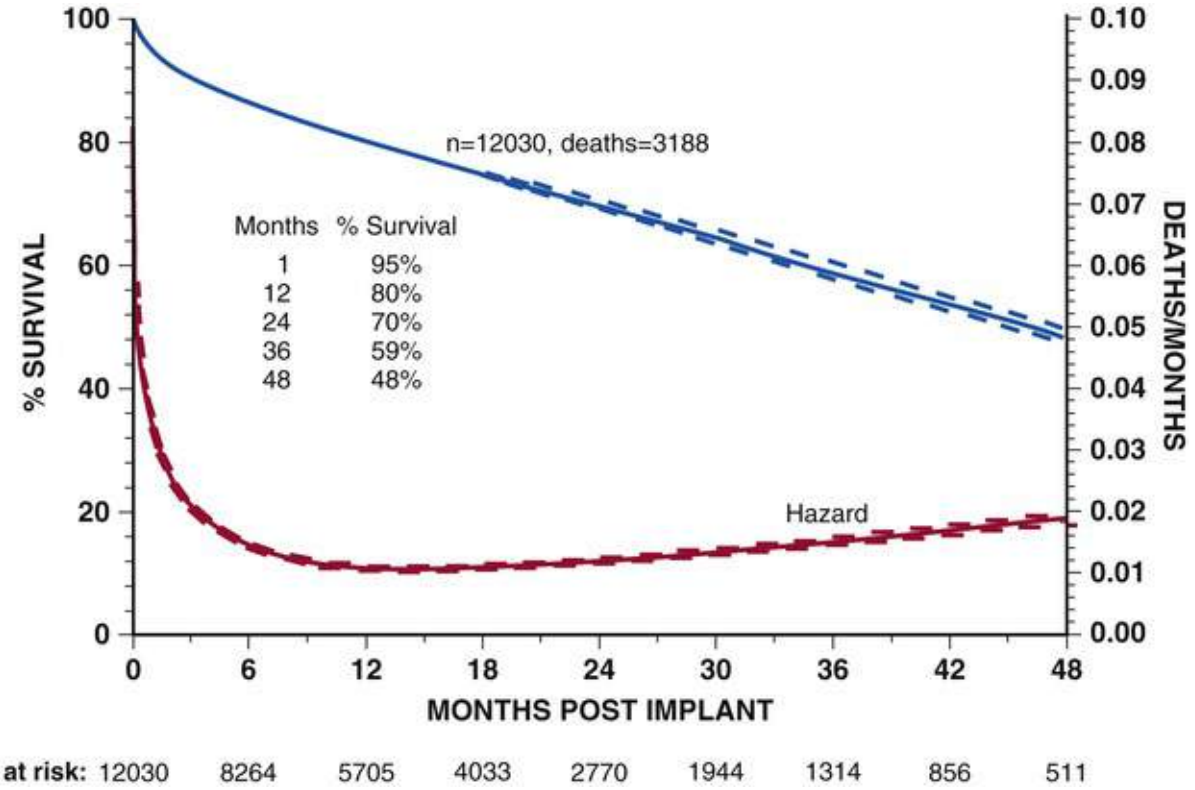

FIGURE 29.11 Actuarial and parametric modeling of survival after implantation of primary continuous-flow LVADs with or without concomitant RVAD support. The *upper curve* displays the Kaplan-Meier survival estimates over time. The *lower curve* indicates the hazard function, or instantaneous risk, over time. The *dashed lines* indicate the 70% confidence limits. (Data from Kirklin JK, Naftel DC, Pagani FD, et al. Seventh INTERMACS annual report: 15,000 patients and counting. J Heart Lung Transplant 2015;34:1495.)

One of the most important contributions to the MCS field has been the development of a subjective classification system based on severity of illness, termed "INTERMACS Patient Profiles," which range from Profile 1 (critical cardiogenic shock) to Profile 7 (advanced NYHA Class III HF)[35] (**Table 29.5**). This classification system has added enhanced resolution of patient outcomes in the advanced stages of HF or cardiogenic shock beyond that offered by the NYHA classification system. INTERMACS patient profiles are associated with short-term survival following LVAD implantation and are used to inform appropriate timing of intervention with durable, implantable MCS devices. Patients undergoing implantation of an MCS device who have critical cardiogenic shock (INTERMACS Patient Profile 1) have worse long-term outcomes than patients with more stable forms of advanced HF (INTERMACS Patient Profile levels 2 through 7).[34] Patients with significant organ dysfunction at MCS device implantation, accompanied by a greater degree of hemodynamic compromise, are significantly more likely to require BiVAD support and are at higher risk for major adverse events and at significantly higher risk for death during use of MCS devices.

TABLE 29.5

INTERMACS Patient Profiles

PROFILE	DEFINITION	DESCRIPTION
1	"Crashing and burning"	Life-threatening hypotension and rapidly escalating inotropic pressor support, with critical organ hypoperfusion confirmed by worsening acidosis and lactate levels.
2	"Inotrope dependent and worsening"	Shows signs of continuing deterioration in nutrition, renal function, fluid retention, or other major status indicator *or* refractory volume overload, ± evidence of impaired perfusion, with inotropic infusion intolerance due to tachyarrhythmias, clinical ischemia, or other.
3	"Stable on inotropes"	Clinically stable on mild-moderate doses of IV inotropes (or has a temporary MCSD) after repeated failures to wean without symptomatic hypotension, worsening symptoms, or progressive organ dysfunction. May be either at home or in the hospital.
4	"Frequent flyer/resting symptoms"	At home on oral therapy but frequently has symptoms of congestion at rest or with ADLs. May have orthopnea, SOB during ADLs, GI symptoms, disabling ascites, or severe lower extremity edema.
5	"Exercise intolerant"	Comfortable at rest but unable to engage in any activity, living predominantly within the house or housebound. No congestive symptoms, but may have chronically elevated volume status, frequently with renal dysfunction, and may be characterized as exercise intolerant.
6	"Walking wounded"	Comfortable at rest without evidence of fluid overload, but able to do some mild activity. ADLs are comfortable and minor activities outside the home can be performed, but fatigue results within a few minutes of any meaningful physical exertion. Occasional episodes of worsening symptoms; likely to have had a hospitalization for heart failure within the past year.
7	"Advanced NYHA Class III"	Clinically stable with a reasonable level of comfortable activity, despite history of previous decompensation that is not recent. Usually able to walk more than a block. Any decompensation requiring IV diuretics or hospitalization within the previous month should make this person a Patient Profile 6 or lower.

Future Perspectives

Recent rapid technological advancements and successful clinical application of mechanical circulatory support have provided a major impetus to extending the use of this modality. Important initiatives that will contribute significantly to future directions in MCS therapy include (1) introduction of new MCS devices that focus on miniaturization and biventricular support applications; (2) implementation of partial-support MCS devices and regimens; (3) design of fully implantable MCS devices, with elimination of the percutaneous lead and introduction of wireless energy transfer; (4) specific developments in the field of pediatric MCS, including appropriately designed MCS devices, clinical trials, and national registry development; (5) evaluation of MCS therapy in patients with less advanced HF; and (6) harmonization of the global MCS experience through international registry initiatives. A number of new MCS devices are under development. The MVAD (Medtronic) is a small, implantable continuous-flow rotary pump with axial design.[6,36] The pump uses hydromagnetic levitation of the impeller that eliminates the need for an internal bearing for impeller support. The small size of the pump facilitates applications to minimally invasive surgical implantation, biventricular support applications, and different inflow and outflow configurations.[36]

The percutaneous lead has been a significant source of morbidity and adversely influences quality of life for patients on MCS support.[37] The introduction of wireless energy transfer will allow MCS systems to receive energy transcutaneously without the need for the percutaneous lead.[38] The entire MCS system will be implantable, with an internal power source providing short periods of support, allowing the patient to pursue activities that are restricted with current technology, such as swimming and bathing. The incorporation of this type of technology, if successful, can be expected to increase patient satisfaction and quality of life significantly.

To date, a majority of MCS devices have been designed to provide complete cardiac output or full support. As MCS therapy moves into populations of patients with less advanced HF, the concept of small,

partial-assist MCS devices has been developed to reverse HF symptoms with only limited assist of cardiac function. The C-Pulse is a counterpulsation device similar in concept to the IABP but is implanted around the ascending aorta, rather than being placed into the circulation.[39,40] The major feature of the device is the reduction in potential risk of stroke, because the device is not incorporated into the circulation and can be turned on and off without risk of device thrombosis (nonobligatory). The Intravascular Ventricular Assist System (iVAS; NuPulse CV, Raleigh, NC) is a small IABP for partial circulatory support that is placed with a minimally invasively approach in the descending aorta via subclavian artery access. As with the C-Pulse, the iVAS is designed to be nonobligatory. A small, wearable pneumatic driver allows full ambulation.

Important developments in the pediatric field include the PumpKIN Trial (Pumps in Kids, Infants and Neonates).[41] PumpKIN is an NHLBI initiative to investigate the use of several novel pump designs and ECLS systems for pediatric MCS application. The trial is investigating two unique miniaturized ECLS systems and an implantable pump design based on the Jarvik 2000 VAD.[41] The initiative is a collaboration among industry, clinical centers, and the New England Research Institutes (NERI), designated as the data-coordinating center for the trial. Two national registries will serve as contemporary observational control arms for the new devices studied in PumpKIN. PediMACS, an INTERMACS initiative dedicated to pediatric patients, will serve as the contemporary observational arm for the PumpKIN trial using the FDA-approved pediatric device Berlin Heart Excor Pediatric VAD. Data for the MCS devices designed for ECLS in the PumpKIN trial will be compared against contemporaneous outcomes for ECLS in the Extracorporeal Life Support Organization (ELSO) Registry.

Widespread interest in MCS therapies has resulted in global adoption and clinical application of this technology. An understanding of international outcomes based on uniform definitions of outcomes and adverse events is essential to the sustainability of MCS therapy and to foster efficient device development and clinical evaluation. IMACS is an international registry collaboration supported by the International Society of Heart and Lung Transplantation and INTERMACS that was initiated to achieve international cooperation on reporting of MCS outcomes.[42] Efforts to create uniform registration and reporting requirements worldwide constitute an important initiative of the FDA to facilitate clinical device evaluation in the United States.[43]

Engineering Designs of Ventricular Assist Devices (VADs)

General Characteristics

VADs share a number of basic components despite the differences in design and indications for use. All systems for left-sided support (arterial system), whether temporary or designed for long-term use, consist of an inflow cannula that drains blood from the heart (most often directly from the left ventricular (LV) apex or from the left atrium via the right superior pulmonary vein or transseptal approach) to the pump and an outflow cannula that carries blood back to the arterial system by way of the aorta or femoral, axillary, or carotid artery, depending on the particular MCS device. For right ventricular (RV) support systems, cannulas usually are positioned to drain blood from the right atrium (most common) or right ventricle and return blood to the pulmonary artery. Temporary devices typically have long cannulas that attach to the heart, traverse the skin, and then connect to the pump. Although the actual pump may reside in the body, as with the Impella device (**see Fig. 29.3**), the motor to drive the pump for temporary MCS devices is located outside the body (in an extracorporeal position) (**Figs. 29.2 to 29.5**). Long-term, implantable MCS devices generally are designed with very short inflow cannulas, as with the HeartMate II (**Fig. 29.7**), or have incorporated the inflow cannula into the pump, as with the HeartMate 3 (**Fig. 29.6**) and HVAD (**Fig. 29.8**). The power supply for implantable pumps is delivered through a percutaneous lead

that traverses the skin and connects the external power system with the internal pump. The external components of an implantable system generally consist of a power source (i.e., batteries or alternating-current [AC] power unit) and a small, portable computer (controller) that controls device speed and monitors device function (**see Fig. 29.9**).

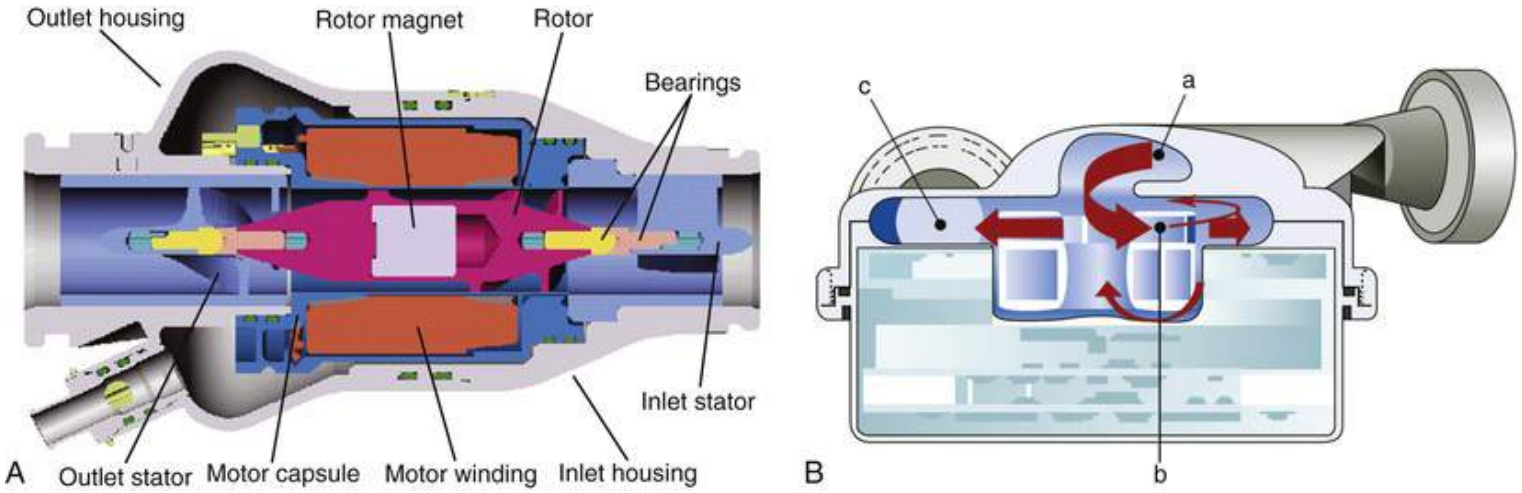
Pulsatile-Flow, Volume-Displacement Pumps

Early MCS devices were based on a volume-displacement design with pulsatile flow that mimicked the phasic contractions of the human heart, but are now largely of historical interest, and are no longer commercially available for adult patients. The major feature of these pulsatile, paracorporeal or implantable pulsatile systems that contributed to their use was the flexibility to provide biventricular support. Today, the use of pulsatile pumps is restricted to temporary MCS support as extracorporeal pumps for bridge to recovery (BTR) or as paracorporeal pumps for bridge to transplantation (BTT) indication in pediatric patients who do not have other options for implantable, durable pumps.

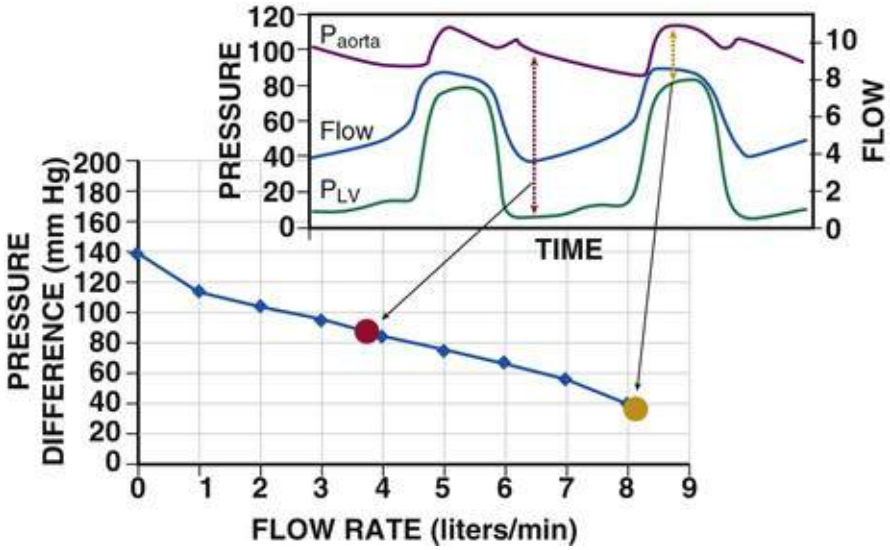
Continuous-Flow Rotary Pumps

The field of MCS has significantly evolved from volume-displacement pulsatile pumps to continuous-flow rotary pumps. This trend has continued for both short- and long-term MCS device designs. Continuous-flow rotary pumps offer several advantages over pulsatile-flow, volume-displacement pumps. These advantages include smaller size, fewer moving parts (resulting in greater durability and reliability), limited blood contacting surfaces, and reduced energy requirements.

A continuous-flow pump consists of blood inlet and outlet ports and a single rotating impeller suspended within a tube that propels blood forward by spinning the internal impeller at high speeds, thereby imparting significant kinetic energy to the blood (**eFig. 29.1**). The spinning of the impeller is accomplished by actuating an electrical current and magnetic field around the impeller, which contains internal magnets. Although continuous flow through the pump occurs throughout the cardiac cycle, there are also superimposed phasic changes in pump flow. Pump flow is greater during native cardiac systole than during native cardiac diastole because native LV contraction raises intracardiac pressure, thereby lowering the pressure gradient (the difference between aortic and LV pressures) the pump must overcome to generate forward flow (**eFig. 29.2**). These phasic changes in blood flow with a rotary pump impart a pulse to the native circulation. The magnitude of pulse pressure typically is diminished compared with that generated with a native heart contraction or pulsatile-flow pump. Under normal circumstances (pump working in conjunction with the native heart contraction), the aortic flow pattern with a rotary pump is more accurately described as being *continuous*, rather than using the description of “nonpulsatile flow.” In circumstances where native heart contraction is absent (e.g., ventricular fibrillation), the flow through a continuous-flow rotary pump is nonpulsatile.



EFIGURE 29.1 Axial and centrifugal pump designs. **A,** Continuous-flow rotary pump with axial flow design. The internal impeller is supported by outflow and inflow stators (mechanical pivot design) with bearings. The internal impeller contains a magnet. Rotation of the impeller is achieved by an alternating magnetic field generated from the motor and electrical coils surrounding the impeller. **B,** Continuous-flow rotary pump with centrifugal design. Internal impeller supported by magnetic levitation. Bearings are eliminated. The impeller rotation is achieved by motor stators that are magnetically coupled to the impeller. Schematic diagram demonstrates the blood flow path from the inflow section (*a*), blood flow path through the impeller and the backflow paths above the shroud and between the rotor and the motor (*b*), and outflow path (*c*). (From Farrar DJ, Bourque K, Dague CP, et al. Design features, developmental status, and experimental results with the HeartMate III centrifugal LV assist system with a magnetically levitated rotor. ASAIO J 2007;53:310.)



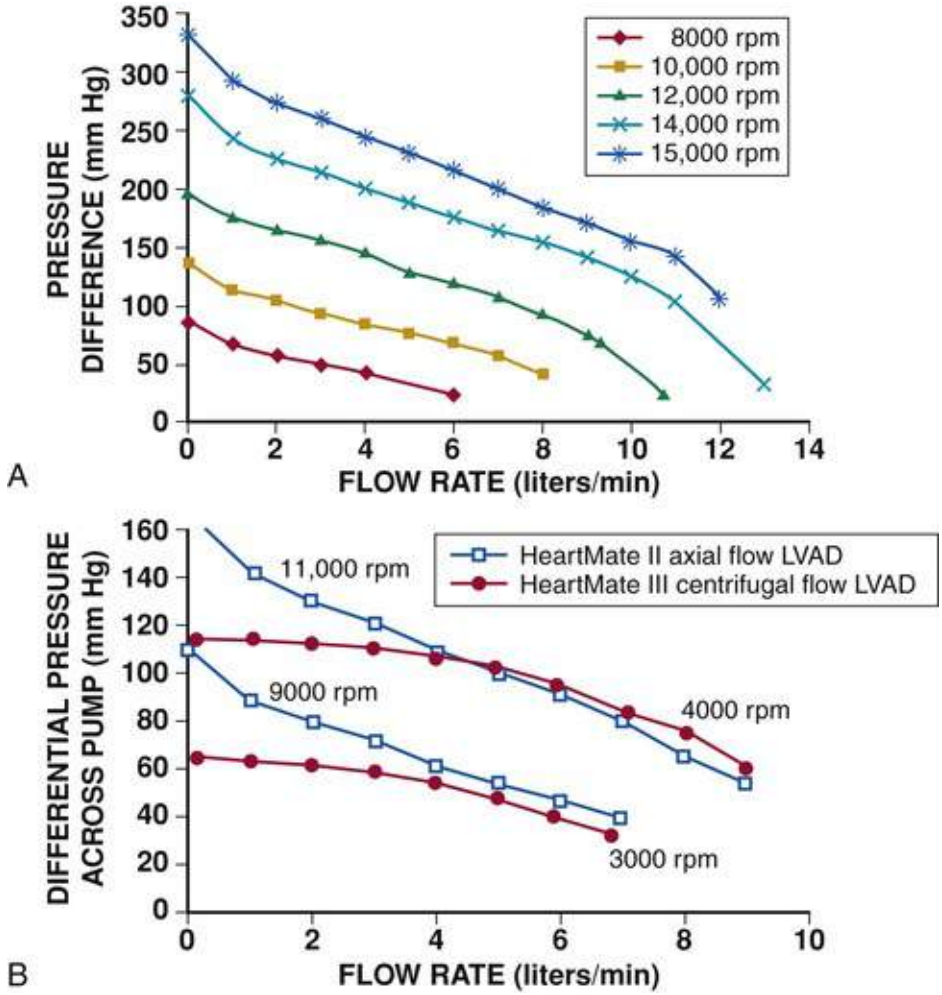
EFIGURE 29.2 Blood flow in a continuous-flow rotary pump is both continuous during the entire cardiac cycle and phasic (more flow through the pump is observed during native cardiac systole than during native cardiac diastole because of the interaction between native heart contraction and hydrodynamic properties of pump). These phasic changes in blood flow with a rotary pump are caused by a change in pressure gradients across the pump resulting from changes in native diastolic and systolic pressures. During diastole, the pressure gradient across the pump (the difference between aortic [P_{aorta}] and left ventricular [P_{LV}] pressures) is greatest, resulting in less flow. During systole, the pressure gradient across the pump (difference between P_{aorta} and P_{LV}) is less, resulting in more flow. These pressure changes induce corresponding changes in flow that impart a pulse to the native circulation.

Other important distinguishing characteristics of continuous-flow pumps are the flow pattern and the mechanism of impeller support (**see eFig. 29.1**). A distinguishing feature of continuous-flow pumps is the method by which the internal impeller is supported. The internal impeller in axial or centrifugal designs may or may not be supported by mechanical bearings (mechanical pivot design). Levitation systems

utilized in more advanced rotary pumps suspend the moving impeller within the blood field without any mechanical contact. Magnetic forces may be *passive* without the consumption of power (permanent magnet) or *active* (induction of magnetic field with electricity) in design. Hydrodynamic levitation depends on fluid forces generated by the rotating impeller. Pump designs can be further distinguished by the use of hydrodynamic levitation only, hydrodynamic levitation working in synergy with magnetic levitation for suspension, or variations of active and/or passive magnetic levitation. Active magnetic levitation of the impeller typically uses complex position sensing and control systems that increase requirements for a larger pump size. Hydrodynamic suspension does not use position sensors, resulting in a less complicated electronic design and ability to miniaturize pump size. However, in circumstances of low rotational speeds or if the pump were to stop, hydrodynamic forces may be inadequate to prevent the impeller from coming into contact with the outer device housing, potentially causing impeller damage or heat generation and leading to thrombus formation.

There are theoretical benefits to incorporation of a bearingless design into pumps. Having bearings present in the blood path to suspend the impeller constitutes a potential point of frictional wear and of heat generation. Frictional wear of the bearing may result in device failure and subsequent need for device exchange. Bearings also may represent a potential site for thrombus formation at the interface of the impeller and bearing if the bearing design does not permit adequate blood “washing” of the bearing surfaces and creates localized areas of blood stasis. Heat generated by the contact of the impeller and bearing is dissipated by blood flow through the pump. Periods of low flow through a pump can result in inadequate heat transfer from the bearing and result in denaturation and deposition of proteins on the bearing. This deposition could contribute to future thrombus formation or hemolysis. Additionally, the presence of stators that support the bearings and act to redirect blood flow in second-generation pumps also represents an obstruction within the blood flow path and a potential site for thrombus deposition.

Blood flow through continuous-flow pumps, both axial and centrifugal, is directly proportional to pump speed and inversely related to the pressure difference across the inlet (LV pressure) and outlet (aortic pressure) orifices of the pump. Centrifugal devices are generally more efficient at energy transfer and provide continuous flow at rotational speeds that are much slower, approximately 2000 to 6000 rpm, compared with 8000 to 15,000 rpm for pumps with axial-flow designs. The relationship between pressure and flow can be displayed in a series of so-called H-Q curves, reflecting blood flow (Q) over varying pressure gradients (H, for pressure head) at specific pump speeds, the pressure-flow relationship (**eFig. 29.3**).



EFIGURE 29.3 Hydrodynamic properties of a continuous-flow rotary pump. **A,** Blood flow through a continuous-flow rotary pump is inversely related to pressure gradient (the difference between aortic and LV pressures) across the pump and directly related to pump speed. This pressure-flow relationship is visualized by a series of pressure-flow curves at different pump speeds. **B,** In this example the pressure-flow relationship for the axial flow pump is steeper than for the centrifugal flow pump. The less steep pressure-flow relationship of the centrifugal flow pump elicits greater variation in pump flows during the cardiac cycle, that is, larger changes. LVAD, Left ventricular assist device.

The relationship between flow and pressure with axial pumps differs from that of centrifugal pumps. With centrifugal blood pumps, the pressure-flow relationship generally tends to be less steep (this may not be the case with all pumps), such that small changes in pressure across a centrifugal pump produce larger changes in blood flow compared with those occurring with an axial pump (**eFig. 29.3**). The more responsive pressure-flow relationship in centrifugal pumps results in a greater degree of flow variability across the cardiac cycle (less flow in diastole and more flow in systole). In theory, the benefits of centrifugal versus axial pumps are a greater aortic pulse pressure and less propensity to create LV collapse or a “suction event” resulting from the greater drop in pump flow as LV end-diastolic pressures decrease. LV collapse or suction events elicited by a VAD may cause ventricular arrhythmias or may increase the propensity for thrombus formation on bearings because of low flow or on the endocardium because of trauma.

Important Medical Conditions in Instituting Mechanical Circulatory Support (MCS)

Valvular Heart Disease

Abnormalities of the cardiac valves have important adverse consequences in patients being considered for MCS and may require repair or replacement to initiate successful MCS or achieve weaning from support. Mild to moderate aortic stenosis (AS) in the absence of insufficiency is not a contraindication to placement of a ventricular assist device (VAD). Severe AS should be corrected before placement of a VAD, preferably with a bioprosthetic valve, to facilitate future weaning or to optimize native heart function in the event of device failure.

The presence of moderate aortic insufficiency can have a significant impact on the effectiveness of MCS therapy. In patients in whom LV assistance is initiated with LA-to-aortic cannulation, aortic insufficiency will result in LV distention in the presence of significant LV dysfunction. LV distention adversely affects subendocardial blood flow and can prevent weaning from MCS. In patients in whom MCS support is initiated with devices that require LV apical-to-aortic cannulation, reductions in LV pressure elicited by MCS increase the pressure gradient across the aortic valve and increase the degree of aortic insufficiency. Blood pumped into the aorta by the LVAD will flow backward across the incompetent aortic valve (aortic insufficiency), decreasing net forward flow and compromising end-organ perfusion. Mild to moderate aortic insufficiency may become more severe with initiation of MCS from an LVAD, because the elevated LV end-diastolic pressure will be significantly reduced by emptying of the LV cavity by the device, and the aortic root pressure will be elevated above baseline because of device flow.

The presence of significant aortic insufficiency can be confirmed by echocardiography, and significant aortic insufficiency (moderate or greater) should be addressed with either aortic valve repair, replacement, or closure of the aortic outflow with a patch sewn to the annulus of the aortic valve. A comparison of techniques (repair versus replacement versus patching) to address aortic insufficiency identified a higher mortality for those who underwent patch closure of the aortic valve annulus, suggesting repair or replacement are more appropriate techniques to resolve aortic insufficiency.[1] Patients with a mechanical valve prosthesis in the aortic valve position should have the mechanical valve replaced with a bioprosthetic valve before institution of LV assistance. During complete unloading of the left ventricle by a VAD, the aortic valve may not open, and the mechanical valve may be prone to thrombus formation. Placing a patch over the mechanical valve may be another alternative, but this may increase thromboembolic risk.

Patients with significant mitral stenosis (MS) at initiation of device support may require correction of the valvular problem before implantation of a device, depending on device selection and site of cannulation. In the setting of significant MS, LV filling is impaired. VADs that use apical ventriculotomy for cannula placement for ventricular drainage may experience limitations in device filling resulting from MS. This problem can be circumvented by correcting the underlying valvular pathologic abnormality (mitral valve repair or replacement with a bioprosthetic valve). The impact of mitral regurgitation on limiting forward flow through a VAD is not well understood, and data to suggest routine repair or replacement of the mitral valve for insufficiency are lacking. However, in patients in whom weaning from MCS may be feasible, correction of the mitral pathologic condition, either stenosis or regurgitation, is

necessary to optimize ventricular function.

Adequate RV function is extremely important for maintaining LVAD flow in the early postoperative period. Severe tricuspid regurgitation (TR) can significantly impair the forward flow of blood from the right ventricle, particularly in situations of high pulmonary vascular resistance (PVR). Severe TR contributes to elevated central venous pressure, hepatic congestion, and renal dysfunction. Severe TR may be present preoperatively in the setting of volume overload and biventricular failure or may develop after institution of LVAD support because of RV dilation from leftward shift of the interventricular septum.[2-4] If severe TR is present during the initiation of LVAD support, tricuspid valve repair should be performed to improve RV performance.

Coronary Artery Disease (CAD)

Patients with significant obstructive CAD or patients with postcardiotomy shock following failed coronary bypass operations may experience angina during MCS. Generally, CAD does not have adverse hemodynamic consequences during the period of MCS. However, the presence of obstructive coronary disease with ongoing ischemia may limit the degree of myocardial recovery and affect the ability to wean from temporary MCS.

Perioperative ischemia of the right ventricle may be of hemodynamic significance during institution of LVAD support. RV ischemia causing myocardial stunning or infarction that occurs during or soon after implantation of an LVAD can elicit RV failure, resulting in decreased flow to the LVAD. In patients who have had coronary bypass surgery and are candidates for MCS, patent bypass grafts, particularly to the right coronary artery (RCA) or left anterior descending coronary artery (LAD), should be preserved to reduce the risk of perioperative RV failure and arrhythmias. In select patients it may be important to perform a coronary artery bypass to the RCA or LAD systems to optimize RV function in the perioperative period if significant obstructive coronary lesions amenable to bypass are present in the distribution of the these arteries.

Arrhythmias

Atrial and ventricular arrhythmias are common in patients with cardiogenic shock and underlying ischemic or idiopathic cardiomyopathies. These arrhythmias generally persist in the immediate postoperative period and subsequently resolve with time as the patient's hemodynamic condition improves and inotropic therapy is weaned. Some patients will have persistent arrhythmias as a result of their underlying pathology (e.g., giant cell myocarditis). Severe ventricular arrhythmias have traditionally been thought to be a contraindication to univentricular support. However, the hemodynamic consequences in patients in whom these arrhythmias develop in the late postoperative period generally are not life threatening. In the absence of pulmonary hypertension and elevated PVR in the postoperative period, patients maintain adequate LVAD flows during ventricular fibrillation (VF). This situation is analogous to a Fontan (systemic vein to pulmonary artery) circulation. In the early perioperative period, some patients with refractory ventricular arrhythmias may require biventricular support until the PVR drops and a Fontan circulation is tolerated. The addition of RV support for hemodynamic compromise because of refractory ventricular arrhythmia is unusual. In patients with elevated PVR, sustained ventricular tachycardia (VT) and VF will result in reduced LVAD flows and may precipitate thrombus formation within the pump. VAD-specific considerations when VT or VF occur include confirmation of proper inflow-cannula position and pump-speed adjustment to reduce suction events. Therapy directed at control

of ventricular arrhythmia must be pursued, including correction of underlying metabolic abnormalities, consideration of antiarrhythmic drug therapy, and in rare cases, radiofrequency ablation for VT. In patients for whom weaning from MCS is feasible or planned, elimination of the ventricular arrhythmias with antiarrhythmic therapy is essential.

Intracardiac Shunts

Intracardiac shunts, such as a patent foramen ovale (PFO) or atrial septal defect (ASD), should be closed at implantation of an LVAD to prevent right-to-left shunting. These anomalies should be identified before surgery using transesophageal echocardiography. During the initiation of LV assistance, left atrial pressure is reduced compared with right atrial pressure. In the presence of ASD or PFO, this gradient results in significant systemic hypoxemia as deoxygenated blood is shunted from the right to the left atrium.

Clinical Trials with the HeartMate II Device

The HeartMate II Pivotal Trial for BTT was an FDA-approved, prospective, nonrandomized, multicenter study of 133 patients with end-stage heart failure (HF) who were on a waiting list for heart transplantation and received implantation of the HeartMate II device (**see Table 29.4**). The primary endpoint was a composite of the proportions of patients who, at 180 days, had undergone transplantation, were explanted for cardiac recovery, or had ongoing MCS with the HeartMate II while remaining eligible for transplantation. Of the 133 patients receiving support with the HeartMate II device, the principal outcomes were observed in 100 patients (75%).[1] At 3 and 6 months, device support with the HeartMate II was associated with significant improvement in functional status (NYHA functional class and 6-minute walk distance) and in quality of life (Minnesota Living with Heart Failure and Kansas City Cardiomyopathy questionnaires).[1] Major adverse events included postoperative bleeding, stroke, right-sided HF, percutaneous lead infection, and device malfunction (**see Table 29.5**). After this initial report of data for 133 patients, a follow-up evaluation was conducted through a continued access protocol (CAP) that included an additional 148 patients.[2] At 18 months, 222 patients (79%) met the primary endpoint, as defined previously for the pivotal trial.[2] The primary causes of death were sepsis, stroke, and right-sided HF. Episodes of bleeding requiring transfusion and surgery were the most common adverse events in the study, followed by stroke, localized infection not related to the device, infection associated with the percutaneous lead, preperitoneal pump pocket infection, and right-sided HF. There were no mechanical failures of the pumping mechanism. The freedom from device replacement for all causes,

including infection, device thrombosis, and percutaneous lead failure, was 92% (95% CI 88% to 97%) at 18 months.[2]

After completion of the FDA pivotal trial for evaluation of the HeartMate II for the bridge to transplantation (BTT) indication, a clinical study of the HeartMate II was performed for the first 169 consecutive patients enrolled in the postapproval phase, and results were compared with those for the first 169 consecutive patients who received another FDA-approved VAD (79% HeartMate XVE, 21% Thoratec IVAD) enrolled in INTERMACS (Interagency Registry for Mechanically Assisted Circulatory Support) who were listed for transplantation or likely to be listed.[3] Kaplan-Meier survival at 12 months was significantly greater for HeartMate II recipients than for controls ($P = 0.001$), and this advantage was sustained after adjustment for significant baseline differences in creatinine, blood urea nitrogen, white blood cell count, heart rate, pump type, and aspartate transaminase (AST) ($P = 0.009$). A greater percentage of patients in the HeartMate II (90%; $n = 152$) versus the control (80%; $n = 130$) group reached the successful outcomes of survival to transplant, recovery of the heart, or ongoing support at 6 months ($P = 0.018$).

The HeartMate II DT Pivotal Trial randomly assigned 200 patients with New York Heart Association (NYHA) Class IIIB to IV symptoms and a left ventricular ejection fraction (LVEF) of 25% or less to receive a HeartMate II or a HeartMate XVE.[4] Eligible patients also needed a maximal oxygen consumption not exceeding 14 mL/kg/min, required treatment with intravenous inotropic agents for 14 days or longer, or had an intra-aortic balloon pump (IABP) for 7 days or longer. The primary endpoint was a composite of survival to 24 months without disabling stroke or the need for an operation to repair or replace the device. The patient population was predominantly male, with a mean age of 62 years. This was a severely ill population, as reflected by a mean LVEF of 17% and mean creatinine 1.6, relatively low use of baseline neurohormonal antagonists, and substantial use of inotropes (77%) and IABP (22%). There was a greater than fourfold increase in the percentage of HeartMate II patients who successfully reached the primary endpoint (46% versus 11%; $P < 0.001$)[5] (**see Table 29.3**). All adverse events were less frequent in the HeartMate II patients, with significant reductions in sepsis, device-related infections, right-sided HF, renal failure, and rehospitalizations. Changes in functional capacity, 6-minute walk distance, and quality-of-life scores were similar between groups, suggesting that the improvements seen in these metrics in VAD-supported patients are more closely linked to the favorable effects of increasing the cardiac output and lowering the left-sided filling pressures, rather than the characteristics of blood flow. The favorable results of the HeartMate II DT Pivotal Trial resulted in FDA approval of this device in 2010 as the second LVAD indicated for long-term support for the destination therapy (DT) indication.

A follow-up study reported the outcomes of patients entered into the HeartMate II Pivotal Trial for Destination Therapy through a CAP to those entered in the original cohort to determine if outcomes in the latter group were superior.[6] The 281 patients who underwent HeartMate II for DT from May 2007 to March 2009 (Mid-Trial group) were compared with the initial 133 HeartMate II patients from March 2005 to May 2007 (Early Trial group). Patient entry criteria were the same, and important baseline characteristics were similar for the two groups. **Table 29.4** provides Kaplan Meier survival data for the Early Trial and Mid-Trial experiences.[6] There were nominal improvements in survival, quality of life, and many adverse events, some of which achieved statistical significance.

Cardiovascular Regeneration and Repair

Kiran Musunuru, Joseph C. Wu

A longstanding quest in cardiovascular medicine is to regenerate injured tissue or to correct fundamental defects in molecular pathways that cause organ dysfunction in the setting of heart disease. Depending on the specific etiologic disorder, the myocardium might comprise diseased cardiac myocytes, fibrous tissue that replaced permanently lost cardiac myocytes, and normal cardiac myocytes (**see Chapter 23**). As shown in **Fig. 30.1**, there are two general strategies to addressing myocardial disorders. The first is a *regenerative therapy* to replace permanently lost cardiac myocytes within the myocardium. A second strategy is to undertake *disease modeling* ex vivo to identify therapeutic strategies that can repair diseased cardiac myocytes or prevent myocytes from becoming diseased, which may entail the use of traditional small-molecule drugs or cutting-edge technologies such as gene therapy and genome editing. After decades of research, significant obstacles remain in translating these strategies into clinical practice, but recent scientific advances have improved the prospects for cardiovascular regeneration and repair to reach patients in the near future.

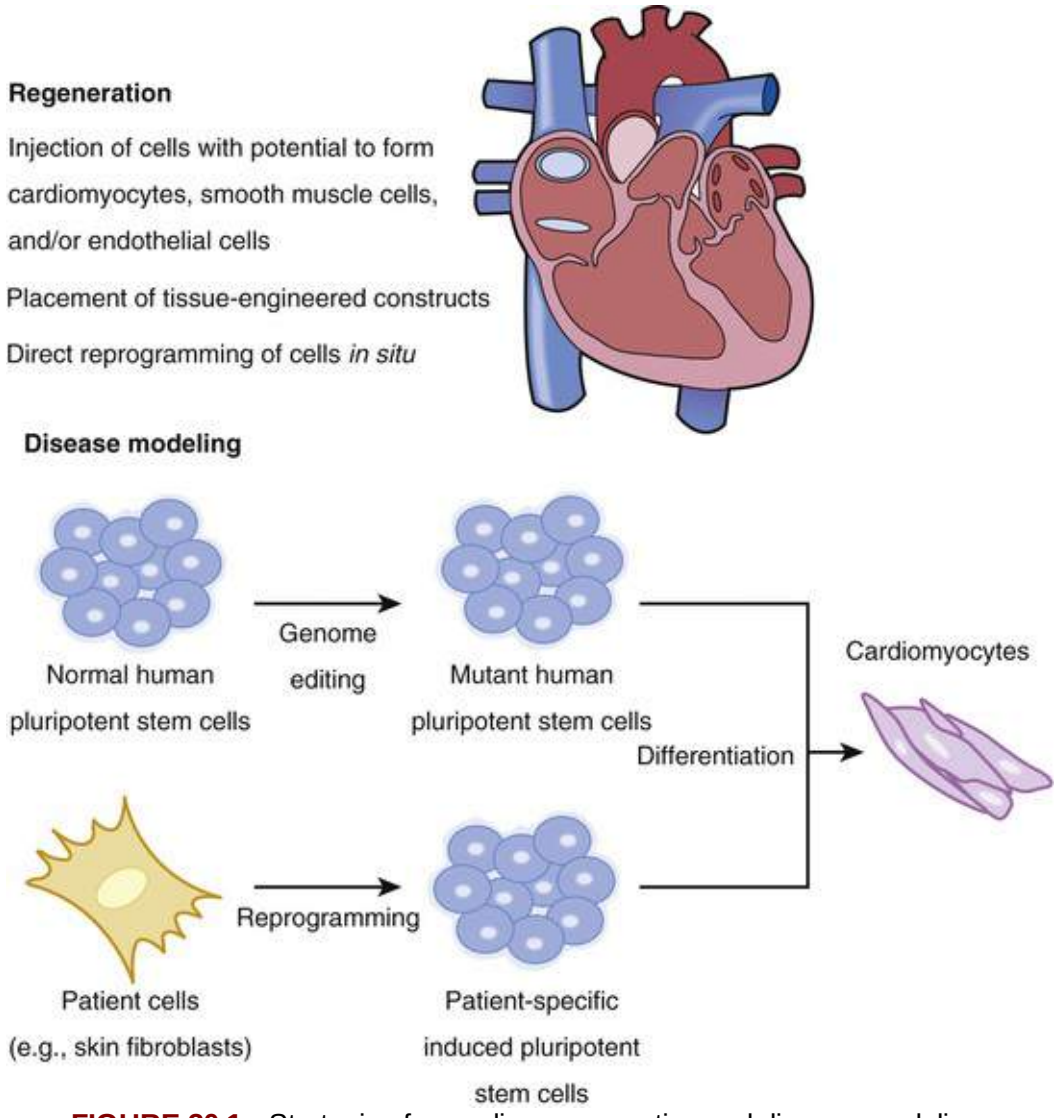

FIGURE 30.1 Strategies for cardiac regeneration and disease modeling.

Regeneration

A primary goal of cardiac cell-based therapy is to repopulate areas of damaged myocardium with three types of cells capable of engraftment: cardiac myocytes, vascular smooth muscle, and endothelium. Although a variety of cellular substrates have been proposed for cardiac regenerative therapy, including bone marrow mononuclear cells, skeletal myoblasts, mesenchymal stem cells, mesenchymal progenitor cells, endothelial precursor cells, and cardiac-derived stem cells, the ability of each of these substrates to productively supply one or more of the three key cardiac cell types within damaged myocardium remains to be firmly established, and initial clinical trials have had mixed results.[1] Rather than attempting to define how each of these cellular substrates might directly convert into, substitute for, or stimulate the growth of the three native cardiac lineages, it is more instructive to review what is known about the normal process of embryonic cardiac development giving rise to functioning myocardium.

Cardiac Development

Our knowledge of cardiac development was elucidated mostly in studies in mice and other model organisms and either has been replicated with human cell-based studies or is otherwise presumed to be relevant to humans.[2,3] Following gastrulation early in development, cardiac mesoderm progenitors migrate

from the primitive streak into the splanchnic mesoderm to form the first heart field and second heart field. These progenitors initially express the transcription factor Brachyury (Bry), which is encoded by a direct target gene of Wnt/β-catenin signaling. On traversal into the splanchnic mesoderm, the inhibition of canonical Wnt/β-catenin signaling and activation of both noncanonical Wnt signaling and eomesodermin signaling in the Bry^+ cells result in the downregulation of Bry and the expression of mesoderm posterior 1 (MesP1), committing these cells to cardiogenesis. The $MesP1^+$ cardiogenic progenitor cells give rise to multipotent cardiovascular progenitor cells within the first and second heart fields. The *first heart field* forms the cardiac crescent and then the heart tube, ultimately contributing most of the cells in the left ventricle. Although specific markers for the multipotent cardiovascular progenitor cells in the first heart field remain to be defined, the influence of bone morphogenetic protein (BMP) and fibroblast growth factor (FGF) signaling eventually gives rise to a population of cells expressing homeobox protein Nkx-2.5 and T-box 5 (Tbx5). These $Nkx\text{-}2.5^+/Tbx5^+$ cells are bipotent, producing both cardiomyocytes and smooth muscle cells.

The *second heart field* ultimately contributes more than two thirds of the cells in the heart, including the atrial and right ventricular chambers, the outflow tract myocardium, the proximal coronary arteries, and much of the conduction system. The multipotent cardiovascular progenitor cells in the first heart field are defined by expression of ISL LIM homeobox 1 (ISL-1), Nkx-2.5, and fetal liver kinase 1 (Flk-1), which are capable of giving rise to cardiomyocytes, smooth muscle cells, and endothelial cells, as determined by the influences of a variety of signaling pathways. Additional contributions to the developing heart, particularly the epicardium, cardiac fibroblasts in the myocardium, coronary arteries, aorta, and autonomic nerve cells, are provided by proepicardial progenitor cells and cardiac neural crest cells.

Understanding of the normal process of cardiac development and the central roles of multipotent cardiovascular progenitor cells in that process provides key insights into how initial attempts at cardiac regenerative therapy can be further improved. Optimal therapeutic approaches might entail either the recruitment, expansion, or differentiation of any rare multipotent cardiovascular progenitor cells still resident in the adult heart or, perhaps more realistically, by enhancing the ability to grow and differentiate large numbers of multipotent or pluripotent cells ex vivo, followed by transplantation.

Human Pluripotent Stem Cells

Human pluripotent stem cells (hPSCs) have several defining properties that are a major focus of interest in the field of regenerative medicine. First, they are human cells with normal human genomes and thus are more appropriate for therapeutic use in humans than transformed or immortalized human cultured cell lines with tumorigenic characteristics. Second, hPSCs are pluripotent and thus have the capacity to differentiate into any human cell types, including cardiac myocytes, smooth muscle, and endothelium. Third, as stem cells, hPSCs have an unlimited capacity for expansion and thus can serve as a renewable source of cells for regenerative therapy.

There are two major types of hPSCs, human embryonic stem cell (hESCs)[4,5] and human induced pluripotent stem cells (iPSCs).[6] (A third type of hPSCs, derived by somatic cell nuclear transfer, is currently too rare to be relevant for therapeutic applications.) hESCs are generated from human embryos, but because they typically entail the destruction of the source embryos, they are not used currently for therapy. By contrast, iPSCs are typically generated from adult cells from living donors. The potential source cells for iPSCs include skin fibroblasts, blood-derived T lymphocytes, and urine-derived renal tubular cells, all of which can be obtained in a minimally invasive manner. The source cells undergo a

process called *reprogramming*, in which a set of factors—classically, Oct3/4, Sox2, Klf4, and c-Myc—are transiently introduced into the differentiated cells, converting them into pluripotent cells. Aside from any mutations that may result from the reprogramming procedure, the iPSCs are perfectly matched to the donors. This is equally true of iPSCs from healthy individuals and those from patients with genetic disorders or genetic predisposition to disease. Because they represent an autologous source of cells, iPSCs are attractive substrates for regenerative therapy, in addition to being well suited for personalized disease modeling, as described later.

Differentiation Into Cardiac Lineages

In vitro differentiation of hPSCs into a desired cell type can be guided by knowledge of the process by which the cell type arises in the body during normal human development. Efforts to develop and optimize protocols to yield pure cardiomyocytes from hPSCs demonstrate this principle.[7,8] Initial attempts entailed the dispersion of hPSCs, culturing in suspension conditions, and formation of three-dimensional aggregates called *embryoid bodies*. Cells within embryoid bodies spontaneously differentiate into any of the three germ layers—endoderm, mesoderm, or ectoderm—resulting in a heterogeneous mix of cells of different lineages. Some proportion of the cells will have cardiomyocyte properties and in principle can be purified away from noncardiomyocyte cells. However, the exact proportion of cardiomyocyte-like cells in any given embryoid body is typically not large and is quite variable, limiting the usefulness of embryoid body–based protocols.

Taking a cue from normal cardiac development, subsequent attempts at cardiomyocyte differentiation explored the exposure of hPSCs to growth factors and signaling-pathway inhibitors thought to be important for cardiogenesis. Thus the differentiation would be directed toward reproducing what naturally occurs in vivo, rather than relying on the spontaneous products. Various protocols along these lines have greatly improved the efficiency and consistency of cardiomyocyte differentiation, particularly when the cells are differentiated in a two-dimensional monolayer format. A widely used protocol sequentially exposes hPSCs to a glycogen synthase kinase 3β inhibitor and then a Wnt inhibitor, with the effect of initially activating canonical Wnt/β-catenin signaling and then blocking it, mimicking the steps that occur in development as embryonic cells are induced into mesodermal progenitors and then transformed into cardiogenic progenitors.[9] The use of these inhibitors reproducibly yields proportions of cardiomyocytes as high as over 90%. As with cardiomyocytes, insights from normal human development have helped improve differentiation protocols for vascular endothelial and smooth muscle cells.

Despite these advances with respect to in vitro cardiomyocyte differentiation, as well as differentiation of other cell types, the lack of purity and lack of maturity remain obstacles. For therapeutic applications, highly pure cardiomyocyte preparations would be optimal. One approach is to sort the desired cells away from noncardiomyocyte cells using antibodies for cardiomyocyte-specific membrane proteins or cardiomyocyte-specific dyes.[10,11] Another approach is to genetically introduce antibiotic resistance cassettes into the hPSCs before differentiation, with the resistance only expressed in cardiomyocytes (e.g., through the use of a cardiac-specific promoter). The treatment with the antibiotic removes noncardiomyocyte cells while sparing the cardiomyocytes. Yet another approach is to exploit the ability of differentiated cardiomyocytes to metabolize lactate, with a prolonged exposure to a lactate-rich, glucose-poor medium that eliminates noncardiomyocyte cells.[12] Each of these approaches has been demonstrated to improve the yield of cardiomyocytes to almost 100%.

Although in vitro they have functional characteristics that are exclusive to cardiomyocytes, differentiated cardiomyocytes have important differences from the mature adult cardiomyocytes in the

human heart. In many respects, they resemble fetal cardiomyocytes, indicating a degree of immaturity that remains a significant obstacle for researchers to overcome.[13,14] Such differences are found in length and shape (smaller length-to-width ratio), in having single rather than multiple nuclei, in lacking well-developed sarcoplasmic reticulum and transverse tubules, and in having fewer mitochondria, higher resting membrane potentials, slower depolarization speeds, and differences in functional gene expression, particularly ion channel and calcium-handling genes (**Table 30.1**). Some of these signs of immaturity can be addressed by building the cardiomyocytes into engineered myocardial structures (e.g., with micropatterning techniques). Another challenge is that in vitro differentiated cardiomyocytes are typically a mix of ventricular-like, atrial-like, and nodal-like cardiomyocytes, although progress is being made in developing methods to direct the differentiation of cells to just one type of cardiomyocyte.[15]

TABLE 30.1

Differences Between Human Pluripotent Stem Cell (hPSC)–Derived Cardiomyocytes and Mature Adult Cardiomyocytes

	hPSC-DERIVED CARDIOMYOCYTES	ADULT CARDIOMYOCYTES
Morphology		
Shape	Round or polygonal	Rod and elongated
Size	20-30 pF	150 pF
Nuclei per cell	Mononucleated	~25% multinucleated
Multicellular organization	Disorganized	Polarized
Sarcomere appearance	Disorganized	Organized
Sarcomere length	Shorter (~1.6 μM)	Longer (~2.2 μM)
Sarcomeric protein: MHC	β > α	β α
Sarcomeric protein: titin	N2BA	N2B
Sarcomeric protein: troponin I	ssTnI	cTnI
Sarcomere units: H-zones and A-bands	Formed after prolonged differentiation	Formed
Sarcomere units: M-bands and T-tubules	Absent	Present
Distribution of gap junctions	Circumferential	Polarized to intercalated disks
Electrophysiology		
Resting membrane potential	Approx. –60 mV	–90 mV
Upstroke velocity	Approx. 50 V/s	Approx. 250 V/s
Amplitude	Small	Large
Spontaneous automaticity	Exhibited	Absent
Hyperpolarization-activated pacemaker (I_f)	Present	Absent
Sodium (I_{Na})	Low	High
Inward rectifier potassium (I_{K1})	Low or absent	High
Transient outward potassium current (I_{to})	Inactivated	Activated
ATP-sensitive K^+ current ($I_{K,ATP}$)	Not reported	Present
Conduction velocity	Slower (~0.1 m/s)	Faster (0.3–1.0 m/s)
Calcium Handling		
Ca^{2+} transient	Inefficient	Efficient
Amplitudes of Ca^{2+} transient	Small and decrease with pacing	Increase with pacing
Excitation-contraction coupling	Slow	Fast
Contractile force	~nN range/cell	~μN range/cell
Ca^{2+}-handling proteins: CASQ2, RyR2, PLN	Low or absent	Normal
Force-frequency relationship	Positive	Negative
Mitochondrial Bioenergetics		
Mitochondrial number	Low	High
Mitochondrial volume	Low	High
Mitochondrial structure	Irregular distribution, perinuclear	Regular distribution, aligned
Mitochondrial proteins: DRP1 and OPA1	Low	High
Metabolic substrate	Glycolysis (glucose)	Oxidative (fatty acid)
Adrenergic Signaling		
Responses to β-adrenergic stimulation	Lack of inotropic reaction	Inotropic reaction
Cardiac α-adrenergic receptor ADRA1A	Absent	Present

ATP, Adenosine triphosphate; *m/s,* meters per second; *nN,* nanonewtons; *μN,* micronewtons; *pF,* picofarads; *V/s,* volts per second.

Tissue Engineering

The original concept of issue engineering was to provide living tissue grafts that could be used surgically to repair or replace dead or congenitally defective myocardium. Constructs of heart muscle can be generated using cell populations seeded within a matrix scaffold to form three-dimensionally engineered cardiac tissue. It has been challenging to generate tissue in vitro with sufficient contractile force and size to support the failing heart.[16] Various culture conditions have been used in combination with multiple cell mixtures (e.g., neonatal cardiomyocytes, fibroblasts, skeletal myoblasts, adult stem cells, in vitro differentiated cardiomyocytes) for creating a range of patches, strips, loops, and chambers of beating myocardial tissue in vitro. hESCs and iPSCs are potential sources for the generation of heart tissue in vitro. Although the survival of human engineered heart tissue implanted in the rat has been demonstrated, the maturation of specific tissue phenotype presents an important challenge, and the long-term engraftment followed by a meaningful functional improvement in the human heart remains an ambitious goal.[17] In addition, the size of typical avascular engineered heart tissue constructs is limited by oxygen diffusion. Accordingly, researchers have fused several individually cultured, single engineered tissue rings or sheets, and various strategies are under development to create vascularized constructs that can be perfused and integrated with the host circulation.

At the interface between tissue engineering and cell therapy, the development of novel biomaterials has seen increasing interest. Biodegradable matrix materials with sophisticated chemical and mechanical properties have been developed to be used as ventricular restraints and to provide scaffolds for in vitro tissue engineering.[18] In addition, the injection of new self-assembling nanomaterials and decellularized natural tissue matrix can modify the intramyocardial cellular microenvironments to augment functional integration of cells for in situ tissue engineering and subsequent cardiac regeneration.

In Vitro Differentiated Cardiomyocytes as Therapy

A number of barriers must be overcome before hPSC-derived cardiomyocytes or other cell types can be used successfully for regenerative therapy in human patients[19] (**Fig. 30.2**). Perhaps the greatest challenge is poor cell engraftment and survival in the heart after transplantation. Existing data suggest that only a small percentage of transplanted cells persist in the heart, limiting their contribution to myocardial regeneration. A related issue is the lack of standards for the tracking of cell fate after transplantation of cells. Labeling of cells before transplantation to allow tracking with imaging techniques after delivery into the body is critical not only for determining whether cells are engrafting in the heart, but also as a means to quantify which strategies to increase engraftment and regeneration (e.g., various routes of delivery into the heart, tissue engineering approaches, use of adjuvants to promote transplanted cell survival) are the most successful, rather than relying on relatively imprecise metrics such as ejection fraction.

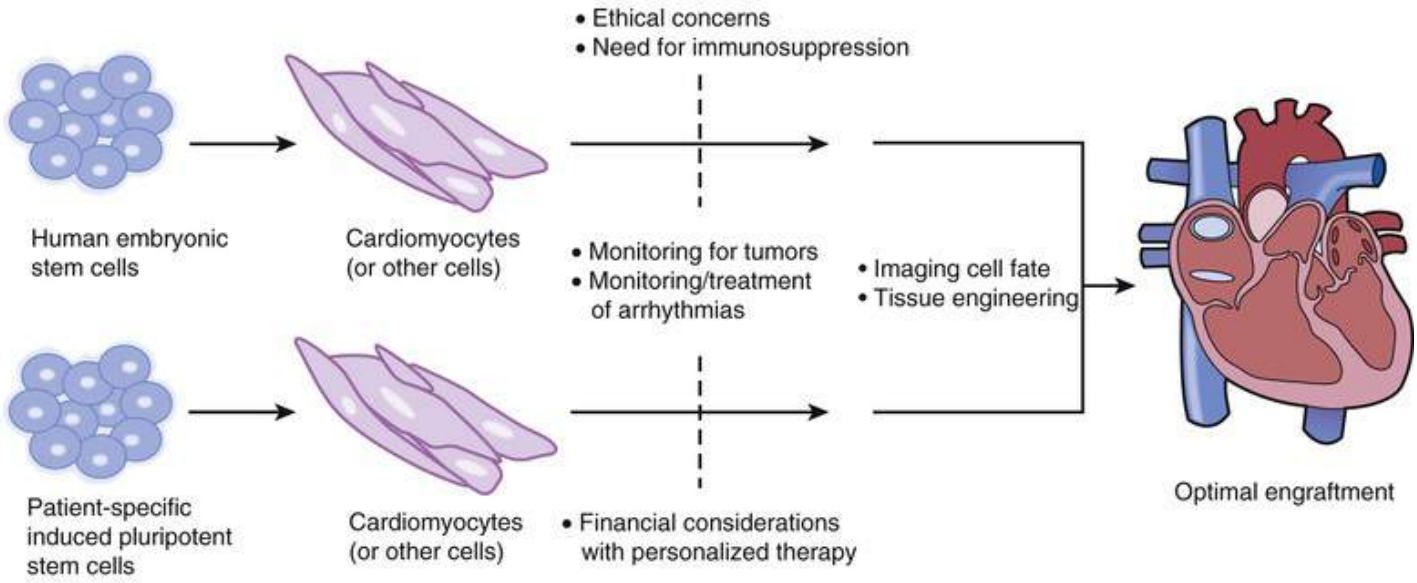

FIGURE 30.2 Obstacles to overcome and possible solutions in the use of human pluripotent stem cells for cardiac regenerative therapy.

As with any transplantation-based therapy, immunogenicity is a substantial concern. If the same standard-issue hPSC-derived cardiomyocytes or other cells are to be used in all patients (i.e., allogeneic therapy), patients will presumably need lifelong immunosuppression to tolerate the engrafted cells, with all the attendant risks. Simply speaking, the use of patient-specific iPSC-derived cardiomyocytes (i.e., autologous therapy) would avoid the risk of rejection. Good manufacturing practice (GMP) conditions would require generating iPSCs from a patient, performing the extensive quality control protocols needed, expanding the cells to large numbers, and differentiating the cells into cardiomyocytes to treat individual patients, an unrealistic prospect given the high costs involved using current technology. Possible solutions include the banking of several hundred prevalidated iPSC lines that are HLA antigen–matched to the majority of the population,[20] which could then be used on demand, or the use of genome-editing technology to engineer universal-donor hPSCs that could be tolerated by all patients.[21]

Other concerns include tumorigenicity and arrhythmogenicity. Tumorigenicity is a particular issue with hPSC-derived cardiomyocytes, because any hPSCs remaining after differentiation have the potential to form teratomas.[22] Although cardiomyocyte differentiation protocols have advanced tremendously in recent years (see earlier), special consideration will need to be given to the prevention of and monitoring for tumor formation in patients receiving hPSC-based therapies. Arrhythmogenicity is a concern for any cell type used for cardiac regenerative therapy. The failure of engrafted cells to integrate seamlessly into the myocardium could create foci for life-threatening ventricular arrhythmias, a risk that will require careful monitoring of patients after transplantation and perhaps even routine prophylactic placement of implantable cardioverter-defibrillators (ICDs).

Some of these concerns are highlighted by the preclinical studies of in vitro differentiated cardiomyocyte transplantation that have been performed to date. A succession of animal studies over many years culminated in the demonstration that hESC-derived cardiomyocytes or monkey iPSC-derived cardiomyocytes could develop extensive grafts in monkey hearts when they were administered after myocardial infarction.[23,24] At least half a billion transplanted cells per animal were needed to achieve these results, and frequent ventricular arrhythmias were observed in the recipients after transplantation. Although findings from these studies raised potential concerns about the clinical use of hPSC-derived cardiomyocytes, a phase 1/2 clinical study reported no adverse arrhythmias after transplantation of hESC-

derived cardiac progenitor cells embedded in a fibrin patch that was sutured directly onto the epicardium.[25] The results of these preclinical and early clinical studies to date indicate that cardiac regenerative therapy may be viable in human patients in the future, but much more work is needed to make this prospect a reality.

Directed Reprogramming

In principle, the process of generating autologous cells for regenerative therapy could be greatly accelerated if adult cells could be directly reprogrammed into expandable, multipotent cardiovascular progenitor cells in vitro. This would reduce the time and cost required to generate patient-specific iPSC lines and to differentiate them into cardiac lineages. Recent studies have established the feasibility of directed reprogramming of mouse fibroblasts into cardiovascular progenitor cells capable of differentiating into cardiomyocytes, smooth muscle cells, and endothelial cells, suggesting that the same will be possible with human fibroblasts.[26,27]

The concept of directed reprogramming of host fibroblasts in vivo has been demonstrated experimentally.[28,29] The expression of the transcription factors Gata4, Mef2c, and Tbx5 in cardiac fibroblasts resulted in conversion of some of the cells into cardiomyocyte-like cells. This raises an interesting new strategy of stimulating cardiac regeneration by inducing the differentiation of endogenous cardiac fibroblasts into cardiomyocytes in a diseased heart. If ultimately proven to be efficient enough to improve function substantially in the diseased heart in various preclinical models, directed reprogramming would be a viable therapeutic approach that avoids most of the difficulties in introducing exogenously produced cells into the myocardium for regeneration. However, difficulties associated with delivery vectors to the heart, specificity of transfecting only fibroblasts, and host immune response against foreign vector/gene products could make this a daunting prospect.

Disease Modeling

Whereas the basis of regeneration is to repopulate damaged areas within the heart with new cells, the basis of disease modeling is to understand the molecular mechanisms resulting in diseased cardiomyocytes in order to prevent heart disease or repair the compromised cells in the heart. Although important insights into disease pathogenesis can be obtained from model organisms, the physiology of the human heart is sufficiently different from that of other model species such that human-based models, if feasible, would be much more informative. hPSCs provide a platform with which to model the effects of patient-specific mutations as well as the effects of medications and other environmental exposures on the myocardium.

Induced PSCs with Patient-Specific Genotypes

The ability to reprogram somatic cells from living people into pluripotent stem cells provides a renewable source of differentiated cells, including cardiomyocytes, which can be genetically matched to individual patients. This makes iPSCs particularly useful for studying monogenic disorders in which single mutations have large phenotypic effects. Even when studying complex disorders that involve the contributions of multiple genes and environmental factors, iPSCs are advantageous because the reprogramming process largely resets any epigenetic changes resulting from environmental exposures during a person's lifetime, thus isolating and clarifying the genetic factors contributing to disease.

Potential disadvantages of iPSCs include the time and expense entailed in generating new lines—several months and thousands of U.S. dollars for each line—and the variability that can result from the reprogramming process, with iPSC lines generated even from the same person potentially showing distinct gene expression profiles. It appears that these issues can be at least partly addressed with automation techniques that allow for higher-throughput, more consistent production of iPSCs.[30] Another consideration is the choice of control iPSC lines against which to compare patient-specific iPSC lines. Confounding factors may result from differences in genetic background (particularly if the iPSC lines are not matched for sex and ethnicity), epigenetic background, the capacity for differentiation into the desired cell type for study, the type of somatic cell used to generate the iPSCs, the means of expressing the reprogramming factors in the source cells, and the passage numbers and adaptation of the iPSCs to a laboratory's cell culture conditions. These sources of confounding can be somewhat mitigated but not entirely eliminated by (1) choosing unaffected first-degree relatives of the affected individuals as the donors for control iPSC lines, with approximately 50% shared genetic background, and (2) using iPSC lines from a sizable number of patients with the disease of interest and iPSC lines from a similar number of control individuals, which sharpens the signal-to-noise ratio with respect to the phenotypic differences that are genuinely related to the disease.

Genome Editing of Human PSCs

Specific disease-associated mutations may be desirable to study, but they are sufficiently rare or unique that it is not possible locally to recruit individuals with the relevant mutations to generate iPSCs. Newly developed genome-editing tools permit the introduction of the mutations or other types of DNA alterations into hPSCs[31] (**Fig. 30.3**). They also permit the correction of pathogenic mutations in patient-derived iPSCs, which may be useful for therapeutic purposes.

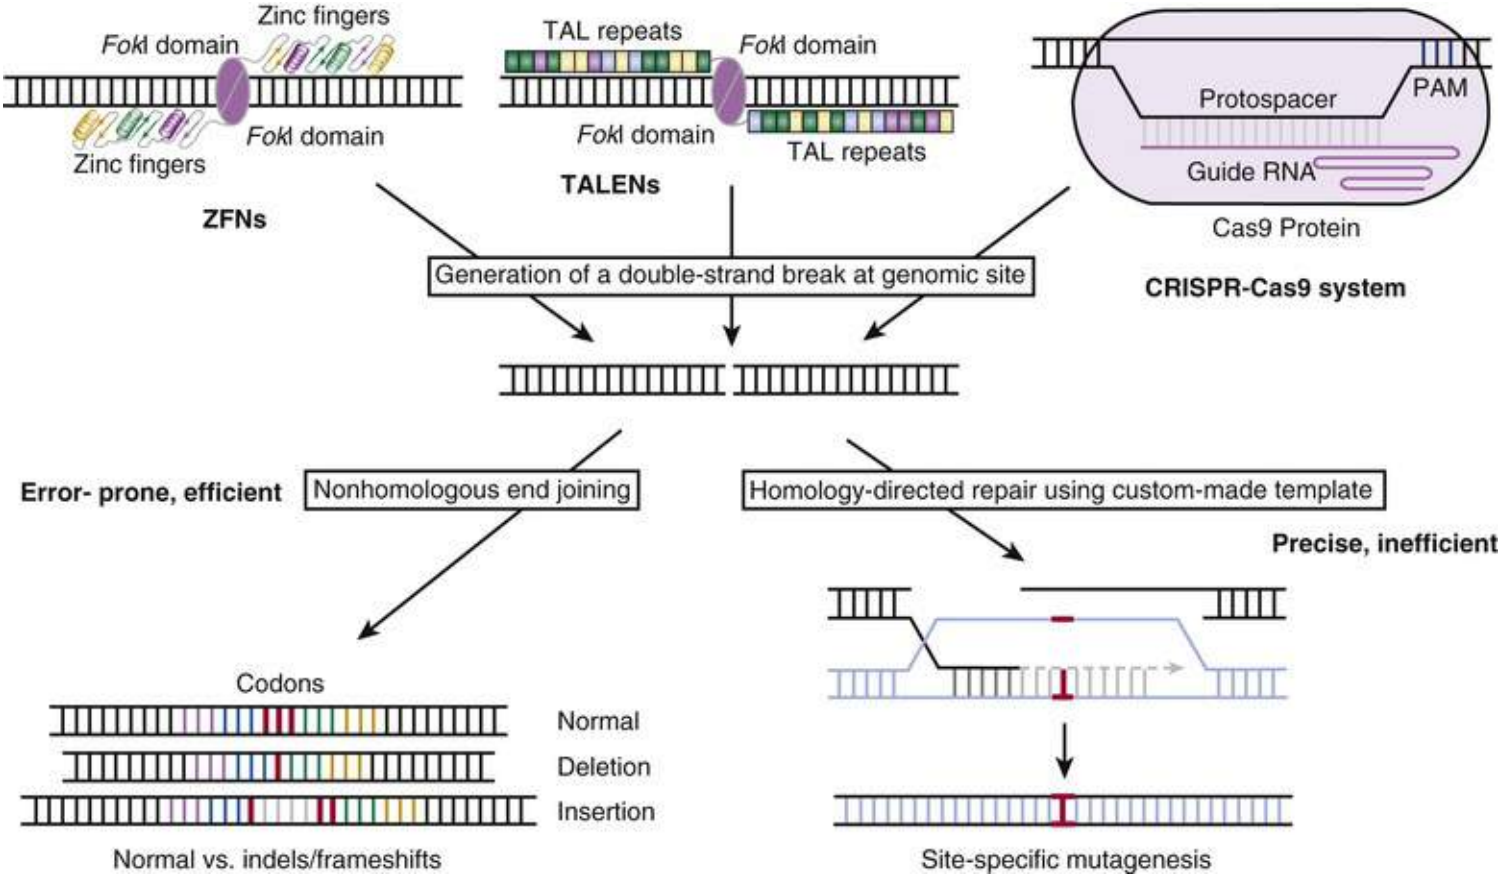

FIGURE 30.3 Genome editing with zinc-finger nucleases (*ZFNs*), transcription activator-like (*TAL*) effector nucleases (*TALENs*), and clustered, regularly interspaced, short palindromic repeats (*CRISPR*)–CRISPR-associated 9 (*Cas9*) by nonhomologous end-joining (NHEJ) or homology-directed repair (HDR). ZFNs use DNA-binding domains, called *zinc fingers,* that recognize three base pairs each, as well as *Fok*I nuclease domains (two are needed in combination to make double-strand breaks). TALENs use DNA-binding domains, called *TAL repeats,* that recognize one base pair each, as well as *Fok*I nuclease domains. CRISPR-Cas9 uses hybridization of part of the sequence of the guide RNA with one strand of DNA (protospacer) along with Cas9 protein recognition of a protospacer-adjacent motif (*PAM*) in the DNA sequence.

The most commonly used genome-editing tools are zinc-finger nucleases (ZFNs), transcription activator-like effector nucleases (TALENs), and clustered, regularly interspaced, short palindromic repeats (CRISPR)-CRISPR-associated 9 (Cas9).[32] Each represents a type of engineered nuclease that can be customized to recognize, bind, and cleave a specific sequence in the genome. Whereas ZFNs and TALENs are entirely protein based, CRISPR-Cas9 has both protein and RNA components. ZFNs and TALENs are modular proteins comprising an array of domains, each recognizing specific nucleotides, and a nuclease domain; for each new DNA sequence to be targeted, new proteins must be assembled from scratch. By contrast, for CRISPR-Cas9, the RNA component confers specificity for the target sequence. Approximately the first 20 nucleotides of the "guide RNA" direct the Cas9 nuclease protein to the target sequence through RNA-DNA hybridization of the sequence. For all three tools, the common consequence is the introduction of a double-strand break (DSB) at the site of the target sequence.

Cells have two major mechanisms for the repair of DSBs: nonhomologous end-joining (NHEJ) and homology-directed repair (HDR). NHEJ operates in all cells during all phases of the cell cycle, repairing the DSB in an error-prone manner that potentially introduces insertions or deletions (*indels*) at the break site. HDR uses a repair template, typically a sister chromatid, to accurately fix the DSB. HDR is typically active only in proliferating cells, during the S and G2 phases of the cell cycle. Whereas NHEJ can be used efficiently to knock out genes in cells through the introduction of frameshift mutations in coding sequences, HDR can be exploited to make specific alterations (e.g., introduction or correction of

mutations) if a researcher introduces into the cells a custom-made repair template that matches the break site but also contains the desired alteration.

ZFNs, TALENs, and CRISPR-Cas9 have all been demonstrated to be effective in hPSCs, although the efficiency varies widely depending on the tool used and the genomic locus to be targeted. Besides its ease of use, CRISPR-Cas9 is advantageous in that it generally works more efficiently in hPSCs than ZFNs and TALENs, and therefore it has become the tool of choice for most projects involving hPSCs.

With respect to disease modeling, genome-edited hPSC lines avoid some of the potential disadvantages of patient-specific iPSC lines. It is often quicker and cheaper to use genome editing to introduce mutations into preexisting hPSC lines than to generate new iPSC lines. Genome editing of an hPSC line results in well-matched control and mutant cell lines with a shared origin, genetic background, and epigenetic background, thus eliminating many possible confounders. Nonetheless, in cases when it is important that cell lines be perfectly genetically matched to patients, iPSCs generated directly from those patients will be preferred.

Modeling of Cardiovascular Genetic Disorders with Human PSCs

A variety of cardiovascular diseases have been modeled with hPSCs, including electrophysiologic disorders, familial cardiomyopathies, valvular and vascular disorders, and metabolic disorders[33] (**Table 30.2**). Some of the earliest diseases to be modeled with iPSCs were long-QT syndromes (LQTSs), monogenic disorders in which mutations in ion channel genes result in delayed repolarization of the heart, thereby placing patients at risk for fatal ventricular arrhythmias.[34,35] The three most commonly involved genes are potassium voltage-gated channel subfamily Q member 1 (*KCNQ1*) and subfamily H member 2 (*KCNQ2*) and sodium voltage-gated channel alpha subunit (*SCNA5*). Patient-specific iPSC-derived cardiomyocytes with mutations in any of these three genes have been reported to have increased action potential durations, abnormal ion currents depending on the affected channels, and in some cases, increased arrhythmogenicity. Similar findings have been reported in iPSC-derived cardiomyocytes from patients with other rare genetic rhythm disorders.

TABLE 30.2

Diseases Modeled with Human Induced Pluripotent Stem Cells or Human Embryonic Stem Cells

DISEASE MODELED	MUTATED GENE
Long-QT syndrome type 1	*KCNQ1*
Long-QT syndrome type 2	*KCNH2*
Long-QT syndrome type 3	*SCN5A*
Jervell and Lange-Nielsen syndrome	*KCNQ1*
Timothy syndrome	*CACNA1C*
Brugada syndrome	*SCN5A*
Catecholaminergic polymorphic ventricular tachycardia type 1	*RYR2*
Catecholaminergic polymorphic ventricular tachycardia type 2	*CASQ2*
Hypertrophic cardiomyopathy	*MYH7, MYBPC3*
Dilated cardiomyopathy	*TNNT2, RBM20, LMNA, DES, PLN, TTN*
Left ventricular noncompaction	*TBX20*
Arrhythmogenic right ventricular dysplasia	*PKP2*
Duchenne muscular dystrophy	*DMD*
Friedreich's ataxia	*FXN*
LEOPARD syndrome	*PTPN11*
Barth syndrome	*TAZ*
Pompe disease	*GAA*
Danon disease	*LAMP2*
Dyslipidemia	*SORT1, ABCA1*
Hypoinsulinemic hypoglycemia and hemihypertrophy	*AKT2*
Lipodystrophy	*PLN1*
Maturity-onset diabetes of the young type 2	*GCK*
Mitochondrial aldehyde dehydrogenase 2 deficiency	*ALDH2*
Hutchinson-Gilford progeria syndrome	*LMNA*
Williams-Beuren syndrome	*ELN* and others
Calcific aortic valve	*NOTCH1*

From Matsa E, Ahrens JH, Wu JC. Human induced pluripotent stem cells as a platform for personalized and precision cardiovascular medicine. Physiol Rev 2016;96:1093.

Patient-specific iPSCs have been particularly informative in modeling familial cardiomyopathies, including hypertrophic cardiomyopathy (HCM), dilated cardiomyopathy (DCM), and left ventricular noncompaction (LVNC). The most common mutant gene linked to familial HCM is myosin, heavy chain 7 (*MYH7*), with mutations in a number of other genes encoding sarcomere components also linked to HCM. In one study of an HCM-linked *MYH7* missense mutation, iPSC lines were generated from 10 affected and unaffected members of a single family.[36] iPSC-derived cardiomyocytes with the mutation showed cellular enlargement, contractile arrhythmia, and abnormal calcium handling at the single-cell level. In a separate study, iPSC-derived cardiomyocytes with a different *MYH7* mutation displayed similar defects.[37] In both studies the defects could be reversed by treatment with the calcium channel blocker verapamil. A large proportion of familial DCM cases are also linked to mutations in genes encoding sarcomere components, such as troponin T, cardiac muscle (*TNNT2*). In studies of a DCM-linked *TNNT2* missense mutation, iPSC lines were generated from several affected and unaffected family members.[38,39] iPSC-derived cardiomyocytes with the mutation showed myofibrillar disarray, reduced contractility, and abnormal calcium handling, which were accentuated with β-adrenergic stimulation. The DCM cells also had increased expression of the phosphodiesterase 2A and 3A genes (*PDE2A* and *PDE3A*) via epigenetic activation connected to the mutant troponin protein, resulting in blunted β-adrenergic signaling. In a study of an LVNC-linked T-box protein 20 (*TBX20*) nonsense mutation, iPSC-derived cardiomyocytes from affected family members compared to those from unaffected family members showed a proliferation defect and abnormal activation of TGF-β signaling, a finding that was reproduced in genetically modified mice.[40]

Genome editing of hPSCs has been useful in introducing or correcting mutations linked to disorders such as familial DCM, Barth syndrome, aortic valve disease, maturity-onset diabetes of the young (MODY), hypoinsulinemic hypoglycemia and hemihypertrophy (HIHGHH), dyslipidemia, and LQTS.

Various lines of evidence—including the discovery of an epidemiologic association between truncating mutations in the titin gene (*TTN*) and familial DCM, the insertion of *TTN* truncating mutations into normal iPSCs followed by differentiation of matched wild-type and mutant iPSCs into cardiomyocytes, and the recognition that mutant cells had sarcomere insufficiency, impaired responses to mechanical and β-adrenergic stress, and attenuated growth factor and cell-signaling activation—now unequivocally demonstrate that *TTN* truncating mutations can be both causal and sufficient for DCM.[41] Similarly, a primary causal relationship between *TAZ* mutations and the dilated-type cardiomyopathy observed in Barth syndrome has been established by evidence showing that the introduction of frameshift mutations into the tafazzin gene (*TAZ*) in wild-type iPSCs reproduced the mitochondrial defects, excess levels of reactive oxygen species, abnormal sarcomere assembly, and impaired contractility observed in iPSC-derived cardiomyocytes from patients with Barth syndrome.[42] Notably, in both the *TTN* and *TAZ* studies, the phenotyping was most informative when performed with engineered myocardial structures where more complex physiologic characteristics could be observed than in single cardiomyocytes.

Mutations in *NOTCH1* have been linked to an inherited form of bicuspid aortic valve with severe calcification of the valve. iPSCs from patients with *NOTCH1* mutations were subjected to genome editing to correct the mutations, followed by differentiation of the matched patient-specific and corrected iPSCs into endothelial cells.[43] When subjected to the in vitro equivalent of vascular shear stress, the mutant endothelial cells did not activate the antiosteogenic, anti-inflammatory, and antioxidant pathways that were observed in corrected endothelial cells, establishing that *NOTCH1* mutations can be both causal and necessary for valvular calcification.

Modeling of Cardiotoxicity with Human PSCs

An important goal during the process of drug development is to assess whether drug candidates have toxic effects that would prevent their clinical use.[33] Cardiotoxicity is a particular concern. Increased risk of ventricular arrhythmia has been involved in 28% of drug withdrawals from the U.S. market, showing that drug candidates that were apparently safe in preclinical models could prove to be unsafe when used by patients. This is clear evidence that standard preclinical models do not faithfully recapitulate some important aspects of human physiology, including cardiac electrophysiology.

Standard preclinical models used to test drug candidates for cardiotoxicity include Chinese hamster ovary (CHO) cells and human embryonic kidney (HEK) cells overexpressing the hERG channel, which is often implicated in drug-induced QT prolongation and ventricular arrhythmias. These cell lines are convenient to use for high-throughput drug screening, but they lack important characteristics of cardiomyocytes, including expression of cardiac ion channels (e.g., the hERG channel is heterologously expressed in the cells). Because of this lack of fidelity, the cell lines can yield incorrect assessments of drug toxicity. For example, verapamil has effects on both potassium channels and calcium channels, which together cancels their opposing effects on QT prolongation and render the drug nonarrhythmogenic. However, when tested in cell lines in which only the hERG potassium channel is expressed, verapamil is incorrectly interpreted as having toxic QT-prolonging activity, creating a false-positive result that could eliminate a safe and potentially valuable drug candidate. Conversely, alfuzosin is a QT-prolonging drug acting on sodium channels rather than hERG, and thus is incorrectly interpreted as nontoxic in hERG-overexpressing cell lines (i.e., false-negative result that “passes” an unsafe and potentially harmful drug candidate). Preclinical animal models also have shortcomings because of their differences in cardiac physiology with humans. For example, the mouse heart beats nine times more quickly than the human heart and has briefer action potentials. Moreover, the hERG channel does not play a major role in

repolarization in mouse cardiomyocytes, and expression of genes involved in sarcomere function and calcium handling differs significantly. Larger animals are more similar to humans with respect to cardiac physiology but can still differ substantially from humans in their drug responses.

hPSC-derived cardiomyocytes have several practical advantages as preclinical models for drug testing. Despite their immaturity compared to adult human cardiomyocytes, they appear to recapitulate drug responses faithfully; for example, they correctly determined verapamil to be nontoxic and alfuzosin to be toxic with respect to QT prolongation.[44] hPSC-derived cardiomyocytes have been used to test the toxicity of a liposomal formulation of doxorubicin, a chemotherapeutic agent known to cause cardiomyopathy in some patients. The finding that there was limited delivery of the drug into the cardiomyocytes and, as a result, no signs of toxicity, contributed to the decision to take the formulation forward into phase I clinical trials.[45] hPSC-derived cardiomyocytes can be produced in large quantities in formats amenable to high-throughput screening. In one study, they were used in a 384-well format to screen 131 different drugs at six concentrations.[46]

Cardiomyocytes can be obtained using patient-specific iPSCs, which potentially offer the ability to predict whether drugs will be toxic or nontoxic when administered to the patients from whom the iPSCs were obtained. For example, iPSCs were generated from breast cancer patients who either developed or did not develop cardiomyopathy on receiving doxorubicin.[47] When treated with doxorubicin, iPSC-derived cardiomyocytes from the cardiomyopathy patients had reduced viability, impaired mitochondrial and metabolic function, impaired calcium handling, decreased antioxidant pathway activity, and increased reactive oxygen species production compared to cardiomyocytes from the noncardiomyopathy patients. Thus, it may be feasible to use iPSCs prospectively to determine which patients are more or less likely to develop doxorubicin-induced cardiomyopathy and tailor their chemotherapeutic regimens appropriately. Similarly, iPSC-derived cardiomyocytes from more than 10 individuals have been used to screen more than 20 U.S. Food and Drug Administration (FDA)-approved *tyrosine kinase inhibitors* (TKIs) used to treat various types of cancer. The data generated allowed the researchers to generate a “cardiac safety index” to assess the cardiotoxicity of existing TKIs.[48] Furthermore, transcriptional profiling of iPSC-derived cardiomyocytes paired with bioinformatics analysis has been used to predict patient-specific drug-induced cardiotoxicity.[49] Also, iPSC-derived cardiomyocytes could potentially be used to assess a patient's risk of an adverse outcome from an environmental exposure other than a drug. For example, they have been used to provide an in vitro model for coxsackievirus B3–induced myocarditis.[50]

Cardiovascular Precision Medicine with Human PSCs

The U.S. National Institutes of Health (NIH) calls precision medicine “an emerging approach for disease treatment and prevention that takes into account individual variability in genes, environment, and lifestyle for each person.” As avatars of people's genetic makeup, iPSCs could have an important role in the practice of precision medicine. As previously discussed, iPSCs offer an opportunity to test whether medications will produce pathology in a patient's cardiomyocytes or, conversely, whether they can repair cardiomyocytes that already are in a diseased state, without exposing the patient to risk. In principle, several alternative medications could be tested in vitro on iPSC-derived cardiomyocytes to help choose the optimal medication beforehand rather than testing each medication individually in the patient.

Early studies suggest that iPSCs may indeed be useful in matching the right treatments to the right patients. In one study, iPSC-derived cardiomyocytes from patients with HCM or LQTS were more vulnerable to the arrhythmogenic effects of cisapride, a drug previously withdrawn from the U.S. market when it was found to cause ventricular arrhythmias in patients with heart failure or preexisting QT

prolongation.[51] In another study, an LQTS patient with frequent ventricular arrhythmias was found to harbor possibly pathogenic mutations in two LQTS-associated genes, *KCNH2* and *SCN5A*; iPSC-derived cardiomyocytes from this patient clarified that the latter gene had the pathogenic mutation, because the cells had sodium channel but not potassium channel current defects.[52] The cells responded better to treatment with one sodium channel blocker, mexiletine, rather than a combination of two sodium channel blockers, mexiletine and flecainide, and the defects were also improved with increased pacing of the cells. Consistent with these findings, the patient's arrhythmias had been found by trial and error to be best controlled by using mexiletine alone and setting the patient's ICD to a high pacemaker rate. Although no examples have yet been reported, it is conceivable that a patient's iPSC-derived cardiomyocytes could be used to perform drug screening to identify a novel or tailored treatment for the patient's disease.

Besides being useful for determining the optimal treatments for patients, hPSCs could play an important role in predicting which individuals are at risk for certain diseases. Although much progress has been made in understanding the genetic basis of both monogenic and complex cardiovascular disorders (**see also Chapter 7**), risk prediction remains an enormous challenge. With clinical exome and genome sequencing now being performed in many patients, a related challenge is that of the "variant of uncertain significance." For example, a patient may be incidentally found to harbor a variant in a gene related to HCM (**Chapter 78**) or DCM (**Chapter 77**), raising the questions of whether the patient is genuinely at risk for cardiomyopathy, whether the patient should be prospectively managed as someone at risk of developing cardiomyopathy, and whether the patient should even be alerted to the finding of the variant. Complicating the issue, computational and population-based methods of discriminating among pathogenic and benign mutations have so far proved to be unreliable.

Human PSCs may be used in various ways to improve risk prediction for diseases such as the cardiomyopathies. For example, because they are genetically matched to patients, iPSC-derived cardiomyocytes could be phenotyped for characteristics that suggest the patients are susceptible for disease, including characteristics such as gene expression signatures, morphologic and functional properties, and pharmacologic responses. Another approach to addressing patient-specific variants of uncertain significance would employ genome editing in hPSCs to obtain functional readouts of the variants. For either strategy to be successful, extensive characterization and comparison of iPSC-derived cardiomyocytes from patients with diseases of interest versus healthy individuals would be needed to define criteria by which to properly classify pathologic versus normal cardiomyocytes—thus the need for large-scale disease-modeling efforts involving cohorts of iPSCs. Recent efforts by funding agencies to establish iPSC biobanks with hundreds of lines from patients with different disorders will be invaluable in this regard.

Future Perspectives and Prospects for Cardiac Repair

The goal of cardiac repair is to reverse the pathologic process in cardiomyocytes leading to heart disease. Currently, several therapeutic approaches have shown promising results in preclinical animal models, all of which must be validated before clinical use can commence (**Fig. 30.4**). The first is the use of traditional small-molecule therapeutics that modify protein activity in such a way as to mitigate the disease process. One example is the development of an inhibitor of myosin adenosine triphosphatase (ATPase) to reduce the contractility of cardiomyocytes, which was shown to halt and even partially reverse the progression of disease in a mouse model of HCM.[53] The second is gene therapy, which

introduces a therapeutic gene into cardiomyocytes via a viral vector based on either adenovirus or adeno-associated virus (AAV). One example is the delivery of sarcoendoplasmic reticulum calcium-ATPase (SERCA) 2a for the treatment of heart failure. This strategy has been tested with encouraging results in a variety of experimental models of heart failure,[54] although results from the recent CUPID 2 trial did not find evidence of improved patient outcomes.[55]

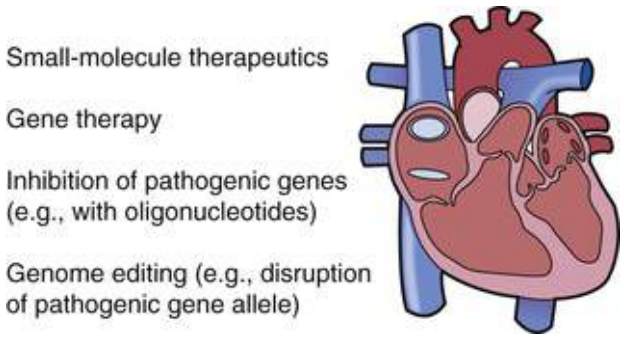

FIGURE 30.4 Possible therapeutic approaches to cardiac repair.

The third therapeutic approach is inhibition of a pathogenic gene in cardiomyocytes. One example is the use of RNA interference to specifically knock down the expression of the dominant mutant allele of *MYH6* responsible for disease in a mouse model of HCM; the therapy slowed the development of disease in mice.[56] The recent emergence of CRISPR-Cas9 genome editing offers a different approach to gene inhibition, creating permanent disruption or correction of the pathogenic gene allele. While gene disruption via NHEJ and gene correction via HDR have been demonstrated to occur at high efficiency in mouse liver in vivo,[57,58] which raises the possibility of addressing metabolic disorders such as dyslipidemia that contribute to cardiovascular diseases, it remains to be seen how efficiently genome editing will work in myocardium. Since HDR is typically only active in proliferating cells, gene repair may not be a viable option in the nonproliferative cardiomyocytes in the adult heart using current genome-editing techniques, although gene disruption by NHEJ may still be feasible.

The past few decades have witnessed extraordinary efforts to advance cardiovascular regeneration and repair. Progress toward the development of human clinical therapies has been slower than researchers and patients alike had hoped, but the next decade will surely see some important steps forward in this area.

Acknowledgments

The authors wish to acknowledge the previous contributions of Drs. Roger J. Hajjar and Joshua M. Hare to this chapter, particularly the introduction and the section on Tissue Engineering.

Management of Patients with Cardiovascular Disease Approaching End of Life

Larry A. Allen, Lynne Warner Stevenson

Thirty years ago, death in patients with cardiac disease often occurred unexpectedly and rarely followed a protracted period of refractory symptoms. Successful therapies have since rerouted the course of almost every cardiovascular disease (**Fig. 31.1**). Early coronary revascularization and secondary prevention have increased survival after acute myocardial infarction, with a parallel increase in the prevalence of

heart failure (**see Chapter 21**). Improved surgical techniques for congenital heart disease have created a growing population of adults with unique structural heart disease (**see Chapter 75**). Advances in cancer chemotherapy and radiation have left many survivors with new, life-threatening cardiac disease (**see Chapter 81**). Widespread use of neurohormonal blockade and implantable devices in patients with reduced left ventricular ejection fraction has contributed to a decrease in sudden death associated with prolongation of life and death with pump failure (**see Chapter 25**). The aging of the population yields an increasing number of patients with senile aortic stenosis and vascular pathology who may now be eligible for percutaneous procedures, but they remain limited by the multimorbidity and frailty that rendered them ineligible for open surgery in the first place[1] (**see Chapter 88**).

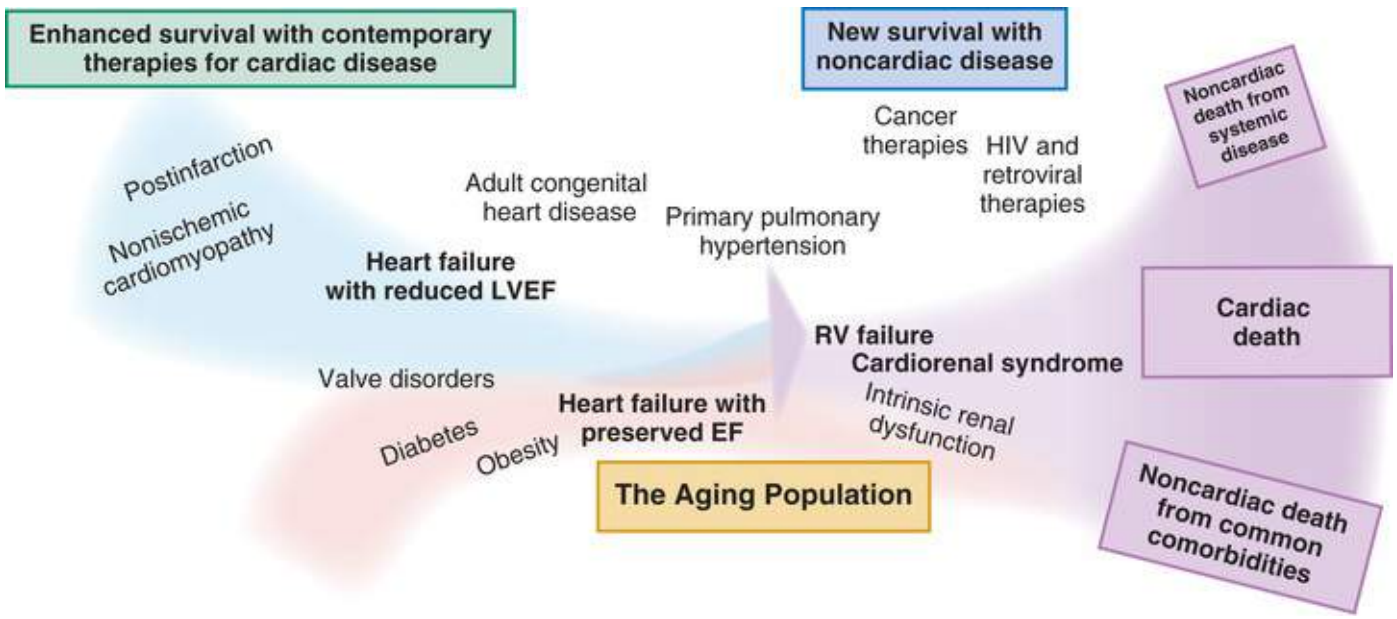

FIGURE 31.1 Complex contemporary pathways to death with cardiac disease. Patients with a history of myocardial infarction or dilated cardiomyopathy have extended survival with good quality of life, particularly because of decreases in ventricular remodeling and decreases in sudden death, as well as decreased reinfarction with coronary artery disease. With prolonged survival, right ventricular (RV) failure and the cardiorenal syndrome are more frequently seen in the late stages of heart failure not only with reduced left ventricular ejection fraction (LVEF), but also with preserved ejection fraction (EF) and in adult survivors with congenital heart disease. Successful therapy of cancer has created a population with cardiac disease resulting from chemotherapy and radiation, and long-term survival with human immunodeficiency virus (HIV) can be accompanied by cardiac disease due to infections and to retroviral therapies. Both heart failure and aortic stenosis are often diagnosed in the aging population, in whom the increased prevalence of diabetes and obesity also increase symptoms and death from noncardiac comorbidities.

Once prolongation of life no longer drives treatment, the focus of disease management shifts to palliation of symptoms. Unfortunately, in practice, this shift too often jolts patients and families as a sudden reversal of strategy from “do everything” to “do nothing,” rather than a gradual transition away from procedural intervention through a phase of care increasingly but not exclusively focused on quality of life. Guiding patients and families to understand prognosis and express goals of care is crucial for them to share in decisions about the intensity and timing of care. When a cardiac condition is likely to cause or accelerate death within the coming year, cardiac specialists may often have a good vantage point from which to survey the disease trajectory and steer the direction of care.[2] Ideally, patients continue to the end guided by health care providers who maintain longitudinal relationships with them and apply palliative care principles to smooth this journey. This chapter clarifies main concepts and provides practical approaches to the management of patients with cardiovascular disease nearing the end of life (**Table**

31.1).

TABLE 31.1

Key Messages for Managing Patients with Cardiovascular Disease Approaching End of Life

1. Worsening disease should trigger preparation with patients and families, but without specifically answering the question of how much time remains, which is usually bounded by wide uncertainty.
2. "What-if" conversations should be standard before any major intervention in the setting of advanced cardiac disease or other serious medical conditions, including frailty.
3. Difficult discussions now will simplify difficult decisions in the future.
4. Shared decisions include a broad spectrum of potential interventions beyond those relating to resuscitation preferences.
5. Deactivation of the defibrillation function of implantable cardioverter-defibrillators should be explained and offered regularly to patients with poor prognosis and must be done before transition to hospice.
6. Palliative care specialist consultation may be particularly helpful to facilitate decision making within challenging family dynamics and to improve relief of refractory symptoms.
7. Clinicians with existing relationships should shoulder the primary responsibility for presenting an end-of-life plan consistent with values and goals expressed by patient and family.
8. The transition separating "do everything" from hospice may be bridged through a phase of "quality survival" during which patients increasingly weigh the benefits, risks, and burdens of initiating or continuing life-sustaining treatments.
9. Revision of the medical regimen for symptom relief and quality of life may involve discontinuation of some recommended therapies and addition of therapies not usually recommended.
10. The end-of-life plan should honor patient preference for the site of death as feasible, with agreement on a "plan B" if that becomes unsupportable.

Integration of Palliative Care Into Cardiovascular Care

Palliative care is designed to improve quality of life for patients and their families through anticipation of declining health status and major events, clarification of goals of care, relief of physical symptoms, provision of psychosocial and spiritual support, coordination of care, and assistance with bereavement[3] (**Fig. 31.2**). Given the high prevalence, morbidity, and lethality of many cardiovascular (CV) diseases, they create a substantial need for palliative care at the end of life[4,5] (**eFig. 31.1**). However, many providers of cardiovascular care do not distinguish between palliative care and hospice or understand the indications for these services.[6] Palliative approaches to care should be integrated throughout the care of patients with CV disease, with intensification during major events and approaching the end of life[2] (**Fig. 31.3**).

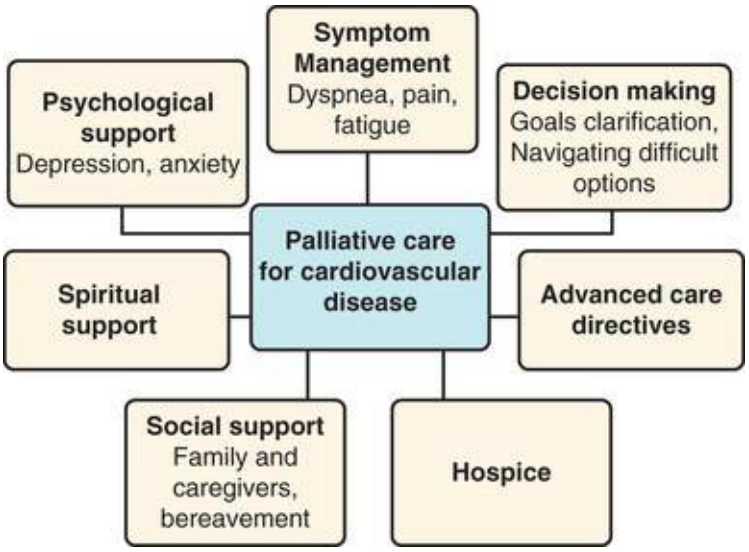

FIGURE 31.2 Components of palliative care for cardiovascular care.

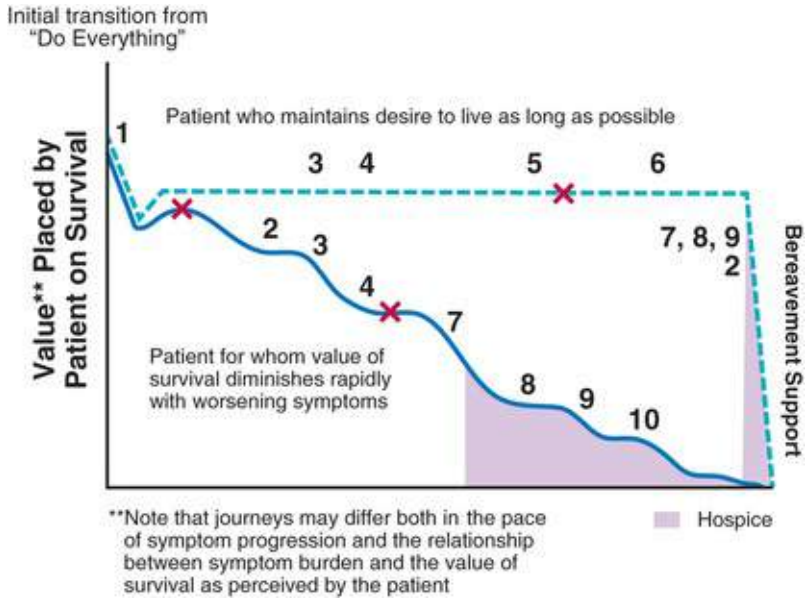

FIGURE 31.3 Examples of differing journeys through the phase of "quality survival" in patients nearing the end of life. *1,* Initial shift from "do everything" to limited intervention and prognosis. Examples of intervention: *2,* Inactivation of defibrillation function of implantable cardioverter-defibrillator. *3,* Screening colonoscopy canceled. *4,* Hospitalization for worsening heart failure symptoms. *5,* Transfusion for hypotension from gastrointestinal bleed (not appropriate for patient in hospice). *6,* Blood cultures to evaluate fever (not appropriate for patient in hospice). *7,* Palliative care nearing end of life can include initiation of opiates for refractory dyspnea whether or not patient is in hospice. *8,* Discontinuation of angiotensin-converting enzyme inhibitors and beta blockers for fatigue with systolic blood pressure less than 80 mm Hg. *9,* Discontinue blood tests. *10,* Benzodiazepines for anxiety. *x,* Possibility of death occurring during sleep or precipitous clinical decline at any point in this phase without time for hospice.

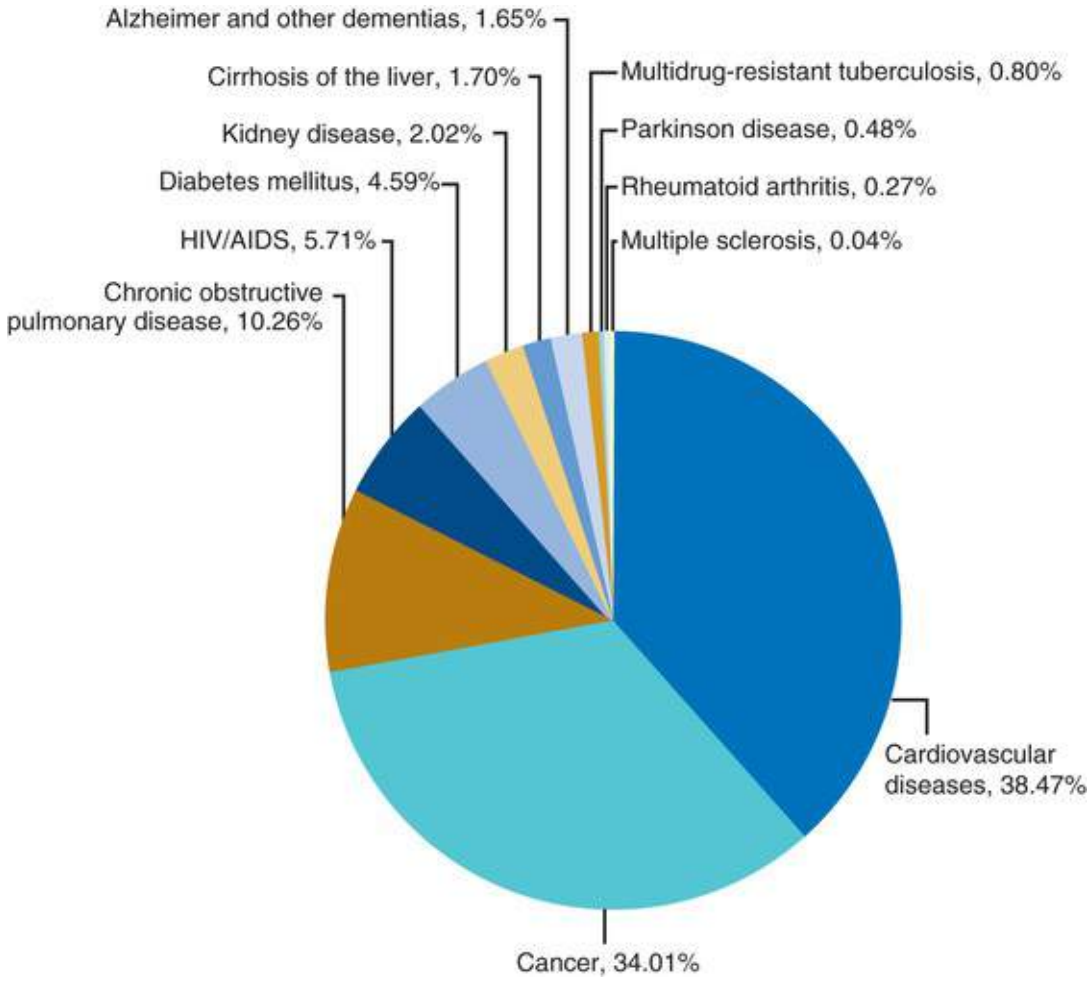


EFIGURE 31.1 Distribution of adults in need of palliative care at the end of life by disease, with cardiovascular diseases constituting the greatest need. (From http://www.who.int/nmh/Global_Atlas_of_Palliative_Care.pdf. Copyright World Health Organization, 2014.)

Primary Palliative Care

All clinicians caring for patients with advanced CV disease play a role to provide supportive and palliative interventions. This role is vital because (1) many of the therapies that improve symptoms and quality of life derive from treatment of the underlying CV disease; (2) prognosis and complex decisions are often best understood by the cardiovascular specialist; (3) integrated care is often preferable to further fragmentation through another consult team; and (4) there are not enough palliative care specialists to provide such services to everyone in need. Provision of supportive care by the usual care team has been designated as *primary* palliative care, to distinguish it from *secondary* or *subspecialty* palliative care.[5] Clinicians supervising inpatient or longitudinal care for patients with CV disease should regard expertise in providing palliative care as integral to their professional competence.

Secondary (Subspecialty) Palliative Care

Palliative care clinicians receive specific training in management of refractory symptoms and facilitation of difficult care planning in life-threatening illnesses. Hospice and Palliative Medicine is a recognized medical subspecialty in the United States,[7] Canada, England, Ireland, Australia, and New Zealand. Master's degree programs have been developed for physicians, nurse practitioners, physician assistants, and nurses who are interested in becoming community palliative care specialists, and specialty certifications are also available for nurses, social workers, and chaplains. In most jurisdictions, specialty

palliative care is provided by an interdisciplinary team who work with a patient's other clinicians to provide an “extra layer” of support.[8]

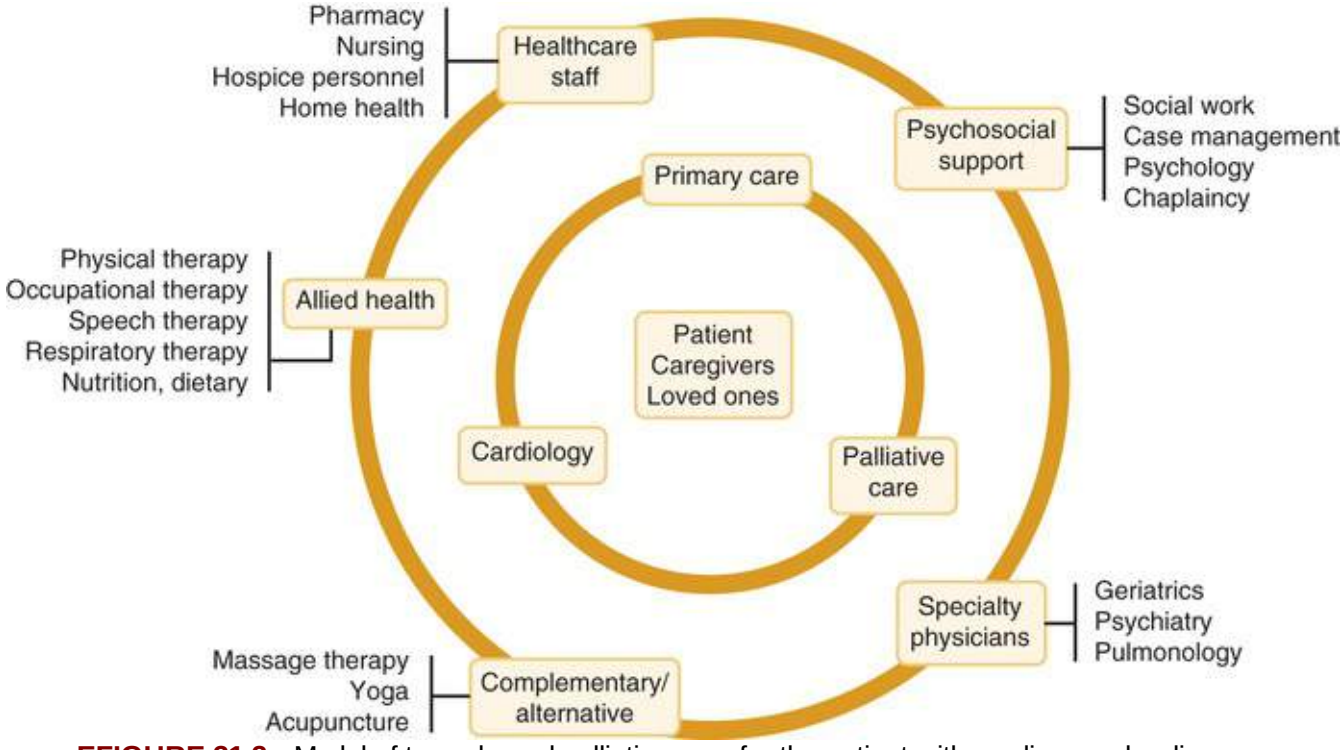
Hospice

The term *hospice* is used to describe a specific model of palliative care offered to patients who are at the end of life with a terminal disease when curative or life-prolonging therapy is no longer a focus of treatment. Historically, hospice was developed for patients with cancer, but it is increasingly used for patients with CV disease, with 14.7% of admissions to U.S. hospices in 2014 having a primary diagnosis of heart disease.[9] Referral is guided by the U.S. Centers for Medicare and Medicaid Services (CMS) hospice eligibility guidelines, which require that a physician estimate that life expectancy is 6 months or less.[10] The 6-month period is rarely reached, but patients who survive longer can usually continue to receive hospice benefits if the prognosis remains poor.

Palliative Care Consultation

Indications

Various specialties may assume the central role in coordination of patient care at different stages of disease progression, often with transition of leadership from primary care to cardiology to palliative care[11] (**eFig. 31.2**). Shared ownership and planning around palliative care needs can improve communication and understanding of patient goals and achieve better end-of-life experiences. Formal consultation may be particularly helpful when symptoms remain intolerable or when medical decision making is particularly challenging. For example, since 2013, national standards require centers that offer permanent mechanical circulatory support to include palliative care specialists as part of the team from evaluation through to death.[12] Similar mandates are anticipated for palliative consultation to review options and “what-ifs” for other major cardiac interventions with high mortality and morbidity.



EFIGURE 31.2 Model of team-based palliative care for the patient with cardiovascular disease.

Benefits

Data are mixed regarding effectiveness of specialty palliative care. Retrospective analysis of Medicaid patients in four New York hospitals from 2004 to 2007 indicated that palliative care consultation during hospitalization for exacerbation of chronic fatal illness, including heart failure, was associated with a $4000 lower cost for discharged patients and $7000 lower cost for patients dying during that hospitalization.[13] The Palliative Care in Heart Failure (PAL-HF), a single-center randomized trial of 150 patients with advanced heart failure, showed that randomization to a multidisciplinary palliative team intervention improved scores for quality of life and functional assessment of chronic illness therapy with palliative care (FACIT-Pal) at 6 months.[14] In a large randomized trial in intensive care settings, however, palliative care specialist supervision of at least two structured family meetings and written information did not decrease anxiety or depression and may have increased post-traumatic stress for families compared to similar intervention led by the intensive care unit teams.[15] To be effective, palliative care consultations need to be targeted to the right patients at the right time and integrated thoughtfully into the overall plan of medical care.

Having Difficult Conversations

High-quality communication is one of the most important interventions for patients with severe CV disease. When done well, such discussions can help to align therapy with patient goals, improve quality of life for both patients and caregivers, and enhance the quality of medical decisions and symptom palliation. End-of-life discussions are sensitive and time-consuming and may be further complicated by discordant priorities of patients and their families. Almost half of older Americans report they have not had any end-of-life planning discussion.[16] In 2016, CMS established specific reimbursement for two advance care planning sessions provided to Medicare beneficiaries by physicians or other practitioners,[17] which will diminish the financial disincentive to engage in these discussions. However, these discussions

are also avoided due to lack of training in palliative and communication techniques. In a multisite survey of 95 cardiology and primary care physicians, nurse practitioners, and physician assistants, almost one-third reported a low or very low level of confidence in initiating prognosis or end-of-life discussions, enrolling patients in hospice, or providing end-of-life care.[18]

Anticipating Disease Trajectory

The disease trajectory for individual patients is variable and characterized by considerable uncertainty. Guidelines recommend using validated scores to estimate mortality risk in cardiac disease.[19] Many cardiovascular risk models are well validated, available online, and increasingly used (e.g., http://www.heartfailurerisk.org, https://depts.washington.edu/shfm/, http://www.gracescore.org/website/WebVersion.aspx). These models may be useful to reduce unrealistic expectations and alert clinicians who have not recognized the need to discuss prognosis with a patient at high risk for adverse events, but cannot replace thoughtful review and recognition of uncertainty.

Timing of Discussions

It is clearly preferable to have these types of discussions prior to the need for urgent decisions. A routinely scheduled "annual review" has been proposed to help patients with significant disease understand their medical trajectory and potential future choices.[2] Then, clinical events and major decisions should trigger reevaluation of disease trajectory, goals, and treatment preferences (**Table 31.2**). These "milestones" include hospitalization for worsening CV disease, development of a new diagnosis such as cancer, or consideration of invasive procedures. Use of an algorithm during hospitalization to trigger palliative care consultation has increased the frequency of goals-of-care conversations.[20] However, it is important to reevaluate resuscitation decisions, because more than 20% of patients have been shown to change their preferences in the subsequent months.[21]

TABLE 31.2

Triggers for Formally Assessing Prognosis and Having Conversations about Goals of Care and Voluntary Advance Care Planning

Routine
"Annual Heart Failure Review" with a scheduled clinic visit
Event-Driven "Milestones" that Should Prompt Reassessment
Increased symptom burden and/or decreased quality of life
Significant decrease in functional capacity
Loss of activities of daily living
Falls
Transition in living situation (independent to assisted or long-term care)
Worsening heart failure prompting hospitalization, particularly if recurrent
Serial increases of maintenance diuretic dose
Symptomatic hypotension, azotemia, or refractory fluid retention necessitating neurohormonal medication withdrawal (renin-angiotensin-aldosterone system inhibitors and beta blockers)
First or recurrent implantable cardioverter-defibrillator shock for ventricular arrhythmias
Initiation of intravenous inotropic support
Consideration of renal replacement therapy
Other important change in comorbidities (e.g., new cancer)
Major "life events" (e.g., death of spouse)

Framing the Conversation.

Most patients and their families desire open, honest, and accurate information.[22] Yet, talking about the end

of life with patients who have CV disease is often an unexpected “bad news” conversation. The clinician should plan carefully before opening the discussion. Asking patients to describe how their activities and symptoms have changed over time often leads them to recognize the progression of their own illness, which can improve acceptance. Shaping discussion around “ask-tell-ask” can help:[23]

- Ask what the patient understands and what information the patient wants.
- Tell information that responds to the patient's questions, correct misunderstandings, and explain other factors important to the patient's decisions.
- Ask the patient to summarize what has been heard and what further questions the patient may have.

The clinician should expect that more than one period of discussion will usually be necessary.

Recognizing Emotion and Cognitive Biases.

During medical decision making for end-stage CV disease, emotion is heightened, and *mortality salience* (awareness that death will happen) is pushed to the front of consciousness.[24] Until emotions are recognized and acknowledged, people can have difficulty engaging in the more cognitive aspects of medical decision making. This can be done by using explicit language normalizing strong emotions and careful framing of information to minimize cognitive biases.

Discussing Prognosis While Recognizing Uncertainty

Multiple studies have shown that patients and clinicians tend to overestimate survival.[25] Particular care should be taken to avoid a numeric answer to the common question, “How long do I have to live?” For example, it has been demonstrated that for patients predicted to die at a certain time with late-stage cancer, about half will either die in less than half the predicted time or survive for more than twice as long.[26] It is better to focus on preparation for the end of life rather than prediction of when it will come. The palliative care motto of “hope for the best and prepare for the worst” can facilitate discussion of prognosis and care planning in all phases of disease.

Goals and Values.

After discussion of what and how the patient wants to know about prognosis, most conversations can pivot naturally to asking the patient about important goals as the overall health status worsens. The Serious Illness Conversation Guide provides one example of how this can be done.[20] Specific fears and worries are elicited from the patient about what might happen, as some may be allayed and others may direct choices that will need to be made. In a related question, patients consider what abilities are so critical to their lives that they could not imagine life without them. One of the most important aspects of patient preference is the answer to the question, “If you become sicker, how much are you willing to go through for the possibility of getting more time?” Studies of patients with advanced heart failure show a wide range of preferences around what they would be willing to endure to increase their likelihood of longer survival.

Decision Support Tools.

Shared decision making recognizes that there are often complex trade-offs in medical decisions and extends beyond the limited legal mandate to inform patients of risks and benefits of a treatment.[27] Patient

decision aids designed to facilitate patient participation in health care decisions can be helpful to convey critical information, elicit patient preferences, and encourage deliberation (https://decisionaid.ohri.ca/azinvent.php).[28] They are not substitutes for conversations with health care providers, but tools to help frame high-quality discussions. The use of decision aids generally improves patient knowledge and awareness of treatment choices.[29]

Medical Decision Making Near the End of Life

Is There Still a Definitive Treatment Option?

After recognizing that a patient may be nearing the end of life with cardiac disease, it is important for the medical team to devote final consideration to whether any major interventions could favorably alter the course of disease. Examples include valve replacement or coronary revascularization. If there is a feasible option to consider in a patient at high risk for procedural complications, it should be presented together with a clear alternative option of palliative care focused on quality of life. The elements of the conversation as previously described would help to determine whether the procedure is aligned with the patient goals and values. Unfortunately, current procedural outcome data often focuses only on survival, with limited objective data on the likelihood of adverse events, loss of independence, and caregiver burden, which are crucial components of decision making for many patients with serious illness. For patients who have chosen to undergo procedures with a high risk of adverse outcomes, preparation before surgery should include discussion about how they would translate their goals to the setting of "what-ifs" (e.g., ventilator dependence or stroke).

The Transition to End of Life Is Not a Point but a Process

The time and extent of transition away from "do everything" varies across diagnoses, patients, and families.[30] The acceptance of death within the near future may be unstable, and for some, may never be fully completed before the end. Usually, however, it is important to accept that there is a point after which major interventions, as exemplified earlier, will not be revisited. At the time of this major transition, it is generally appropriate and reassuring to continue all therapies that patients have been receiving for disease stabilization. However, the patient and family should understand that therapies can be added or removed for the goal of improving symptoms and quality of life, even if the change might shorten survival, unless maximizing the remaining survival remains the predominant goal for the patient. Additional content is available in the online supplement for this chapter (Removing Therapies and Futility).

Advance Care Planning Documentation

Advance care planning, defined as "planning for and about preference-sensitive decisions often arising at the end-of-life," is an ongoing process in which patients, families, and health care providers discuss current and future health care choices in the context of what is medically reasonable.[31] Such discussions can unfold in many ways but include a review with expression of preferences (**eTable 31.1**), resulting in various types of documentation (**Table 31.3**). The health care proxy should have been completed long before this stage of disease but should be confirmed at this time. The general principles guiding the completion of these documents are derived from the discussions of goals, values, and preferences (as outlined previously). An important distinction clarified in medical orders for life-sustaining treatment

(MOLST) forms is between the use of life-support interventions for an indefinite period versus a brief period, such as mechanical ventilation for chronic respiratory failure versus a pneumothorax, or dialysis for chronic renal failure versus iatrogenic hyperkalemia. Although the resuscitation decision in hospitals receives appropriate attention as a signpost for other decisions, the frequency of cardiopulmonary resuscitation was only 1.1% in a study of 1.4 million heart failure hospitalizations. Of those patients, 73% died before discharge, 10% were discharged to a skilled nursing facility, and only 16% were discharged home.[32]

TABLE 31.3

Types of Advance Care Directives and Documentation

- A **living will** is a signed, witnessed (or notarized) document called a "declaration" or "directive." A living will can be very specific or very general. Most declarations instruct an attending physician to withhold or withdraw medical interventions from its signer if he/she is in a terminal condition and is unable to make decisions about medical treatment.
- A **health care proxy** (Durable Power of Attorney for Health Care) is a legal document in which an individual designates another person to make health care decisions if he/she is rendered incapable of making their wishes known. The health care proxy has, in essence, the same rights to request or refuse treatment that the individual would have if capable of making and communicating decisions.
- A **combination advance directive** is a signed, witnessed (or notarized) document that contains specific written directions that are to be followed by a named agent (e.g., Five Wishes).
- **Medical orders for life-sustaining treatment** (MOLST, or physician orders, POLST) is a medical order form that tells others the patient's medical orders for life-sustaining treatment. MOLST is generally for patients with serious health conditions. All health care professionals must follow these medical orders as the patient moves from one location to another, unless a physician examines the patient, reviews the orders, and changes them.

ETABLE 31.1

Components of Advance Care and Preparedness Planning Discussion

Characterize clinical status.	Assess current functional ability, symptom burden, mental status, and quality of life. Review recent disease trajectory. Integrate impact of noncardiac diseases. Solicit perceptions from caregivers for corroboration.
Acknowledge prognosis and uncertainty.	Recognize uncertainty. Review different possible clinical courses and causes of death. Consider incorporating objective risk modeling data into qualitative messaging within wide time frames.
Solicit patient values and beliefs.	Clarify values as they relate to trade-offs (e.g., aggressive vs. nonaggressive care, quality versus quantity of life). Identify major life goals. Envision physical limitations that would be unacceptable. Elicit general care preferences.
Review treatments.	Evaluate indicated and contraindicated cardiac medications and devices. Consider overlap and interactions with comorbidities. Factor in declining relevance of routine preventive care.
Consider options.	Anticipate major treatment choices on the horizon.
Document.	Document in the medical record surrogate decision makers, resuscitation preferences, and preferences for and location of end-of-life care. Communicate "do-not" outside the hospital (e.g., Medic-Alert bracelet, posting on refrigerator).

Complex Treatment Decisions

Although advance care planning documents provide important guidance, many complex medical decisions may arise that are neither anticipated nor addressed by the specific details of the documents (**eTable 31.1**). Additional content is available in the online supplement for this chapter (Complex Treatment Decisions).

Treatment of Symptoms Approaching End of Life

Progressive symptoms are the most common reason for reduced health status in patients with CV disease.[33] Among patients with heart failure (HF)—the final common pathway for many heart diseases—symptom burden at the end of life is often greater than for patients with advanced lung or pancreatic

cancer.[34] Thus, design of the cardiovascular regimen and general palliative approaches are critical near the end of life.

Ongoing Role for Cardiovascular Treatments

The best treatment to relieve late-stage cardiac symptoms is often continuation of the regimen that was initiated to decrease progression from earlier stages of disease. For example, the treatment of angina at any stage of ischemic heart disease involves reducing myocardial oxygen supply/demand mismatch. The primary treatment of symptomatic congestion remains diuretic therapy. Supplementation with oral, sublingual, or topical nitrates can temporarily help redistribute volume when adequate diuresis cannot be achieved. If symptoms are related to diuretic resistance or hypotension, a decrease in or discontinuation of neurohormonal antagonists may improve comfort by enhancing diuretic response and increasing systemic blood pressure (**eTable 31.2**). Although discontinuation of these agents is associated with worsening HF over time in stable patients, it is unlikely to worsen cardiac function or symptoms in the final days of life. Caution is required in certain situations; for example, withdrawal of beta-adrenergic receptor blockers may worsen symptom burden in patients with frequent angina or tachyarrhythmias. Relaxation of chronic sodium and fluid restriction often worsens symptoms of congestion; however, favorite foods and beverages can be a major factor in quality of life and social interaction for some patients at a time when few other shared pleasures remain.

ETABLE 31.2

Common Cardiovascular Medications and Changing Indications at End of Life (EOL)

COMMON MEDICATIONS FOR CARDIAC DISEASE	USUAL INDICATIONS TO MODIFY DISEASE AND IMPROVE LONG-TERM OUTCOMES	POSSIBLE SHORT-TERM SYMPTOM BENEFIT OF CONTINUING AT EOL	POTENTIAL HEMODYNAMIC IMPACT DURING EOL	POSSIBLE DELETERIOUS EFFECT AT EOL	COMMENTS ON DISCONTINUATION AT EOL
ACEIs/ARBs	To prolong survival, prevent reinfarction, and improve ventricular function. Decrease HF hospitalizations. Treat HTN.	Not expected	Lower blood pressure	Symptoms of hypotension and declining diuretic response	Renal function likely to improve. Symptoms of hypotension may improve.
Beta blockers	As above. Decrease recurrence of ventricular tachycardia. Decrease ventricular rate of atrial fibrillation.	Decrease angina. Decrease tachyarrhythmias.	Higher filling pressures Lower cardiac output Lower blood pressure	Worsening dyspnea Worsening fatigue Symptoms of hypotension	Energy and symptoms of hypotension may improve. Renal function might improve. Be alert to exacerbation of angina or symptomatic arrhythmias.
Sacubitril/valsartan*	To prolong survival and decrease hospitalizations in chronic HF	May decrease dyspnea and edema.	Lower blood pressure	Symptoms of hypotension	Symptoms of hypotension may improve. Diuretic requirement may increase.
Mineralocorticoid Antagonist	Decrease fibrosis, improve survival, and decrease HF hospitalizations.	Weak synergy with other diuretics. Decreases need to take oral potassium.	Possible slightly lower filling pressures	Need for potassium binders if serum potassium is high	Renal function may improve. Less risk of hyperkalemia, but hypokalemia may cause cramps and muscle fatigue.
Loop diuretics†	Treat congestion and maintain fluid balance. Facilitate titration of neurohormonal antagonists.	Most effective treatment of dyspnea and edema through diuresis.	Most effective therapy to lower filling pressures and valvular regurgitation	Increased need to take potassium	Marked exacerbation of dyspnea and other congestive symptoms patients with fluid retention.
Nitrates†	Relief of angina. With hydralazine, to improve outcomes in African American patients. Treat HTN.	Decrease dyspnea. Decrease chest pain.	Lower blood pressure Lower filling pressures and valvular regurgitation	Can cause headaches	Relief of nitrate headaches Worsening of dyspnea Symptoms of hypotension may improve.
Hydralazine	With nitrates, to improve survival, symptoms, and decrease hospitalization in African American patients. Treat HTN.	Might decrease dyspnea or angina with severe mitral regurgitation	Modestly lower filling pressures and blood pressure if baseline vasoconstriction Less mitral regurgitation	Can cause nausea	Nausea may improve. Dyspnea might worsen if mitral regurgitation severe.
Statin therapy	Improve outcomes with atherosclerotic disease.	None		Can cause or aggravate myalgias	No known benefit at EOL
Digitalis glycosides	Decrease hospitalization in symptomatic HF. Decrease rate in atrial fibrillation.	Decrease rate in atrial fibrillation.	Modestly higher cardiac output	Nausea Visual disturbances Digoxin toxicity if declining renal function	Discontinuation known to exacerbate HF symptoms. May discontinue to avoid toxicity if progressive renal dysfunction.
Sodium (Na) and fluid restriction	Decrease fluid retention. Treat HTN.	Decrease dyspnea and edema.	Restriction is likely to decrease filling pressures and valvular regurgitation.	Diminished enjoyment of food and social contact Diminished quality of life May accelerate cachexia Family conflict regarding adherence	Relaxation of Na restriction may improve quality of life, nutrition, and social contact. Generally relaxed only for special occasions or when death anticipated within a few days. May reduce patient-family conflict related to adherence.
Nonsteroidal anti-inflammatory drugs contraindicated in HF	Contraindicated because of potential for worsening HF, fluid retention, and renal function	Use may diminish musculoskeletal pain, especially from gout.	May increase filling pressures and valvular regurgitation	Dyspnea and edema may increase with fluid retention and renal dysfunction.	Intermittent use may improve comfort and mobility. Benefit must be weighed against effects to decrease renal function and increase fluid retention.

*Insufficient experience to anticipate effects of withdrawal near end of life.

†Note alternative routes of administration for patients with difficulty swallowing medications.

ACEIs, Angiotensin-converting enzyme inhibitors; *ARBs,* angiotensin receptor blockers; *HF,* heart failure; *HTN,* hypertension.

Inotropic Infusion (see also Chapter 24).

Continuous inotropic infusions are selectively used to treat symptoms of refractory HF. Even when intended to be temporary, the decision to start inotropic therapy should be undertaken only after careful consideration of next steps. For patients discharged on home inotropic infusions, reported survival has improved from less than 50% at 6 months to approximately 50% at 1 year.[35] The decreased mortality may be related to lower dosing, increased presence of implantable cardioverter-defibrillators (ICDs), or use in patients with less advanced disease. Patients should not be discharged on intravenous inotropic infusions with the anticipation that death will occur peacefully at home, since many are readmitted with recurrent symptoms, infectious complications, or breaks in the indwelling catheters. The potential complications and the inconvenience for patients and families warrant repeated attempts to wean inotropic therapy before discharge, which can be facilitated by stopping neurohormonal antagonists, in some cases with substitution of hydralazine and nitrates and cautious use of digoxin. An additional concern is that many home nursing agencies are not able to offer the benefits of hospice care to patients receiving relatively costly continuous infusions.[36]

General Palliation for Refractory Symptoms.

Even with expert cardiovascular management, symptoms are rarely completely relieved and often worsen as the disease becomes increasingly refractory to CV-focused therapies.[30] The basic principles, strategies, and expected benefits of palliative care approaches to symptoms pertain to severely symptomatic and functionally limited patients with end-stage CV disease.[4] Furthermore, CV disease rarely occurs in isolation, so integrated approaches to care, which consider symptoms arising from multiple causes, apply to most patients with HF. A palliative care specialist is rarely needed to prescribe the interventions; most primary care or cardiology clinicians should learn to provide these services.

Joint and body pain is a common symptom in patients with end-stage CV disease, with prevalence rising to 40% to 75% among persons with advanced HF.[37] Clinicians should inquire about pain and develop strategies for management. When this appears to be musculoskeletal in nature, discontinuation of statin therapy is reasonable.[38] Arthritis is common in older persons, but the nonsteroidal anti-inflammatory drugs (NSAIDs) are relatively contraindicated in patients with significant HF and vascular disease.[39] Local treatments such as lidocaine patches, application of heat or cold, and physical therapy should be considered in an integrated approach to pain management. However, if joint pain at the end of life is particularly severe, particularly from episodic gout, consideration may be given to cautious intermittent use of NSAIDs with close monitoring for fluid retention and worsening renal function (if laboratory tests are still being performed).

Antiemetics should be considered for nausea. Lorazepam is less likely to prolong the QT interval than other antiemetics, although this is often not a major concern if the end of life is anticipated.[39] Weight loss from anorexia and the hypercatabolic state of end-stage cardiac disease may be treated with a variety of agents—progesterone analogues (e.g., megestrol acetate), cannabinoids (e.g., dronabinol), mirtazapine, corticosteroids, and anabolic agents (e.g., testosterone)—although use should be continued only when it improves symptoms and help meet goals of care.[40] For patients having difficulty swallowing pills and taking in oral nutrition and hydration, placement of feeding tubes or indwelling lines is rarely indicated at this stage and should be undertaken only after full consideration of the potential implications. The number and size of daily pills can often be decreased with thoughtful review.

Narcotics for Pain and Dyspnea

Pain at the end of life is most often treated with opioids, which are very effective for dyspnea as well as

pain. For patients with dyspnea refractory to hemodynamic interventions (diuretics, afterload reduction, inotropes) and oxygen, international guidelines recommend the use of opioids,[41] although not all studies have been positive.[42] Low dosages of opioids are often sufficient to achieve relief of dyspnea. Because the response may increase, only cautious dose increases should occur within the first week. Opioids must be accompanied by laxatives in time to prevent rather than reverse constipation. Renal function is impaired in many older patients with advanced CV disease, so oxycodone may be preferred to morphine (some metabolites of morphine can accumulate and cause confusion). Clinicians report fear of adverse respiratory effects and addiction as important barriers to opioid prescription, despite studies showing limited adverse effects and low rates of dependence and addiction in appropriately treated patients.[43] Scopolamine is occasionally used to decrease secretions but should not be used routinely because it often causes disorientation and confusion.

Psychosocial Support

The impact of HF on quality of life for both the patient and the family is complex and extends beyond physical symptoms.

Depression

Depression in symptomatic HF and after myocardial infarction has an estimated prevalence of 20% to 40%, is associated with worse clinical outcomes, and increases with worsening disease severity[44] (**see Chapter 96**). The first step is treat its causes, including pain and dyspnea. Unfortunately, limited data are available on pharmacologic, cognitive, and exercise therapy for depression in patients with advanced CV disease. A trial of 469 patients with symptomatic HF found no significant difference in depression or CV status in the treatment group compared with placebo.[45] In another trial of 158 HF patients, cognitive-behavioral therapy was effective in the treatment of depression compared with usual care (12.8 [10.6] versus 17.3 [10.7]; $P = 0.008$), but did not influence self-care.[46] Despite these mixed data, many clinicians continue to try pharmacologic therapy with selective serotonin reuptake inhibitors (SSRIs), psychostimulants (e.g., methylphenidate), or tricyclic antidepressants (e.g., nortriptyline, which has less significant anticholinergic effects such as orthostatic hypotension than other TCAs). Medication side effects that may warrant monitoring in some patients include QT prolongation with TCAs and hyponatremia with SSRIs.[39]

Emotional, Spiritual, and Social Support.
The loss of physical and social function is devastating. Patients with advanced CV diseases may fear dying, worry about burdening families, and experience hopelessness, isolation, disability, and uncertainty regarding their course. Clinicians should acknowledge patients' losses and sources of grief, screen for spiritual concerns, and engage chaplaincy and patients' religious communities when appropriate.[47]

Caregiver Burden, Bereavement, and Support.
Although most family and friends embrace the opportunity to help, they and informal caregivers report scheduling, financial, and family burdens. As patients approach the end of life, these burdens increase.[48] Advances in technology have also created challenging and even traumatic situations around death, as has been seen with left ventricular assist devices.[49] Health status and emotional well-being of family

caregivers can be impaired. Therefore, careful attention to family and other caregivers is an important part of the end-of-life process, including grief counseling services after bereavement.[50]

The Site for the End of Life

An important component of end-of-life care planning is to determine where the patient and family anticipate that the final days should occur. Patients most often prefer this to be at home. Hospice use is substantially lower in advanced HF patients than in those with advanced cancer, but rates are increasing, with more than 40% of Medicare patients with HF dying in hospice.[50] Home hospice care includes extended availability for calls and visits to help with symptoms and events at the end; however, dying at home requires continuous support from family or friends, which is not always possible or desired. Inpatient hospice is limited in most areas and usually entails substantial costs not covered by insurance. Alternatively, some end-of-life services can be provided in a long-term skilled nursing facility. Patients who are receiving high-intensity therapies are generally not eligible for home hospice or transfer to a skilled nursing facility. For example, intravenous inotropic infusions or dialysis can be substantial obstacles to peaceful end-of-life care. In these situations, the high level of support must usually be stopped before discharge, in full recognition that death may occur in the hospital. Regardless of the anticipated course, it is always prudent to have a “plan B” to implement if the patient planning to die in the hospital does not do so quickly, or if the patient planning to die at home or his family faces unanticipated difficulties.

Future Perspectives

The integration and quality of palliative care for patients with heart failure warrants substantive improvement, including changes in medical education and performance measures for advanced HF certification of clinicians and hospitals, as well as cultural acceptance of the end of life and end-of-life planning. Smoothing the transition between “do everything” and “do nothing except for comfort” requires attention to what happens in between, after recognition that survival is limited. If the shift in focus from maximizing survival to enhancing quality of life has been successful—minimizing symptom burden, enhancing meaningful interactions, and encouraging achievement of short-term goals—patients and families will often seek to prolong the duration of this phase of “quality survival” before hospice care is indicated. Additional content is available in the online supplement for this chapter (Changing the Culture of Palliative Care). As providers, we need to develop a responsive model of care that honors patient and family goals, as well as stewardship of finite resources, throughout their journey with cardiac disease.

Removing Therapies and Futility

Deactivation of Cardiac Rhythm Devices

Decisions around withdrawal of therapies are often more complex than the decisions to start them is.[1] In end-stage heart disease, dilemmas arise around deactivation of cardiac implantable electronic devices. Providers rarely discuss implantable cardioverter-defibrillator (ICD) deactivation,[2] and many patients with ICDs are not aware of the option to deactivate them.[3] The result is that ICDs remain active until and sometimes during death; disturbingly, this can even happen in hospice.[4,5] Turning off the defibrillator function should be presented as a simple step that may be consistent with the goal of preserving quality of life during the dying process. Although this option relates to resuscitation preferences, patients often have strong and disparate views on external and internal defibrillation. In difficult situations, consultation with palliative care can help clarify the relationship of the device to goals of care.[6] Planned replacement of the

device generator at battery end of life should be carefully reviewed in the context of patient preferences, illness trajectory, and reliance on pacing and cardiac resynchronization therapy.

Futility

Certain therapeutic options may be considered unreasonable or become impossible for an individual patient and therefore are not provided, even if demanded by a patient or family. For example, cardiopulmonary resuscitation may not be appropriate in a patient with progressive cardiogenic shock without a reversible underlying etiology. Fortunately, situations of *medical futility*, where members of the health care team disagree with the patient and/or family about whether therapies have an acceptable likelihood of benefiting patient goals, are uncommon.[7] Referral to a specialty palliative care or involvement of a hospital ethics committee should be considered for assistance when there are disagreements about potentially futile care.

Complex Treatment Decisions

Although advance care planning documents provide important guidance, many complex medical decisions may arise that are neither anticipated nor addressed by the specific details of the documents[1] (**eTable 31.1**). Some of these decisions may be whether to attempt cure or palliation of serious new diagnoses such as cancer, whereas others may be for symptomatic relief such as hip replacement. When decisions involve an elective procedure, particularly for surgery, there is time for shared discussion, which should include not only consideration of usual risks and benefits, but also the time frame in which such benefits would be enjoyed after procedural discomfort and recovery. There may be decisions that arise emergently about procedures to prevent death from a catastrophic event such as an intracranial hemorrhage or ruptured bowel; these should be guided strongly by the goals, values, and preferences previously elicited.

Standard care practices established for asymptomatic disease (e.g., surgery for a large abdominal

aortic aneurysm) or incidental findings (e.g., biopsy of a pulmonary mass) would not likely be performed in a patient with end-stage cardiac disease, but evaluation for these conditions may at times proceed farther than warranted. Perhaps the most common oversight, emblematic of the impact of computerized algorithms, is to perform routine screening for malignancy. The net benefit from routine colonoscopy is clearly negative in patients with end-stage cardiac disease, in whom the fluid and electrolyte shifts and the sedation pose some risk and even the minor discomforts are unwarranted.

Even though not definitive, some cardiac procedures may be reasonable to treat new or recurrent conditions in a patient still otherwise clinically stable. For example, cardioversion of atrial flutter or angioplasty for worsening angina could be considered in patients for whom some survival with improved quality is still anticipated. However, the decision for any such procedure should include careful review of the likelihood and response for the adverse "what-if" outcomes, such as cardiac arrest, coronary artery laceration, or acute stroke.

During hospitalization within months of anticipated death, initial triage and therapy often occur without appreciation of the disease trajectory. Although often begun with intent for temporary use, intravenous inotropic therapy, dialysis, and catheters for pleural or peritoneal fluid drainage may lead to difficult decisions about continuation. This becomes particularly important when the primary goal becomes discharge to home.

Changing the Culture of Palliative Care

Policies Mandating for Palliative Care in Cardiovascular Care

The integration and quality of palliative care for patients with heart failure warrants substantive improvement, which may be triggered by a number of initiatives. The Accreditation Council for Graduate Medical Education now includes "interpersonal and communication skills" as one of its six core competencies, but how this will improve care for patients with severe illness is unclear.[1,2] The Joint Commission has introduced performance measures for advanced heart failure certification that include discussions of advance care planning and advance directive documentation, but few hospitals participate in such certification.[3] The Centers for Medicare and Medicaid Services plan to reimburse physicians for engaging patients in advance care planning discussions should ease the financial disincentive to schedule the time required,[4] but serious obstacles remain.[5] Change is symbolized by stronger mandates for shared decision making before high-risk device interventions, such as Medicare requirements for palliative care with left ventricular assist device (LVAD) teams[6] and "a formal shared decision-making interaction with an independent non-interventional physician using an evidence-based decision tool" before payment for a left atrial appendage closure device.[7] However, despite the details of how these mandates will be met for payment, the details of what each of these mandates means for payment are still being elaborated by the National Quality Forum and others.[8]

Death Not as Failure

Cultural acceptance of end-of-life planning requires cultural acceptance of the end of life, and both are vital. When death is viewed as a deviation or failure rather than as the inevitable outcome, patients and families will not be prepared when disease progresses beyond therapies. One example of how end-of-life culture can evolve is found in La Crosse, Wisconsin, where the Gundersen Health System implemented the Respecting Choices program for advance care planning and decision making in 1991,[9,10] which within the next 5 years enhanced the prevalence of advance directives and the understanding of preferences by families and physicians. A subsequent study 10 years later using the same advance care planning model showed further improvement in completion of advance directives and fewer treatments at the end of life.[11] There is hope that such efforts can be more widely disseminated for impact generalized to communities rather than isolated to specific diagnoses.

Respecting the "Quality Survival Phase" of Life

Smoothing the transition between "do everything" and "do nothing except for comfort" requires attention to what happens in between, after recognition that survival is limited. If the shift in focus to quality of life has been successful—minimizing symptom burden, enhancing meaningful interactions, and encouraging achievement of short-term goals—patients and families will often seek to prolong survival in this phase.

Although major procedural interventions are not usually warranted, benefit may yet be obtained from therapy directed beyond immediate symptom relief. This may be for new problems, such as intravenous antibiotics for pneumonia, or for intensification of therapy during heart failure hospitalization, which frequently increases toward the end of life. Symptoms and quality of life frequently improve after hospitalization, even in advanced disease,[12] so it is difficult to determine when hospitalization is not indicated. When surveyed before discharge, many patients close to the end of life describe their lives as continuing to have value.

Health care providers need to recognize, respect, and support this phase of "quality survival" nearing the end of life. However, it is an obvious target for reducing hospitalizations and avoidance of financial penalties. This may trigger increased efforts to persuade patients to enter hospice while they are still reluctant to give up the options of hospitalization and treatment such as antibiotics or intravenous inotropic therapy. We need to develop a new model of care responsive to the goals of this phase as well as to our stewardship of constrained resources.

PART V
Arrhythmias, Sudden Death, and Syncope

OUTLINE

32

Approach to the Patient with Cardiac Arrhythmias

Gordon F. Tomaselli, Douglas P. Zipes

The evaluation of patients with suspected cardiac arrhythmias is highly individualized. However, two key features—the history and electrocardiogram (ECG)—are pivotal in directing the diagnostic evaluation and treatment. The physical examination is focused on determining whether there is cardiopulmonary disease that is associated with specific cardiac arrhythmias. The absence of significant cardiopulmonary

disease often, but not always, suggests a benign cause of a cardiac rhythm disturbance. The judicious use of noninvasive diagnostic tests is an important element in the evaluation of patients with arrhythmias, and the most important is the ECG, particularly if recorded at the time of symptoms.

An evidence-based approach to the history and physical examination is presented in **Chapter 10**. This chapter focuses on features most germane to the patient with cardiac rhythm disturbances. However, it is essential to understand that the general medical condition of the patient may profoundly influence the presentation of any cardiac arrhythmia. This chapter discusses the general approach to the patient with a suspected arrhythmia. Details of the diagnostic evaluation of such patients are presented in **Chapter 35**.

Signs and Symptoms

General Approach

Patients with cardiac arrhythmias exhibit a wide spectrum of clinical presentations, ranging from asymptomatic incidental ECG abnormalities to survival from sudden cardiac arrest (SCA). The presenting features may vary with circumstances, and arrhythmias are common in the setting of cardiovascular (CV) and medical diseases, leading to overlap of symptoms and signs. The history is key to directing the evaluation of patients. In general, the more severe the presenting symptoms, the more aggressive are the evaluation and treatment. Loss of consciousness believed to be of cardiac origin typically mandates an exhaustive search for the etiology and may require invasive, device-based diagnostic evaluation and treatment. The presence of structural heart disease and prior myocardial infarction (MI) often dictates a change in the approach to the management of syncope or ventricular arrhythmias. A family history of a significant cardiac arrhythmia may not directly inform the prognosis of a patient, but it should alert the practitioner to the possibility of a heritable trait that may increase susceptibility to development of an arrhythmia.

Palpitations

Palpitations are the awareness of the heartbeat that may be caused by a rapid heart rate, irregularities in heart rhythm, or an increase in the force of cardiac contraction, as occurs with a post–extrasystolic beat; however, this perception can also exist in the setting of a completely normal cardiac rhythm. Patients who complain of palpitations describe the sensation of an unpleasant awareness of a forceful, irregular, or rapid beating of the heart. Many patients are acutely aware of any cardiac irregularity, whereas others are oblivious, even to long runs of a rapid ventricular tachycardia or atrial fibrillation (AF) with rapid ventricular rates. The latter is particularly noteworthy because if untreated, it may be associated with stroke or may produce a tachycardia-induced cardiomyopathy. Patients may use terms such as a “pounding” or “flipping” sensation in the chest; a fullness or pounding in the throat, neck, or chest; or a pause in the heartbeat, or “skipped a beat.” The skip often results from the pause after a premature ventricular complex (PVC) or the resetting of sinus rhythm after a premature atrial complex (PAC). Usually, the premature beat, particularly if it is a ventricular extrasystole, occurs too early to permit sufficient ventricular filling to cause a sensation when the ventricle contracts. The ventricular systole that ends the compensatory pause is often responsible for the actual palpitation, the result of a more forceful contraction from prolonged ventricular filling or increased motion of the heart in the chest. Anxiety over such symptoms is usually the complaint that brings the patient to the physician's office.

Premature atrial or ventricular complexes constitute the most common causes of palpitations. If the

premature complexes are frequent, or particularly if a sustained tachycardia is present, patients are more likely to have additional symptoms, such as lightheadedness, syncope or near-syncope, chest discomfort, fatigue, or shortness of breath. The context and symptoms associated with palpitations can be diagnostically and prognostically informative. Low-risk features include isolated palpitations not induced by exercise, the absence of structural heart disease or symptoms such as syncope or chest pain, no family history of sudden cardiac death (SCD), and a normal 12-lead ECG. Associated symptoms, such as syncope or chest pain, the presence of structural heart disease, or a documented arrhythmia, and family history of SCD may be associated with a more ominous cause of palpitations.[1] In the setting of structural heart disease, the differential diagnosis is broad. The age of the patient and the presence of associated CV problems influence the nature of the symptoms. For example, a supraventricular tachycardia (SVT) at a rate of 180 beats/min can provoke chest pain in a patient with coronary artery disease (CAD) or syncope in a patient with aortic stenosis, but may result in mild breathlessness in an otherwise healthy young person.

The onset and offset of palpitations can suggest the etiology of the arrhythmia. A sudden, abrupt, onset, "like a light switch turning on," is consistent with a paroxysmal tachycardia such as atrioventricular nodal reentrant tachycardia (AVNRT; **see Chapter 37**), whereas gradual speeding and slowing are more consistent with atrial or sinus tachycardia. However, even tachycardias that start abruptly can begin and end with extra beats appearing to have a more gradual onset and offset. Termination by Valsalva maneuver or carotid sinus massage suggests a tachycardia incorporating nodal tissue in the reentrant pathway, such as sinus node reentry, atrioventricular reentrant tachycardia (AVRT), or AVNRT (**see Chapters 34 and 37**).

The rate of an untreated tachycardia often narrows diagnostic possibilities, and patients should be taught to count their radial or carotid pulse rate, noting whether it is regular or irregular. Ventricular rates of 150 beats/min should always suggest the diagnosis of atrial flutter with 2 : 1 atrioventricular (AV) block (**see Chapter 37**), whereas most SVTs, such as those caused by AVNRT or AVRT, usually occur at rates exceeding 150 beats/min. The rates of ventricular tachycardias (VTs) overlap with those of the SVTs.

Patients with bradyarrhythmias may have symptoms of low cardiac output, including fatigue, weakness, dizziness, dyspnea, and syncope (**see Chapter 40**). Palpitations can result from an increased force of contraction associated with longer ventricular filling times and may be prominent symptoms in bradycardias.

Syncope, Presyncope, and Altered Level of Consciousness

Syncope, commonly referred to as "fainting" or "passing out," is a transient, self-limited loss of consciousness and posture resulting from a drop in blood pressure with cerebral hypoperfusion and should always prompt a search for a cause (**see Chapter 43**). It is important to distinguish syncope from other causes of transient loss of consciousness, such as seizures, metabolic disorders (hypoglycemia, hypoxia [e.g., airline decompression]), intoxication, cataplexy, and pseudosyncope. The etiologies of true syncope are varied with similarly diverse prognoses. The unheralded loss of consciousness in any patient, even if benign from the cardiac perspective, can be dangerous depending on the circumstances (e.g., while driving a vehicle, at the top of a flight of stairs). However, because syncope can be a harbinger of SCD, it is important to identify cardiac from more benign causes of syncope[2] (**eTable 32.1**).

ETABLE 32.1

Syncope: Criteria for Immediate Evaluation*

Presence of Structural Heart Disease
Heart failure
Significant left ventricular dysfunction or hypertrophy
Prior myocardial infarction
Clinical Features
Exertional syncope
Syncope while supine
Palpitations associated with syncope
Family history of sudden death
Electrocardiographic Features
Ventricular tachycardia
Bifascicular block
Intraventricular conduction delay (QRS duration >120 msec)
Sinus bradycardia (heart rate <50 beats/min), sinoatrial block†
Preexcited QRS complex
Prolonged or short QT interval
Brugada pattern on ECG
T wave inversion and late potentials in right precordial leads‡
Significant Comorbidities
Anemia
Electrolyte disturbance

*Based on European Society of Cardiology (ESC) guidelines.

†In the absence of medications with negative chronotropic effects.

‡Suggestive of arrhythmogenic right ventricular dysplasia/cardiomyopathy.

When caused by a cardiac arrhythmia, the onset of syncope is rapid and the duration is brief, with or without preceding aura, and is not typically followed by a postictal confusional state. It can be associated with bodily injury if the patient falls while unconscious. Palpitations preceding syncope may support an arrhythmic cause of syncope but are often absent if the loss of consciousness is rapid. Seizure activity is uncommon and occurs mostly after prolonged asystole or a rapid ventricular arrhythmia. Therefore, the seizure does not begin with or anticipate the syncope, whereas in epileptic seizures, convulsive movements start within seconds of the onset of syncope. Tongue biting or incontinence is also uncommon in cardiac syncope. In summary, syncope with early seizure activity is frequently caused by epilepsy, whereas later seizure activity is more likely caused by a cardiac arrhythmia with cerebral hypoperfusion. The history of syncope should be elicited and interpreted carefully, because older people who have fallen might deny loss of consciousness during the event because of retrograde amnesia. Common arrhythmic causes of syncope include bradyarrhythmias caused by sinus node dysfunction or AV block and tachyarrhythmias, most often ventricular but on occasion supraventricular. Bradycardia can follow tachycardia in patients with the bradycardia-tachycardia syndrome, and treatment of both may be necessary.

Of the reflex syncopes—neurocardiogenic, carotid hypersensitivity, and situational—neurocardiogenic is the most common. It should be differentiated from syncope caused by orthostasis, which may be seen in autonomic failure (e.g., due to diabetes).[3] Vasodepressor and cardioinhibitory syncope usually unfold more slowly and can be preceded by manifestations of autonomic hyperactivity such as nausea, abdominal cramping, diarrhea, sweating, or yawning. In fact, palpitations are common in this setting. On recovery, the patient may be bradycardic, pale, sweaty, and fatigued, unlike the patient recovering from a Stokes-Adams attack or an episode of VT, who may be flushed and may have a sinus tachycardia, usually without persistent mental confusion. Palpitations and presyncope on standing can be symptoms of postural orthostatic tachycardia syndrome.

Drug-induced (orthostatic hypotension, bradyarrhythmia) and nonarrhythmic cardiac causes such as aortic stenosis, hypertrophic cardiomyopathy, pulmonary stenosis, pulmonary hypertension, and acute MI

can be excluded by the history, physical examination, ECG, echocardiography, and other laboratory tests. Noncardiac causes of syncope, such as hypoglycemia, transient ischemic attack, and psychogenic causes, often can be excluded by a careful history (**see Chapters 35 and 43**).

Sudden Cardiac Arrest and Aborted Sudden Cardiac Death

SCD is common, although estimates of the incidence are confounded by inadequate case identification and secular trends that have influenced both the rates and the etiologies of sudden death (**see Chapter 42**). SCD caused by cardiac arrhythmias is most often the result of VT or ventricular fibrillation (VF) but can result from profound bradycardia, as might be observed in complete heart block, or asystole. A variety of noncardiac conditions may be associated with life-threatening arrhythmias, including neurologic diseases (stroke, intracranial hemorrhage, epilepsy, neuromuscular disease, Parkinson disease), diabetes, obesity, cirrhosis, anorexia, and bulimia. In well-adjudicated cases, coronary heart disease (CHD) is the most common finding in SCD and can be the first and last manifestation. Up to 80% of cases of SCD occur in patients with some form of structural heart disease, such as CHD, cardiomyopathy, or congenital heart disease. Other cardiac causes of SCD, referred to as "autopsy negative," include primary electrical diseases such as long-QT syndrome (LQTS), Brugada syndrome, catecholaminergic polymorphic ventricular tachycardia (CPVT), idiopathic ventricular fibrillation (IVF), and under some circumstances, Wolff-Parkinson-White (WPW) syndrome (**see Chapters 33 and 37**). The remaining sudden deaths are usually not cardiac in etiology.

For the purposes of evaluation, SCA should be considered as SCD that someone has survived. It is essential that patients who have SCA undergo a comprehensive evaluation to identify the cause and proper treatment. A history of cardiac disease is critically important in directing the evaluation and management, as is a family history of SCD or significant cardiac arrhythmias. The circumstances at the time of SCA are often informative. Cardiac symptoms that predate the SCD suggest preexisting structural heart disease. A variety of precipitating factors can provide clues to the etiology of SCA. Exercise, emotional upset, or stress may precipitate cardiac arrest in the setting of a variety of structural heart diseases, arrhythmogenic cardiomyopathy (arrhythmogenic right ventricular cardiomyopathy/dysplasia, ARVD/C), and primary electrical diseases such as LQTS (types 1 and 2) and CPVT. SCD in LQTS3 or Brugada syndrome is more likely to occur at rest or with sleep. Fever is common precipitant of the characteristic ECG abnormality (**Fig. 32.1**) and arrhythmias in Brugada syndrome. Medications and recreational drugs can increase the risk of lethal arrhythmias; patients should be asked about use of antiarrhythmics, stimulants, decongestants, psychotropics, antibiotics, alcohol, amphetamines, cocaine, and supplements, especially those used for weight loss and energy enhancement. Patients with LQTS and Brugada syndrome should be cautioned about the use of medications that may increase risk of arrhythmias. Drugs that should be avoided are listed on https://www.crediblemeds.org/ and http://www.brugadadrugs.org/, respectively. Structural heart diseases, such as dilated (DCM) or hypertrophic (HCM) cardiomyopathy are associated with delayed ventricular repolarization, an acquired form of LQTS, and the same drugs can produce life-threatening arrhythmias in these patients.

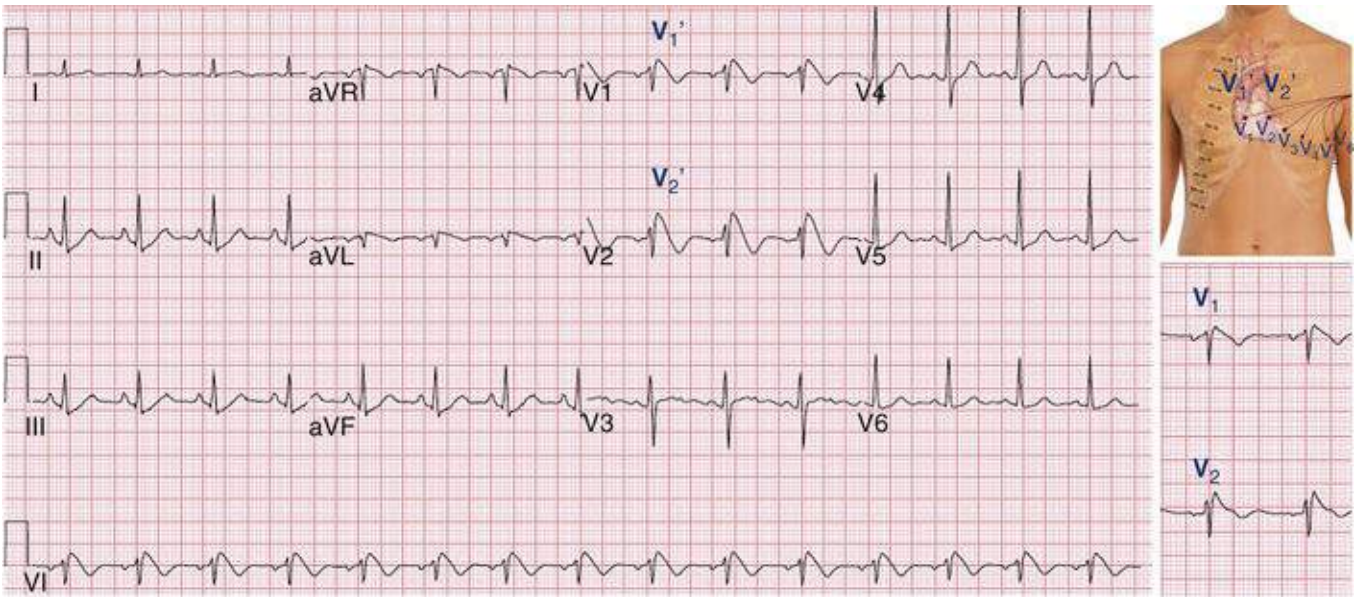

FIGURE 32.1 12-Lead electrocardiogram (ECG) with V_1' and V_2' recorded in the second intercostal space, as shown on the torso. *Inset,* Appearance of leads V_1 and V_2 in the standard positions in this patient.

The presence of a family history of serious ventricular arrhythmias, premature sudden death, stillbirths, sudden infant death syndrome (SIDS), unexplained motor vehicle and other accidents, and relatives with permanent pacemakers or implantable cardioverter-defibrillators (ICDs) may be relevant and will influence the evaluation of presumed heritable arrhythmias. If available, biologic materials from related decedents may be suitable for genetic testing or a molecular autopsy in suspected cases of heritable causes of SCD.

Physical Findings

The physical examination is focused on determining whether CV disease is present. The absence of significant cardiopulmonary disease often, but not always, suggests benignity of a rhythm disturbance. In contrast, palpitations, syncope, or near-syncope in the setting of significant heart or lung disease have a more ominous prognosis. In addition, the physical examination may reveal the presence of a persistent arrhythmia such as AF. The detailed approach to the CV physical examination is outlined in **Chapters 10 and 35**. The general physical examination is also important and can identify medical conditions associated with cardiac manifestations and arrhythmias. Inspection of the skin may reveal erythema chronicum migrans, the rash associated with Lyme disease; hair loss and exophthalmos may reflect the presence of thyroid disease; and ptosis and skeletal muscle wasting or myotonia may indicate the presence of neuromuscular disease (**see Chapter 97**).

If a tachycardia is present, the priority is to obtain a 12-lead ECG if the patient is hemodynamically stable. If it is not possible to obtain an ECG, several clues on the physical examination can help to make a diagnosis. The presence of regular cannon A waves in the jugular venous pulse would be consistent with a 1 : 1 retrograde ventriculoatrial activation, as in tachycardias such as AVRT, AVNRT, and some junctional tachycardias and VTs. In contrast, patients may have physical examination features of AV dissociation, such as intermittent cannon A waves, variable intensity of the first heart sound, and variable peak systolic blood pressure, consistent with arrhythmias, including VT and nonparoxysmal AV junctional tachycardia, without retrograde capture of the atria (**see Fig. 10.4**).

Carotid sinus massage (CSM) during the physical examination can be useful to interrupt arrhythmias

sensitive to autonomic tone and identify the patient with a hypersensitive carotid sinus reflex. The examiner first needs to listen carefully over both carotid arteries to be certain that no bruit is present, palpate lightly to determine that a normal carotid pulse is present, and then gently depress or rub the carotid sinus. Gentle massage is usually sufficient to terminate a sensitive tachycardia or produce significant periods of sinus arrest or AV block in susceptible patients. The most definitive responses to CSM are tachycardia termination, as may be observed in AVRT, AVNRT, sinus node reentry, adenosine-sensitive atrial tachycardia (AT), and idiopathic right ventricular outflow tract tachycardia. CSM can gradually slow a sinus tachycardia without termination and decrease the ventricular response to AT, atrial flutter, and AF without termination, allowing examination of atrial activity. CSM transiently terminates the permanent form of AV junctional reciprocating tachycardia, which then restarts when carotid massage ceases. CSM generally does not affect reentrant ventricular or junctional tachycardias (**Fig. 32.2**).

FIGURE 32.2 Right carotid sinus massage (CSM) produces sinus arrest and a 7.2-second pause in a patient with episodic dizziness. (Image courtesy Dr. Joseph Marine.)

Clinical and Laboratory Testing

The history, physical examination, and ECG are of paramount importance in the evaluation of patients with a suspected arrhythmia. A number of other studies, alone or in combination, may assist in the diagnosis and management of patients with cardiac arrhythmias.

Cardiac Imaging

The prognostic implications of a cardiac arrhythmia depend on context, most importantly the presence of structural heart disease. The presence of structural heart disease may be apparent from the history and physical examination, chest radiograph, and ECG itself. Cardiac imaging plays an important role in the detection and characterization of myocardial structural abnormalities that can render the heart more susceptible to arrhythmias. Ventricular tachyarrhythmias, for instance, occur more frequently in patients with ventricular systolic dysfunction and chamber dilation, in HCM, and in the setting of infiltrative diseases such as sarcoidosis. Supraventricular arrhythmias may be associated with particular congenital conditions, including AV reentry in the setting of Ebstein anomaly (**see Chapter 75**). Echocardiography (**see Chapter 14**) is frequently employed to screen for disorders of cardiac structure and function. Increasingly, magnetic resonance imaging (MRI) of the myocardium (**Chapter 17**) is being used to screen for scar burden, fibrofatty infiltration of the myocardium as seen in ARVC, and other structural changes that affect arrhythmia susceptibility. Both contrast-enhanced MRI and ^{18}F-fluorodeoxyglucose positron emission tomography with computed tomographic transmission (^{18}F-FDG PET/CT) have been used in the diagnosis, management, and treatment response of cardiac sarcoidosis[4] (**Fig. 32.3**).

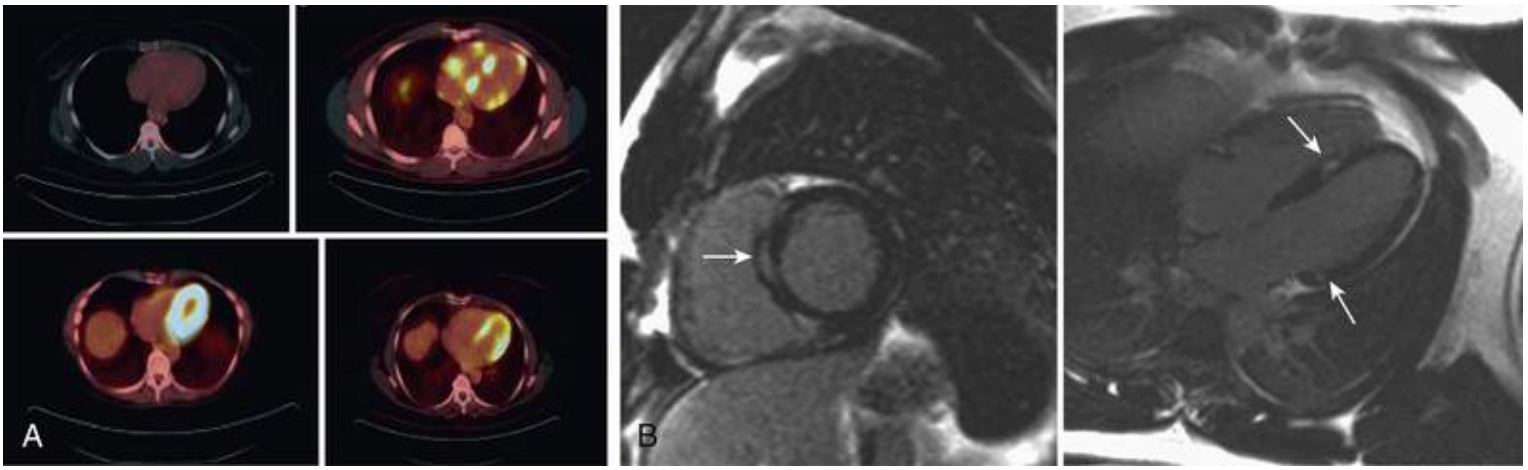

FIGURE 32.3 Sarcoidosis **A,** Four images show the pattern of ^{18}F-fluorodeoxyglucose uptake on positron emission tomography (PET) scan. **B,** Two cardiac magnetic resonance images show evidence of delayed gadolinium enhancement in the midwall of the left ventricle (*arrows*). (Modified from Hamzeh N, Steckman DA, Sauer WH, et al: Pathophysiology and clinical management of cardiac sarcoidosis. Nat Rev Cardiol 2015;12:278.)

Resting Electrocardiographic Recording

The judicious use of noninvasive diagnostic tests is an important element in the evaluation of patients with arrhythmias, and there is no test more important than the ECG (**see Chapter 12**). Uncommon but diagnostically important signatures of electrophysiologic disturbances may be unearthed on the *resting* ECG, such as delta waves in WPW syndrome, prolongation or shortening of the QT interval, right precordial ST-segment abnormalities characteristic of Brugada syndrome (**see Fig. 32.1**), and epsilon waves in ARVD/C.

Signal-averaged electrocardiography (SAECG) uses signal-averaging techniques to amplify small potentials in the body surface ECG that are associated with slow conduction in the myocardium (**see eFig. 35.1**). The presence of these small potentials, referred to as *late potentials* because of their timing with respect to the QRS complex, and prolongation of the filtered (or averaged) QRS duration are indicative of slowed conduction in the ventricle and have been associated with an increased risk of ventricular arrhythmias after MI (**see Chapter 35**).

Holter Monitoring and Event Recording

The fundamental diagnostic principle in managing patients with an undocumented cardiac rhythm disturbance is to record the ECG during a symptomatic episode and establish a causal relation between arrhythmia and symptoms. In patients not suspected of having a life-threatening arrhythmia, Holter monitoring and event recording, continuously or intermittently, record the ECG over longer periods, enhancing the possibility of observing the cardiac rhythm during symptoms (**eTable 32.2**). Continuous ECG recording may also be useful in assessing dynamic changes in ECG segments and intervals. Changes in the ST-T waves may signal the presence of myocardial ischemia and the dynamics of heart rate (HRV) and QT interval (QTv) variability may indicate arrhythmic risk. The type and duration of ECG monitoring depend on the frequency of symptoms. Most continuous recording systems are equipped with patient-triggered recording to enable correlation of the ECG with symptoms (**see Chapter 35**).

ETABLE 32.2

Wireless ECG Recording Systems

DEVICE	COMPANY	URL	DESCRIPTION
Continuous			
eMotion ECG mobile	Mega Electronics	http://www.megaemg.com/products/emotion-ecg/	3-Lead ECG transmitted via a wearable sensor to a mobile phone via Bluetooth; then over a mobile network to a server; data can be monitored in real time or stored and analyzed.
BodyGuardian	Preventice	http://www.preventice.com/	Patch monitor of ECG, activity, respirations, and body position
Zio XT Patch	iRhythm	http://www.irhythmtech.com/?utm_campaign=Listly&utm_medium=list&utmsource=lastly	14-day continuous ECG monitoring with a single adhesive chest wall patch; mailed to iRhythm for analysis
NUVANT Mobile Cardiac Telemetry System	Corventis	http://www.corventis.com/	Automatic and patient-triggered 30-day cardiac rhythm monitoring; transmits information wirelessly to the Corventis Monitoring Center
Ambulatory ECG	iHealth	http://ces.cnet.com/8301-35284_1-57616620/at-ces-2014-health-monitors-join-thewearables-parade/	Sensor attaches to chest and transmits ECG to smartphone
Intermittent			
Alivecor System	Alivecor	http://www.alivecor.com/	Application to skin records, analyzes, and prints ECGs as PDFs; ECG data sync between the application and online ECG hub.
ECG Check	Cardiac Designs	http://cardiacdesigns.com/	Application to skin records, analyzes, and prints ECGs as PDFs; ECG data sync between the application and online ECG hub.
EPI Mini (also EPI Life)	EPI Mobile Health Solutions	http://epimhealth.com.sg/	Device that transmits ECG to smartphone, which can forward it to a "health concierge" service for interpretation
12-Lead ECG	MobilECG	http://mobilecg.hu/	USB-based open-source 12-lead clinical ECG
Implantable			
Reveal LINQ Reveal XT	Medtronic	http://www.medtronicdiagnostics.com/us/cardiac-monitors/reveal-linq/index.htm	LINQ smaller than an AAA battery (1 cc), up to 3 years of monitoring; automated and patient-triggered data storage; magnetic resonance conditional data storage
SJM Confirm	St. Jude Medical	*	6.5 cc, 3 years of monitoring; automated and patient-triggered data storage; magnetic resonance conditional data storage

Modified from American Heart Association; Walsh JA III, Topol EJ, Steinhubl SR. Novel wireless devices for cardiac monitoring. Circulation 2014;130:573-81.

Short-term continuous Holter monitoring may be sufficient to adjudicate daily symptoms related to arrhythmias such as palpitations or presyncope, quantify a particular arrhythmia phenomenon (e.g., PVC burden, AF burden, variation in QT interval, ST-T changes in ischemia or Brugada syndrome), or assess response to therapy. If the arrhythmia does not occur with sufficient frequency, 24-hour, or even 48-hour, recording is not likely to be useful. A longer-term monitoring system is required for arrhythmias that occur less frequently. These systems also record the ECG continuously by chest electrodes attached to a pager-sized sensor. The sensor wirelessly transmits collected data to a portable monitor that analyzes the rhythm data. If an arrhythmia is detected, the monitor automatically transmits recorded data wirelessly via the Internet to a central monitoring station for subsequent analysis. Newer, more compact systems have been developed that contain all the components in a wearable patch (**eFig. 32.1**). Continuous recording systems do not require patient recognition of an arrhythmia but do allow for patient-activated ECG data transmission.

EFIGURE 32.1 **A,** Adhesive electrocardiographic patch that allows for long-term continuous recording of the ECG. **B,** Summary page illustrating three patient-triggered events: wide-complex rhythm during atrial

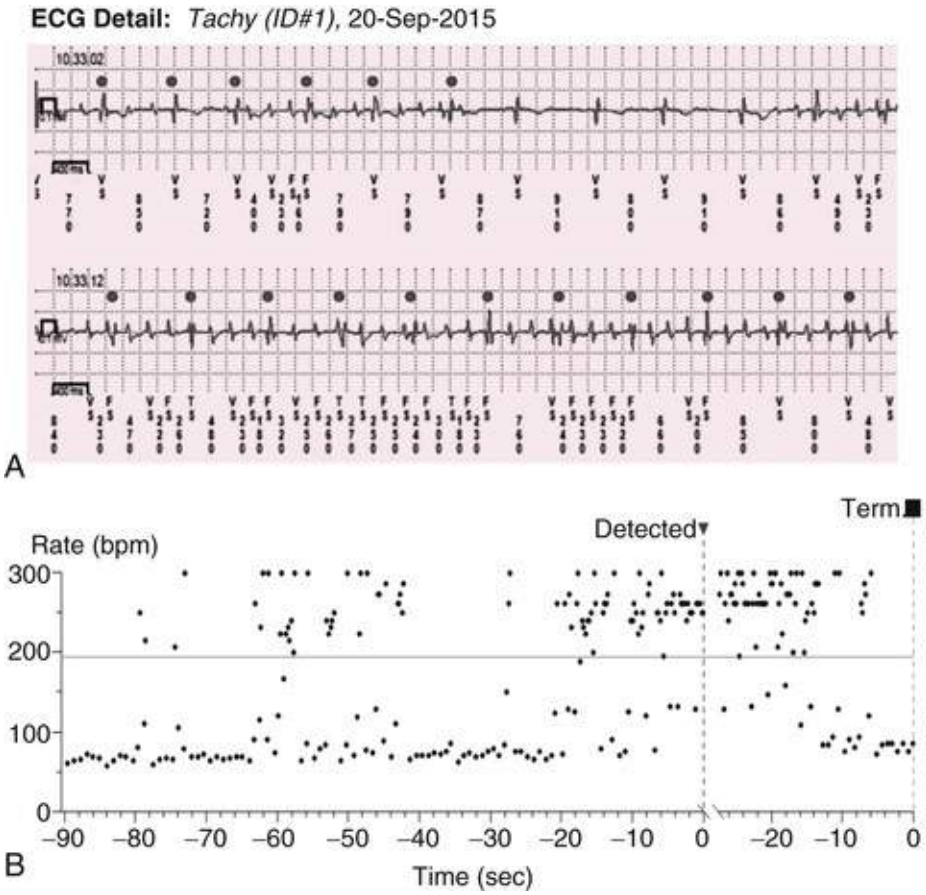
fibrillation (AF), a 4.9-second pause with termination of a paroxysm of AF, and AF with rapid ventricular response. **C,** Greater detail of the pauses; both are patient-triggered events. (**A,** From iRhythm Technologies, San Francisco.)

Event recorders are indicated when symptoms occur less frequently (e.g., several episodes per month), and because the monitors are typically patient-activated, are well-suited for correlating symptoms with rhythm disturbances. Event recorders can be continuous with auto-triggered or patient-activated recording. Discontinuous transtelephonic monitoring systems without looping memory require patient activation (**see Chapter 35**).

Mobile technology is ubiquitous, and anyone who has a smartphone or tablet carries an easily configured ECG monitoring system. Applications are available for real-time ECG monitoring in both iPhones and Android phones. These phones and tablets may use electrical recording systems or camera-based plethysmography to assess the cardiac rhythm and are accurate and easy to use. They are useful for on-demand arrhythmia diagnosis and monitoring arrhythmia burden and are being used as a phenotyping platform in population studies[5] (**eFig. 32.2**).

EFIGURE 32.2 Real-time monitoring of the ECG. Finger contact with electrodes on the case of a cellular phone (right) activates ECG recording of bipolar lead I and is transmitted to the smartphone (left). (From AliveCor, Mountain View, Calif.)

Implantable monitors or *implantable loop recorders* (ILRs) are typically used for the evaluation of suspected serious arrhythmias that occur infrequently and cannot be provoked at diagnostic electrophysiologic study. An ILR, a single-lead ECG monitoring device placed subcutaneously, monitors the cardiac rhythm for as long as 24 to 36 months. These devices have both auto-triggered and patient-activated arrhythmia-recording capabilities (**eFig. 32.3**). Use of such devices has been successful in recording tachyarrhythmias and, more often, bradyarrhythmias. ECG recordings can be sent to an analyzing center transtelephonically and then to physicians via the Internet. Interrogation of ILRs can also be performed remotely over a landline telephone. ILRs have primarily been used in the evaluation of syncope, but their use is increasing in monitoring arrhythmia density, especially AF. Technological advances have resulted in further reduction in size and ease of implantation of ILRs, with the likely increase in clinical deployment of these devices.[6]



EFIGURE 32.3 Implantable loop recorders (ILRs) are implanted subcutaneously and can continuously record a single-lead ECG for up to 36 months. The smallest ILRs are 45 × 7 × 4 mm, the length and width of a paper clip. **A,** Rhythms recorded by an ILR and interrogated remotely by landline telephone in a patient with Parkinson disease. Artifact from the movement disorder is interpreted as tachycardia; the *dots* identify the QRS complexes. **B,** A time series plot of the detected rates at the time of the artifact.

Dual-chamber pacemakers can record atrial and ventricular high-rate episodes and can be correlated with the arrhythmia (**see Chapter 41**). Apart from detecting and treating ventricular arrhythmias, a dual-chamber ICD also helps in identifying cycle length, duration, and frequency of atrial arrhythmias. Remote monitoring facilitates arrhythmia diagnosis in patients with implanted pacemakers and ICDs.

Stress Electrocardiography

Exercise electrocardiographic stress testing may be particularly useful in the evaluation of patients who experience symptoms with exertion (**see Chapter 13**). Exercise stress testing is important in determining the presence of myocardial demand ischemia and other arrhythmic substrates, such as alterations in repolarization and the dynamic behavior of the QT interval (**see Chapter 33**). Microscopic alterations in the T wave (T wave alternans; **see Chapter 35**) at low heart rates may identify patients at risk for ventricular arrhythmias. Altered heart rate recovery may indicate autonomic dysfunction associated with heightened arrhythmic risk.

It is important to recognize that not all arrhythmias induced by exercise have an ominous prognosis. Approximately one third of individuals without heart disease will have ventricular ectopy associated with exercise. Typically, this manifests as occasional uniform PVCs, more likely to occur at faster heart rates and not reproducible from one test to the next. Multiform PVCs, pairs of PVCs, and VT are an infrequent response to exercise in healthy individuals; thus the development of more complex ventricular arrhythmias during exercise testing should prompt a search for underlying structural heart disease.[7,8]

Ventricular ectopy occurs in about half of patients with CAD, generally appearing more reproducibility

and at lower heart rates (<130 beats/min) than healthy individuals and often in the early recovery period. Frequent PVCs (>10 per minute), polymorphic PVCs, and VT are more likely to occur in patients with CAD. PVCs at rest can be suppressed by exercise in patients with CAD; therefore this observation does not necessarily imply a benign prognosis or absence of underlying structural heart disease.

Exercise testing also has diagnostic or prognostic value in patients with primary electrical abnormalities such as LQTS, CPVT, and Brugada syndrome (**see Chapter 33**). Since the QT interval can be normal in up to one quarter of patients with genetically proven LQTS, exercise testing can stress repolarizing reserve and can be useful to expose ECG abnormalities in these patients. An abnormal response of the QT interval to the heart rate acceleration produced by standing is seen in patients with LQTS compared with normal patients. Exercise testing can unmask polymorphic PVCs and VT in CPVT patients (**Fig. 32.4**). In patients with Brugada syndrome, significant ST-segment elevation with coving of the ST segment during recovery phase predicts arrhythmic events during follow-up.[9,10]

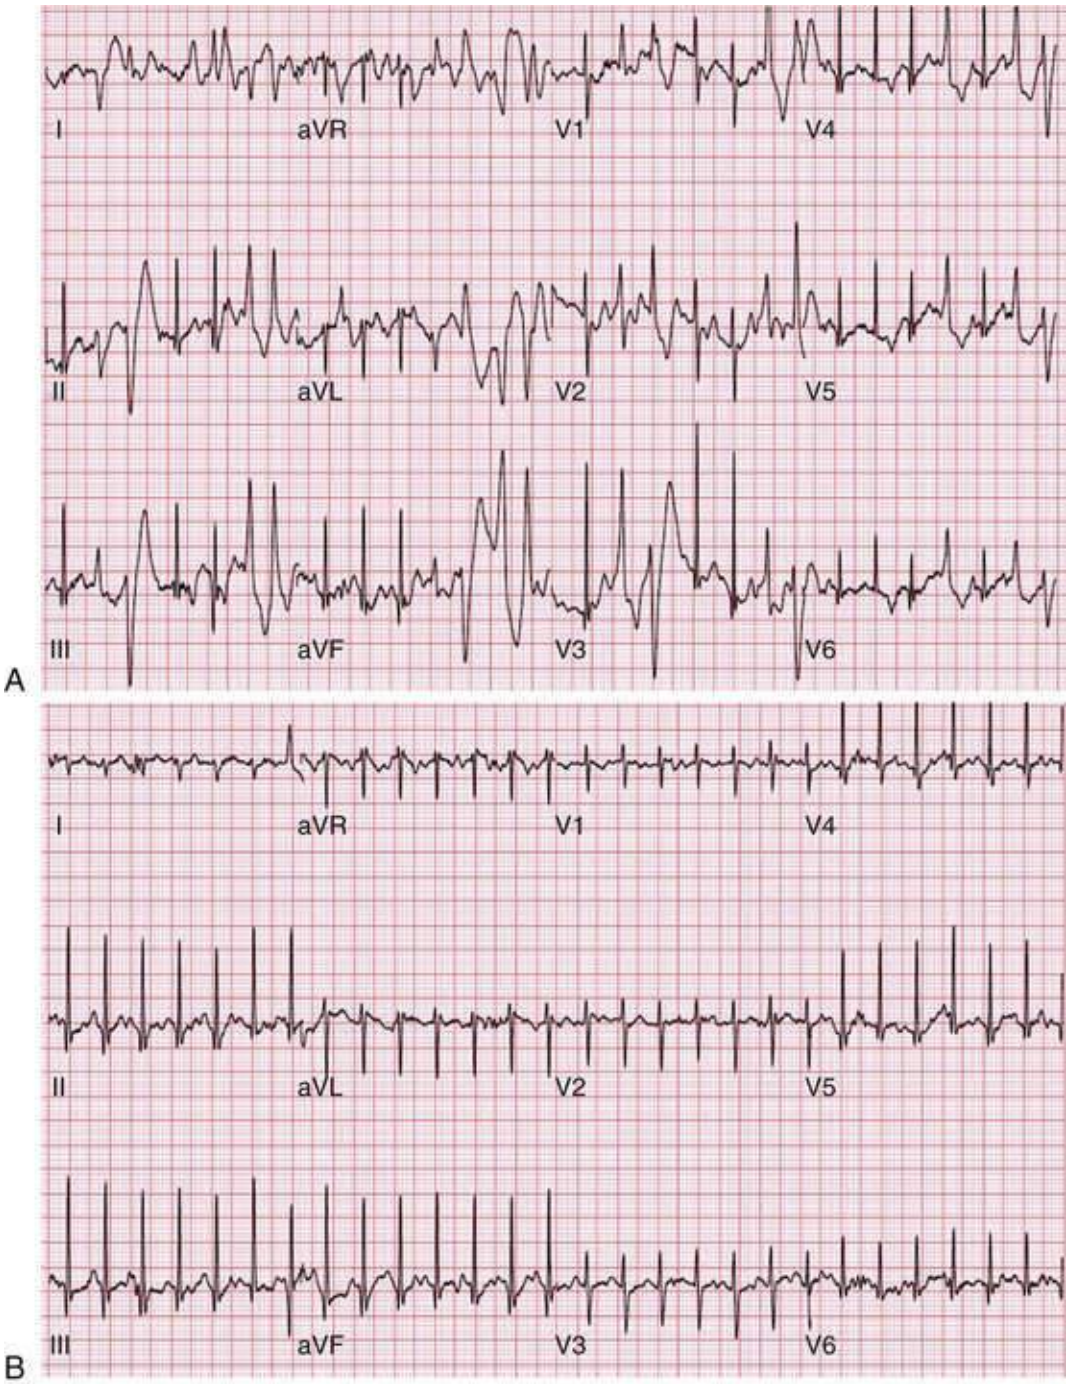


FIGURE 32.4 Exercise-induced polymorphic premature ventricular complexes (PVCs) and ventricular tachycardia (VT) in a young woman with presyncope; palpitations caused by a ryanodine receptor (RyR2) mutation producing catecholaminergic polymorphic VT. **A,** ECG at peak exercise before treatment. **B,** ECG while receiving treatment with nadolol and flecainide.

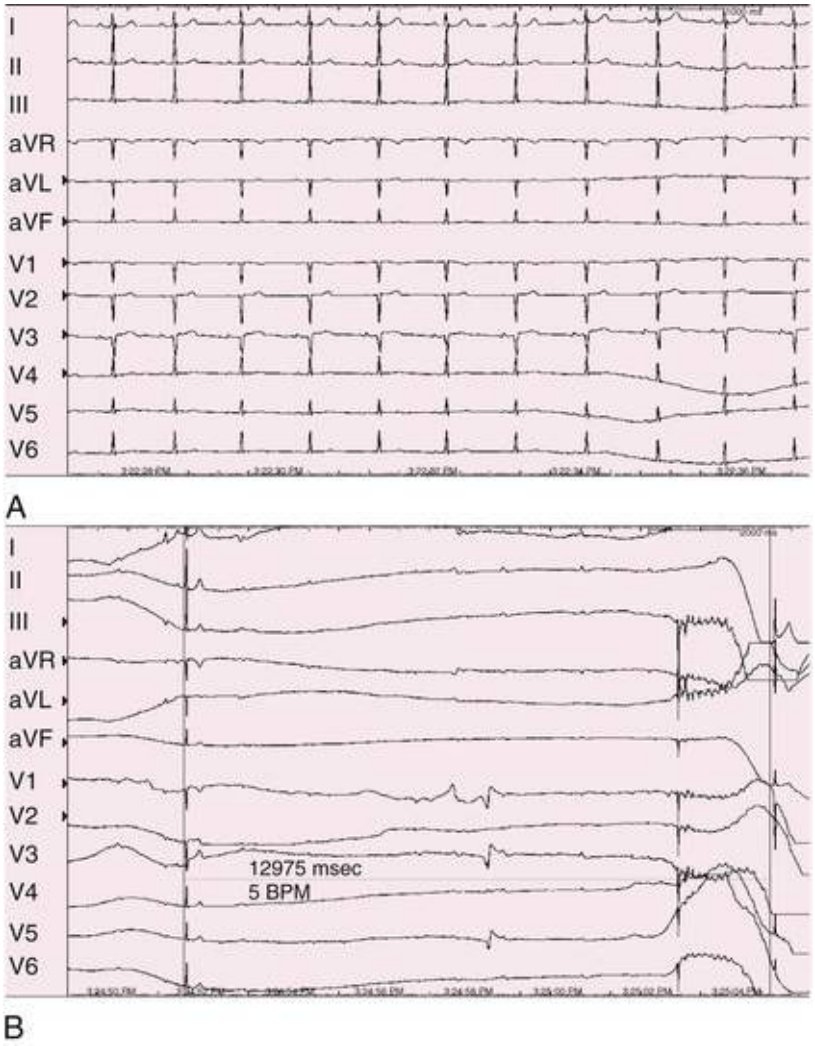
Head-Up Tilt-Table Testing

Tilt-table testing (TTT) is useful in the evaluation of patients with syncope in whom there is a suspicion that exaggerated vagal tone producing cardioinhibitory and/or vasodepressor responses may play a causal role. The physiologic response to TTT is incompletely understood; however, redistribution of blood volume and increased ventricular contractility occur consistently. Exaggerated activation of a central reflex in response to TTT produces a stereotypic response of an initial increase in heart rate, followed by drop in blood pressure and then a reduction in heart rate characteristic of neutrally mediated hypotension. Varied responses to TTT can be observed in which either cardioinhibitory or vasodepressor responses predominate. In patients with orthostatic hypotension and autonomic insufficiency, blood pressure will

drop with only a minimal increase in heart rate. *Postural orthostatic tachycardia syndrome* (POTS) is a variant of neurocardiogenic intolerance characterized by the inability to tolerate the upright posture and a dramatic increase (>30 beats/min) in heart rate (>120 beats/min) within 10 minutes of assuming an upright posture. A wide array of symptoms complicates the diagnosis of POTS, which is often confused with anxiety disorder, inappropriate sinus tachycardia, chronic fatigue syndrome, and fibromyalgia.[11] Data from an international registry suggest that endurance- and strength-training programs may be useful in managing POTS.[12]

TTT is used most often in patients with recurrent syncope, although it may be useful in patients with a single syncopal episode with associated injury, particularly in the absence of structural heart disease (**eFig. 32.4**). In patients with structural heart disease, TTT may be indicated in those with syncope in whom other causes (e.g., asystole, tachyarrhythmias) have been excluded. TTT has been suggested as a useful tool in the diagnosis of and therapy for recurrent idiopathic vertigo, chronic fatigue syndrome, recurrent transient ischemic attacks, and repeated falls of unknown etiology in elderly patients (**see Chapter 35**). Importantly, TTT is relatively contraindicated in the presence of severe CAD with proximal coronary stenoses, known severe cerebrovascular disease, severe mitral stenosis, and obstruction to left ventricular outflow (e.g., aortic stenosis).



EFIGURE 32.4 Head-up tilt-table response in a patient with syncope in the absence of structural heart disease. **A,** 12-Lead ECG immediately before syncope. **B,** Sinus bradycardia and atrioventricular block produce hypotension and syncope 15 minutes after head-up tilt-table test. Invasive Electrophysiologic Testing

The electrophysiologic study (EPS) is central to the understanding and treatment of many cardiac arrhythmias (**see Chapter 35**). The indications for EPS fall into several broad categories: to define the mechanism of an arrhythmia, to deliver catheter-based ablative treatment, and to determine the etiology of symptoms that may be caused by an arrhythmia (e.g., syncope, palpitations). An EPS is performed by introducing a number of multipolar electrode catheters into specific regions of the heart. Positioning of these catheters is guided by complementary imaging modalities, including fluoroscopy, intracardiac echocardiography (ICE), and electroanatomic mapping (EAM), often using MRI and CT to merge cardiac images with the EAM information.

The components of the EPS are baseline measurements of conduction under resting and stressed (rate or pharmacologic) conditions and maneuvers, both pacing and pharmacologic, to induce arrhythmias. A number of electrical mapping and catheter-guidance techniques have been developed to facilitate catheter-based therapeutics in the electrophysiology laboratory. EPS is most effective in the evaluation and management of SVTs and VTs that have occurred spontaneously and can be induced in the laboratory. However, a number of conditions present during EPS (e.g., sedation, differences in autonomic tone or hemodynamics, ischemia) may prevent the induction of a clinically relevant arrhythmia. Failure to induce an arrhythmia does not exclude the possibility that it is present clinically and is responsible for the patient's symptoms.

Ideally, the EPS would induce a clinical and prognostically important arrhythmia in only patients who are at risk for a spontaneous arrhythmia. Unfortunately, this is not the case, and depending on the aggressiveness (e.g., number and coupling interval of extra stimuli) of programmed electrical stimulation nonspecific tachyarrhythmias, in particular flutter and fibrillation in both atria and ventricles, are typically induced.

Approach to Specific Symptoms/Conditions

SCA Survivors, SCD Risk

In patients who have survived and recovered from SCA that is not associated with acute transmural MI, or who are deemed to be at risk for arrhythmic SCD, should undergo an evaluation with the goal of defining a susceptible myocardial substrate and arrhythmic triggers (**see Chapter 42**). The approach to primary or secondary prevention of SCD is defined by the presence of underlying structural heart disease and the reversibility of the initiating events. The history and physical examination as well as structural and functional imaging of the heart are essential. Significant CAD may require revascularization in addition to specific antiarrhythmic therapies that may include drugs, devices, or surgery. Other structural abnormalities of the heart associated with SCA may require directed therapy to improve function (DCM, HCM) or reduce inflammation (e.g., myocarditis, sarcoidosis) but generally mandate ICD placement because of the high risk of recurrence of SCA.

Survivors of SCA who have structurally normal hearts often require defibrillator implantation because of the unpredictability of their clinical course. Often, these ICDs can be completely extravascular (S-ICD) (**see Chapter 41**). SCA deemed to result from AF in the presence of ventricular preexcitation in WPW syndrome can be managed with catheter ablation of the accessory pathway alone.

Patients with heritable arrhythmia syndromes (LQTS, SQTS, CPVT, ARVD, Brugada syndrome) who survive SCA should have an ICD placed. However, the proper management of patients with these

conditions and no history of SCA continues to evolve (**see Chapter 33**). In many cases, pharmacotherapy such as beta blockers in CPVT or LQTS types 1 and 2, and in some patients lifestyle modifications alone, may be sufficient.

Syncope (see Chapter 43)

The majority of patients with syncope have a noncardiac cause, with more than one third having neurocardiogenic syncope and up to one fourth with orthostatic hypotension.[13] A key challenge for the physician is identifying patients with potentially lethal causes of syncope. Initial evaluation includes careful history taking and ECG. If a cardiac cause is suspected, echocardiography and ambulatory ECG monitoring is indicated. EPS can occasionally define the mechanism of syncope (**see Chapter 35**). Evaluation of patients suspected of neurocardiogenic causes often includes TTT. Patients who have syncope from a noncardiac cause usually have an excellent prognosis, whereas those who have syncope from a cardiac cause have a greater risk of SCD. Although it is important to establish the cause and risk-stratify patients with syncope, currently available tools are not sufficiently discriminating.[2]

Bradyarrhythmias (see Chapter 40)

Resting and ambulatory ECG recording is a cornerstone in the management of patients with bradyarrhythmias. Many patients have asymptomatic bradyarrhythmias; in most circumstances it is important to establish that the bradycardia produces symptoms before assuming that therapy is required. Patients that present with a symptomatic bradyarrhythmia may require no further diagnostic testing. Certain electrocardiographic and electrophysiologic findings may define therapeutic decisions in patients without symptoms. For example, in patients who have type II second-degree AV block, the demonstration of His-Purkinje block, even in the absence of symptoms, may be sufficient to justify pacemaker implantation because of the risk for progression to complete AV block. It is important to keep in mind that asymptomatic sinus bradycardia in patients with heart rates of 35 to 40 beats/min, sinus arrhythmia with pauses of 2 to 3 seconds, Wenckebach second-degree AV block (particularly during sleep), wandering atrial pacemaker, and junctional escape complexes can be completely normal, especially in young people and in well-conditioned athletes.

EPS is indicated when a causal relation between the appearance of the bradycardia and the patient's symptoms cannot be established or to exclude a tachyarrhythmia as the cause of symptoms. In patients with AV block the site of block, which often dictates the clinical course and the need for pacemaking, can usually be determined from analysis of the ECG. Exercise, atropine, or isoproterenol can shorten the PR interval and increase the ratio of conducted P waves during type I (Wenckebach) AV nodal block, whereas these maneuvers can increase the number of blocked P waves in type II second-degree AV block, and thus may help to define the level of AV block, prognosis, and management.

Tachyarrhythmias (see Chapters 37-39)

A 12-lead ECG recording during tachycardia is invaluable. A QRS morphology that is identical to that present during sinus rhythm, even if abnormal, suggests that the tachycardia is supraventricular. Wide-complex tachycardias without a typical right or left bundle branch block configuration of the QRS, particularly if different from the QRS in sinus rhythm, and especially in patients with a history of MI, are almost always VT (**see Chapter 39**).

Supraventricular tachycardias can be classified based on the temporal relationship of the P wave and R wave. When a P wave occurs closer to the preceding R wave (i.e., in the first half of the R-R interval), the tachycardia is called a *short* RP′ tachycardia, whereas if a P wave occurs in the second half of the RR cycle, the arrhythmia is called a *long* RP′ tachycardia. The differential diagnosis of a short RP′ tachycardia includes AVNRT, AVRT, junctional tachycardia, and AT with a markedly prolonged PR interval. If no P waves or other evidence of atrial activity are apparent, and the R-R interval is regular, AVNRT is the most likely cause. If a retrograde P wave is apparent in the ST segment, AVRT is most likely. Long RP′ tachycardias include sinus tachycardia, atypical AVNRT, permanent junctional reciprocating tachycardia, and AT. Regardless of the RP′ interval, the P waves of sinus and atrial tachycardias do not exhibit consistent coupling with the preceding R wave. The presence of conduction over an accessory pathway during sinus rhythm or during tachycardia suggests that WPW syndrome with its associated accessory pathway is responsible for the arrhythmia.

Evaluation and Management of Athletes with Arrhythmias

Highly trained athletes often exhibit remodeling of the heart. *Cardiomegaly* is an adaptation to generate the sustained increase in cardiac output required for regular high-intensity exercise. Endurance training such as long-distance running or cycling produces a sustained volume load to the heart, resulting in four-chamber enlargement and increased stroke volume at rest and exercise. Strength training such as weightlifting presents a pressure load to the heart that may be accompanied by a concentric increase in left ventricular (LV) wall thickness. Some sports, such as basketball, present a combination of both types of loads. At times the physiologic increases in heart size may be difficult to distinguish from early manifestations of cardiomyopathy.[14] The ECG will often reflect this structural remodeling and may reveal left ventricular hypertrophy (LVH, approximately 40% of athletes), T wave inversion in precordial leads V_1 to V_4 (14% of African American athletes), QT prolongation, frequent PVCs, and sinus bradycardia as well as various degree of AV block due to increased vagal tone. These ECG changes can mimic ARVD/C, Brugada syndrome, or LQTS and may confound diagnostic decisions in athletes.

Arrhythmias occur with increased frequency in competitive athletes. The most devastating is arrhythmic SCD/SCA. The most common medical cause of death in a study of National Collegiate Athletic Association (NCAA) athletes was SCD (1 in 53,703 athlete-years), with autopsy-negative SCD the most common.[15] Similarly, a national registry of the use of automated external defibrillators (AEDs) in high schools with 4.1 million student-years of follow up demonstrated a SCA rate of 1.14/100,000 in student-athletes, about a 3.65-fold increased risk compared to nonathletes.[16]

In some cases, intense exercise can trigger arrhythmogenic SCD in an athlete with occult cardiac disease. Risk assessment for serious arrhythmias or SCD during athletic activity is challenging, and the proper pre-participation evaluation continues to be debated. A particular controversy concerns the routine use of 12-lead ECG screening.[17] Several countries, such as Italy and Israel, have mandated ECG-based screening, whereas others, such as Denmark, have rejected this approach, citing extremely low event rates. The elements that are generally agreed on are a comprehensive understanding of the athletic endeavor and the role of the athlete. Guidelines from the American Heart Association (AHA) and American College of Cardiology (ACC) advocate the use of a 14-point preparticipation history and physical examination acknowledging that athletes with underlying CV disease may manifest warning signs and symptoms elicited by a careful history and physical examination.[18] The 14-point evaluation includes elements of the personal history: chest discomfort, unexplained syncope or near-syncope, excessive and unexplained fatigue/dyspnea or palpitations with exercise, prior recognition of a heart murmur, elevated

blood pressure, prior restriction from sport, or prior cardiac testing ordered by a physician. Components of the family history include premature sudden and unexpected death in a family member less than 50 years old, disability from heart disease in a family member less than 50 years old, and family history of a heritable heart disease, cardiomyopathy, or primary electrical disease. The elements of the physical examination in the evaluation include heart murmurs, evaluation of the femoral pulses, the presence of stigmata of Marfan syndrome, and brachial blood pressure measurement.[17] Any of these findings should trigger a referral for further evaluation. A number of ECG findings in athletes should also prompt further evaluation. These include significant bradycardia, pauses, AV and intraventricular conduction system disease, SVT, and VT[19] (**eTable 32.3**).

ETABLE 32.3

Indications for Referral or Workup of Arrhythmias in Athletes

ARRHYTHMIA	INDICATION
Severe sinus bradycardia	Heart rate ≤30 beats/min, *or* Bradycardia sinus pause >3 seconds while awake, *or* Signs/symptoms of sinus node disease
First-degree AV block	Does not resolve with hyperventilation or exercise, *or* Cardiac symptoms, *or* Family/personal history suggestive of heart disease, *or* Physical examination indicative of heart disease
Second-degree type I AV block	Does not resolve with hyperventilation or exercise, *or* Cardiac symptoms, *or* Family/personal history suggestive of heart disease, *or* Physical examination indicative of heart disease
Second-degree type II AV block	All cases
Third-degree AV block	All cases
Incomplete RBBB	Cardiac symptoms, *or* Family/personal history suggestive of heart disease, *or* Physical examination indicative of heart disease
Complete RBBB	All cases
LBBB	All cases
LVH by voltage criteria	ECG markers of pathologic LVH, *or* Cardiac symptoms, *or* Family/personal history suggestive of heart disease, *or* Physical examination indicative of heart disease
Repolarization abnormalities	Early repolarization in inferior and/or lateral leads, *or* Cardiac symptoms, *or* Family/personal history suggestive of heart disease, *or* Physical examination indicative of heart disease
Atrial fibrillation	All cases
Atrial flutter	All cases
AVRT/AVNRT	All cases
WPW	All cases
Premature ventricular complexes (PVCs)	2 or more PVCs on screening ECG, *or* Increased PVC frequency during exercise, *or* Cardiac symptoms, *or* Family/personal history suggestive of heart disease, *or* Physical examination indicative of heart disease

AV, Atrioventricular; *AVRT,* AV reentrant (reciprocating) tachycardia; *AVNRT,* AV nodal reentrant (reciprocating) tachycardia; *LBBB,* left bundle branch block; *LVH,* left ventricular hypertrophy; *RBBB,* right bundle branch block; *WPW,* Wolff-Parkinson-White syndrome.

From McClaskey D, Lee D, Buch E. Outcomes among athletes with arrhythmias and electrocardiographic abnormalities: Implications for ECG interpretation. Sports Med 2013;43:979.

Other recommendations included standardization of questionnaires for examiners of athletes and potential athletes and utilization of electrocardiography and other noninvasive testing in the context of a history and physical examination suggestive of underlying cardiac disease, but not universal screening.[18] Recommendations regarding sports participation in individuals with established cardiac disease are specific to those diseases and are covered in other chapters.

Physical activity in patients with ICDs is often a question. Recent registry data suggest that patients

with ICDs can safely participate in some athletic activities without the development of inappropriate or appropriate shocks, personal injury, or failed-device therapies. With some restrictions on the type of activity, physical activity and sports are safe for defibrillator patients.[20]

Genetics of Cardiac Arrhythmias

David J. Tester, Michael J. Ackerman

Potentially lethal and inheritable arrhythmia syndromes involve electrical disturbances with the propensity to produce fatal arrhythmias in the setting of a structurally normal heart. Collectively called the “cardiac channelopathies,” these often-unassuming electrical abnormalities have the capacity to cause the heart of an unsuspecting individual to develop a potentially lethal arrhythmia, leading to the sudden and early demise of an otherwise healthy individual. In fact, it is now recognized that almost one third of autopsy-negative sudden unexplained death (SUD) in young persons and approximately 10% of sudden infant death syndrome (SIDS) stem from these genetically inherited cardiac channelopathies.[1]

Molecular advances in the field of cardiovascular genetics have uncovered the underlying genetic basis responsible for many inherited cardiac arrhythmia syndromes, and for others, their underlying genetic substrates are on the cusp of discovery. Over the past decade a particular set of themes, including extreme genetic heterogeneity, reduced or incomplete penetrance, and variable expressivity, have proved to be common among the cardiac channelopathies. For some disorders, however, important genotype-phenotype correlates have been recognized and have provided diagnostic, prognostic, and therapeutic impact.

Given the potentially devastating impact that these genetic disorders can have on families and their communities, this chapter provides the clinical description, genetic basis, and genotype-phenotype correlates associated with these inherited arrhythmia syndromes. Specifically, we focus first on the subset of "QT-opathies"—long QT syndrome (including calmodulin mediated), triad in knockout syndrome, Andersen-Tawil syndrome, Timothy syndrome (TS), cardiac-only Timothy syndrome, short-QT syndrome, and drug-induced torsade de pointes—and then discuss the other channelopathies, including Brugada syndrome, early repolarization syndrome, idiopathic ventricular fibrillation, progressive cardiac conduction disease, sick sinus syndrome, catecholaminergic polymorphic ventricular tachycardia, "ankyrin-B syndrome," and familial atrial fibrillation.

The QT-Opathies

Long-QT Syndrome

Clinical Description and Manifestations

Congenital long-QT syndrome (LQTS) comprises a distinct group of cardiac channelopathies characterized by delayed repolarization of the myocardium, QT prolongation (QTc >480 msec as the 50th percentile among individuals with genetically confirmed LQTS), and increased risk for syncope, seizures, and sudden cardiac death (SCD) in the setting of a structurally normal heart and otherwise healthy individual. The incidence of LQTS may exceed 1 in 2500 persons.[2] Individuals with LQTS may or may not manifest QT prolongation on a resting 12-lead surface electrocardiogram (ECG). This repolarization abnormality almost always is without consequence; rarely, however, triggers such as exertion, swimming, emotion, auditory stimuli (e.g., alarm clock), or during the postpartum period, can cause the heart to become electrically unstable and develop potentially life-threatening and sometimes lethal arrhythmia of torsade de pointes (**see Chapter 39**). Although the cardiac rhythm most often spontaneously returns to normal, resulting in only a transient episode of syncope, 5% of untreated and unsuspecting LQTS individuals succumb to a fatal arrhythmia as their sentinel event. However, it is estimated that almost half of individuals experiencing SCD, stemming from this treatable arrhythmogenic disorder, may have exhibited prior warning signs (i.e., exertional syncope, family history of premature sudden death) that went unrecognized. LQTS may explain approximately 20% of autopsy-negative SUD in young persons and 10% of SIDS cases.[1]

Genetic Basis.

LQTS is a genetically heterogeneous disorder largely inherited in an autosomal dominant pattern, previously known as "Romano-Ward syndrome." Rarely, LQTS is inherited as the recessive trait first described by Jervell and Lange-Nielsen and is characterized by a severe cardiac phenotype and sensorineural hearing loss. Spontaneous or sporadic germline mutations can account for approximately

5% to 10% of LQTS cases. To date, hundreds of mutations have now been identified in 14 LQTS susceptibility genes responsible for a nonsyndromic "classic" LQTS phenotype. In addition, two extremely rare, multisystem disorders associated with marked QT prolongation (Timothy syndrome, formerly annotated as LQT8) and prolonged QU intervals (Anderson-Tawil syndrome, formerly annotated as LQT7), as well as LQT4, which is better classified as "ankyrin-B syndrome," have also been described.

Approximately 75% of patients with a clinically robust diagnosis of LQTS host either loss-of-function or gain-of-function mutations in one of three major LQTS genes (**Table 33.1**): *KCNQ1*-encoded I_{Ks} ($K_v7.1$) potassium channel (LQT1, approximately 35%; loss of function), *KCNH2*-encoded I_{Kr} ($K_v11.1$) potassium channel (LQT2, 30%; loss of function), and *SCN5A*-encoded I_{Na} ($Na_v1.5$) sodium channel (LQT3, 10%; gain of function). These genes are responsible for the orchestration of the cardiac action potential (**Fig. 33.1**). Approximately 5% to 10% of patients have multiple mutations in these genes, and patients with multimutation LQTS present at a younger age and with greater expressivity.[1]

TABLE 33.1

Summary of Heritable Arrhythmia Syndrome Susceptibility Genes

GENE	LOCUS	PROTEIN
Long-QT Syndrome (LQTS)		
Major LQTS Genes		
KCNQ1 (LQT1)	11p15.5	I_{Ks} potassium channel alpha subunit (KVLQT1, $K_v7.1$)
KCNH2 (LQT2)	7q35-36	I_{Kr} potassium channel alpha subunit (HERG, $K_v11.1$)
SCN5A (LQT3)	3p21-p24	Cardiac sodium channel alpha subunit ($Na_v1.5$)
Minor LQTS Genes (listed alphabetically)		
AKAP9	7q21-q22	Yotiao
CACNA1C	12p13.3	Voltage-gated L-type calcium channel ($Ca_v1.2$)
CALM1	14q32.11	Calmodulin 1
CALM2	2p21	Calmodulin 2
CALM3	19q13.2-q13.3	Calmodulin 3
CAV3	3p25	Caveolin-3
KCNE1	21q22.1	Potassium channel beta subunit (MinK)
KCNE2	21q22.1	Potassium channel beta subunit (MiRP1)
KCNJ5	11q24.3	Kir3.4 subunit of I_{KACH} channel
SCN4B	11q23.3	Sodium channel $beta_4$ subunit
SNTA1	20q11.2	Syntrophin-$alpha_1$
Triadin Knockout (TKO) Syndrome		
TRDN	6q22.31	Cardiac triadin
Andersen-Tawil Syndrome (ATS)		
KCNJ2 (ATS1)	17q23	I_{K1} potassium channel (Kir2.1)
Timothy Syndrome (TS)		
CACNA1C	12p13.3	Voltage-gated L-type calcium channel ($Ca_v1.2$)
Cardiac Only Timothy Syndrome (COTS)		
CACNA1C	12p13.3	Voltage-gated L-type calcium channel ($Ca_v1.2$)
Short-QT Syndrome (SQTS)		
KCNH2 (SQT1)	7q35-36	I_{Kr} potassium channel alpha subunit (HERG, $K_v11.1$)
KCNQ1(SQT2)	11p15.5	I_{Ks} potassium channel alpha subunit (KVLQT1, $K_v7.1$)
KCNJ2 (SQT3)	17q23	I_{K1} potassium channel (Kir2.1)
CACNA1C (SQT4)	12p13.3	Voltage-gated L-type calcium channel ($Ca_v1.2$)
CACNB2 (SQT5)	10p12	Voltage-gated L-type calcium channel $beta_2$ subunit
CACN2D1 (SQT6)	7q21-q22	Voltage-gated L-type calcium channel 2 $delta_1$ subunit
Catecholaminergic Polymorphic Ventricular Tachycardia (CPVT)		
RYR2 (CPVT1)	1q42.1-q43	Ryanodine receptor 2
CASQ2 (CPVT2)	1p13.3	Calsequestrin 2
KCNJ2 (CPVT3)	17q23	I_{K1} potassium channel (Kir2.1)
CALM1	14q32.11	Calmodulin 1
CALM3	19q13.2-q13.3	Calmodulin 3
TRDN	6q22.31	Cardiac triadin
Brugada Syndrome (BrS)		
SCN5A (BrS1)	3p21-p24	Cardiac sodium channel alpha subunit ($Na_v1.5$)
Minor BrS Genes (listed alphabetically)		
ABCC9	12p12.1	ATP-binding cassette, subfamily C member 9

CACNA1C	2p13.3	Voltage-gated L-type calcium channel ($Ca_v1.2$)
CACNA2D1	7q21-q22	Voltage-gated L-type calcium channel 2 $delta_1$ subunit
CACNB2	10p12	Voltage-gated L-type calcium channel $beta_2$ subunit
FGF12	3q28	Fibroblast growth factor 12
GPD1L	3p22.3	Glycerol-3-phosphate dehydrogenase 1–like
KCND3	1p13.2	Voltage-gated potassium channel (I_{to}) subunit $K_v4.3$
KCNE3	11q13.4	Potassium channel $beta_3$ subunit (MiRP2)
KCNJ8	12p12.1	Inward rectifier K^+ channel Kir6.1
HEY2	6q	Hes-related family BHLH transcription factor with YRPW motif 2
PKP2	12p11	Plakophilin-2
RANGRF	17p13.1	RAN guanine nucleotide release factor 1
SCN1B	19q13	Sodium channel $beta_1$
SCN2B	11q23	Sodium channel $beta_2$
SCN3B	11q24.1	Sodium channel $beta_3$
SCN10A	3p22.2	Sodium voltage-gated channel $alpha_{10}$ subunit ($Na_v1.8$)
SLMAP	3p14.3	Sarcolemma associated protein
Early Repolarization Syndrome (ERS)		
ABCC9	12p12.1	ATP-binding cassette, subfamily C member 9
CACNA1C	2p13.3	Voltage-gated L-type calcium channel ($Ca_v1.2$)
CACNA2D1	7q21-q22	Voltage-gated L-type calcium channel 2 $delta_1$ subunit
CACNB2	10p12	Voltage-gated L-type calcium channel $beta_2$ subunit
KCNJ8	12p12.1	Inward rectifier K^+ channel Kir6.1
SCN5A	3p21-p24	Cardiac sodium channel alpha subunit ($Na_v1.5$)
SCN10A	3p22.2	Sodium voltage-gated channel $alpha_{10}$ subunit ($Na_v1.8$)
Idiopathic Ventricular Fibrillation (IVF)		
ANK2	4q25-q27	Ankyrin B
CALM1	14q32.11	Calmodulin 1
DPP6	7q36	Dipeptidyl-peptidase-6
KCNJ8	12p12.1	Inward rectifier K^+ channel Kir6.1
RYR2	1q42.1-q43	Ryanodine receptor 2
SCN3B	11q23	Sodium channel $beta_3$ subunit
SCN5A	3p21-p24	Cardiac sodium channel alpha subunit ($Na_v1.5$)
Progressive Cardiac Conduction Disease/Defect (PCCD)		
SCN5A	3p21-p24	Cardiac sodium channel alpha subunit ($Na_v1.5$)
TRPM4	19q13.33	Transient receptor potential cation channel, subfamily M, member 4
Sick Sinus Syndrome (SSS)		
ANK2	4q25-q27	Ankyrin B
HCN4	15q24-q25	Hyperpolarization-activated cyclic nucleotide–gated channel 4
MYH6	14q11.2	Myosin, heavy chain 6, cardiac muscle, alpha
SCN5A	3p21-p24	Cardiac sodium channel alpha subunit ($Na_v1.5$)
“Ankyrin-B Syndrome”		
ANK2	4q25-q27	Ankyrin B
Familial Atrial Fibrillation (FAF)		
ANK2	4q25-q27	Ankyrin B
GATA4	8p23.1-p22	GATA-binding protein 4
GATA5	20q13.33	GATA-binding protein 5
GJA5	1q21	Connexin 40
KCNA5	12p13	I_{Kur} potassium channel ($K_v1.5$)
KCNE2	21q22.1	Potassium channel beta subunit (MiRP1)
KCNH2	7q35-36	I_{Kr} potassium channel alpha subunit (HERG, $K_v11.1$)
KCNJ2	17q23	I_{K1} potassium channel (Kir2.1)
KCNQ1	11p15.5	I_{Ks} potassium channel alpha subunit (KVLQT1, $K_v7.1$)
NPPA	1p36	Atrial natriuretic peptide precursor A
NUP155	5p13	Nucleoporin 155 KD
SCN5A	3p21-p24	Cardiac sodium channel alpha subunit ($Na_v1.5$)

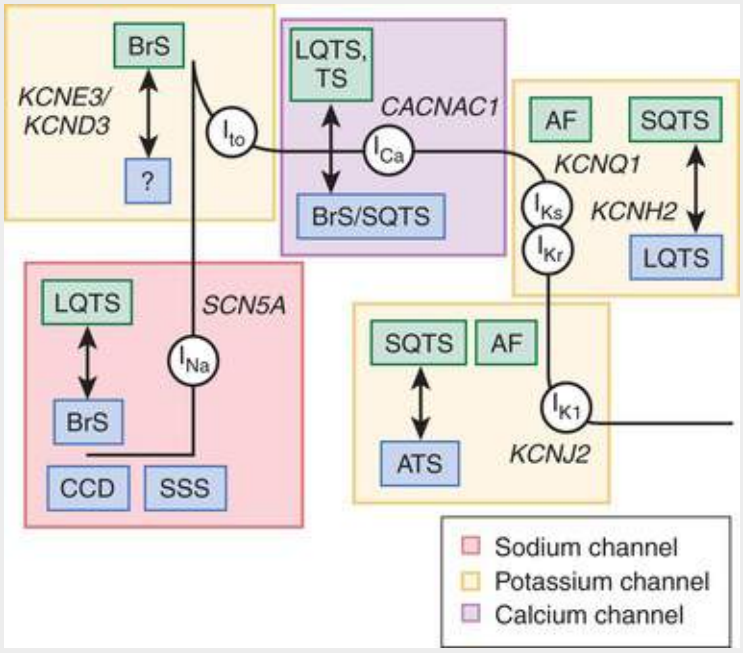

FIGURE 33.1 Cardiac action potential disorders. Illustrated are the key ion currents (*white circles*) along the ventricular cardiocyte's action potential that are associated with potentially lethal cardiac arrhythmia disorders. Disorders resulting in gain-of-function mutations are shown in *green rectangles* and those with loss-of-function mutations in *blue rectangles.* For example, gain-of-function mutations in the *SCN5A*-encoding cardiac sodium channel responsible for I_{Na} lead to long-QT syndrome (*LQTS*), and loss-of-function *SCN5A* mutations result in Brugada syndrome (*BrS*), cardiac conduction disorder (*CCD*), and sick sinus syndrome (*SSS*). *AF,* Atrial fibrillation; *ATS,* Andersen-Tawill syndrome; *SQTS,* short-QT syndrome.

In 2012, Boczek and colleagues,[3] following their whole-exome sequencing, genomic triangulation, and systems biology approach, identified a novel genetic substrate (P857R-*CACNA1C*) for a large, 15-member (8 affected) multigenerational pedigree with autosomal dominant "classic" LQTS. Functional characterization of the mutation using whole-cell patch-clamp technique revealed a gain-of-function mutation in peak $I_{Ca,L}$ consistent with cardiac action potential prolongation and the clinical phenotype of LQTS. Their subsequent mutational analysis of 102 unrelated patients with robust clinical evidence of LQTS has indicated that 3% to 5% of genetically elusive LQTS may be attributed to *CACNA1C* mutations, making *CACNA1C* potentially the fifth most common genetic substrate for nonsyndromic LQTS. The majority of the mutations identified reside in the *CACNA1C*-encoded L-type calcium channel (LTCC) critical PEST domain, which signals for rapid protein degradation. These mutations presumably result in a biogenic increase in LTCCs at the cell surface membrane. In addition, Fukuyama and colleagues[4] in 2014 and Wemhöner and colleagues[5] in 2015 identified gain-of-function *CACNA1C* missense mutations in 4 of 278 (1.4%) and 6 of 540 (1.1%) patients with LQTS, respectively.

The remaining seven minor LQTS susceptibility genes encode for either cardiac ion channels or key cardiac channel interacting proteins (ChIPs) that generally regulate the native ion channel current and collectively explain perhaps 5% of LQTS cases. The most recent ChIP to be implicated in LQTS is calmodulin. In 2013, Crotti and colleagues[6] performed a parent-child trio, whole-exome sequencing strategy to elucidate the underlying genetic cause for two unrelated sporadic cases of infantile LQTS with recurrent cardiac arrest and extreme QT prolongation. Both infants hosted sporadic de novo mutations (D130G-CALM1 and D96V-CALM2) in genes (*CALM1* and *CALM2*) that encode for *calmodulin,* a ubiquitously expressed and essential calcium signaling protein that is critically involved in many physiologic functions, including as a Ca^{2+} sensor for Ca^{2+}-dependent inactivation of the LTCC ($Ca_v1.2$), inactivation of the cardiac sodium channel ($Na_v1.5$), and activation of the voltage-gated potassium

channel (K_v7.1).

The calmodulin genes represent an interesting and rare phenomenon in human biology. There are three distinct calmodulin genes with distinct loci: *CALM1*, Chr.14q32.11; *CALM2*, Chr.2p21; and *CALM3*, Chr.19q13.2-q13.3. Although they share 76% homology at the DNA nucleotide level, these three genes encode for an identical 149–amino acid protein called calmodulin. All three genes are expressed in cardiac myocytes, with transcript expression levels highest for *CALM3*, followed by *CALM2* and *CALM1*.[6] Since the initial report by Crotti and colleagues,[6] mutations in all three of the *CALM* genes have been implicated in LQTS.[7,8] These calmodulin missense mutations localize to critical EF-hand calcium-binding motifs, reduce calmodulin's calcium-binding affinity, and attenuate Ca_v1.2 inactivation through loss of calcium-dependent inactivation of the LTCC.[8,9]

Calmodulin-positive LQTS patients exhibit the common cardiac features of life-threatening ventricular arrhythmias occurring very early in life, frequent T wave alternans, greatly prolonged QT intervals (QTc >600 msec), and intermittent 2 : 1 atrioventricular (AV) block (3 of 4 patients).[6] Ventricular fibrillation is often triggered by adrenergic activation occurring either spontaneously or preceded by a short episode of torsade de pointes that is not pulse dependent.[6,8] Additionally, patients often have some degree of neurodevelopmental delay, ranging from mild delay in language development to severe cognitive or motor development.[8]

The vast majority of LQTS susceptibility mutations are coding-region single-nucleotide substitutions or small insertions/deletions resulting in nonsynonymous missense (amino acid substitution for another amino acid), nonsense (amino acid substitution for a termination codon), splice-site alterations (resulting in exon skipping or intron inclusion), or frameshift mutations (altered normal amino acid coding resulting in early termination). Recently, a few large gene rearrangements involving hundreds to thousands of nucleotides and resulting in single or multiple whole-exon deletions/duplications have been described.[1] Importantly, there is no quintessential mutational “hot spot” within these genes, because the vast majority of unrelated families have their own unique, “private” mutation. In 2017 it is important to note that almost 20% of clinically definite cases of LQTS remain genetically elusive.

In contrast to rare, pathogenic LQTS-associated channel mutations, present in less than 0.04% (1 : 2500) of persons and in 75% of clinically robust LQTS cases, comprehensive genetic testing of *KCNQ1*, *KCNH2*, and *SCN5A* for more than 1300 ostensibly healthy volunteers has revealed that approximately 4% of Caucasians and up to 8% among non-Caucasians host rare nonsynonymous genetic variants (<0.5% allelic frequency) in these specific cardiac channel genes.[10] In fact, a total of 79 distinct channel variants were detected among these healthy individuals, including 14 variants in *KCNQ1*, 28 in *KCNH2*, and 37 in *SCN5A*.[10] This has enabled a case-control mutational analysis of the properties and localization of case-associated mutations compared to the compendium of presumably innocuous variants.[10] The probabilistic rather than binary nature of genetic testing is depicted in **Fig. 33.2**, showing that rare mutations other than missense mutations (approximately 20% of the LQTS spectrum of mutations) are high-probability LQTS-associated mutations, whereas the probability of pathogenicity for the most common mutation type, missense mutations (i.e., single amino acid substitutions), is strongly location dependent. For example, missense mutations localizing to the transmembrane spanning/pore domains of the LQT1- and LQT2-associated potassium channels are high-probability disease mutations, whereas a similarly rare missense mutation that localizes to the domain I-II linker of the Nav1.5 sodium channel is indeterminate, a variant of uncertain significance (VUS). Without cosegregation or functional data, such a mutation has a point estimate for probability of pathogenicity of less than 50%.

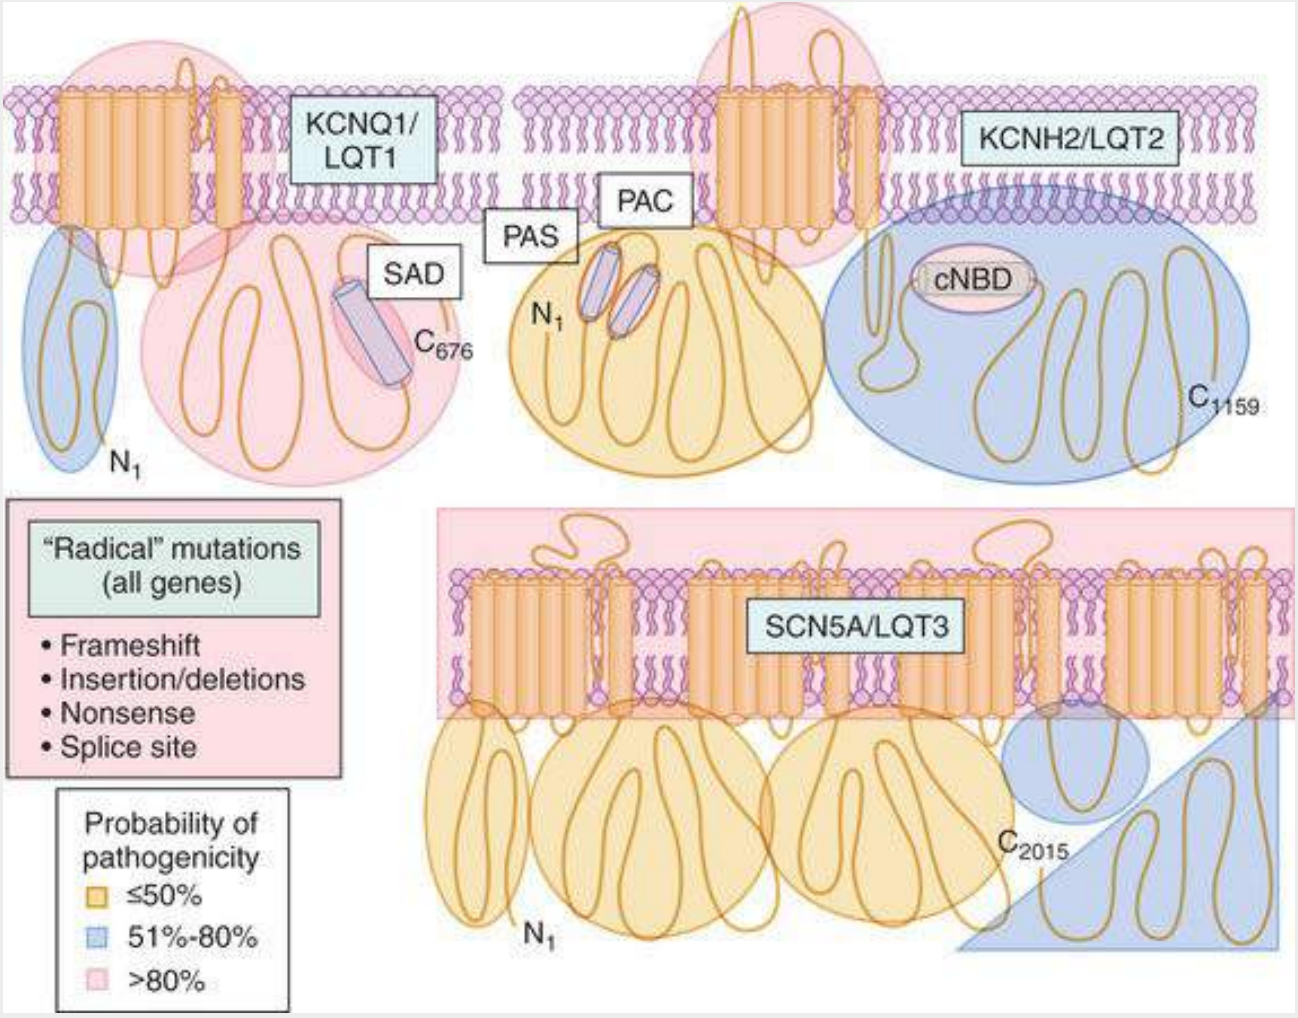

FIGURE 33.2 Probabilistic nature of LQTS genetic testing. Depicted are the three major ion channels causative for LQTS with areas of probability of pathogenicity shown for mutations localizing to these respective areas. Although "radical" mutations have a greater than 90% probability of being a true pathogenic mutation, the level of probability for missense mutations vary depending on their location for each channel protein. Missense mutations residing in *red-shaded areas* have a high probability (>80%) of being pathogenic, those in *blue* are possibly (51% to 80%) pathogenic, and those in *yellow-shaded areas* truly represent variants of uncertain significance (VUS, ≤50% probability) clinically.

Besides this background frequency (4% to 8%) of rare variants in health, 15 unique common polymorphisms (allelic frequency >0.5%) have been identified in the four potassium channel subunit genes (*KCNQ1*, *KCNH2*, *KCNE1*, and *KCNE2*), and eight common polymorphisms have been identified in the sodium channel gene (*SCN5A*). Many of these rare and common polymorphisms represent innocent bystanders; however, a layer of complexity is added to the genetics of these channelopathies and the management of patients when otherwise apparently innocuous variants can modify disease. For example, the most common sodium channel variant, H558R with a minor allelic frequency of approximately 29% in African Americans, 20% in Caucasians, 23% in Hispanics, and 9% in Asians, can provide a modifying effect on the disease state through "intragenic complementation" (the interaction of two mutations within the same gene that produce a novel functional effect) of other *SCN5A* mutations.[11] In fact, several studies indicate that some of these common polymorphisms may be clinically informative and relevant to the identification of those at risk for cardiac arrhythmias, particularly in the setting of torsade de pointes–inducing drugs or other environmental factors, as discussed later.

Phenotypic Correlates for the Three Canonical LQTS Genotypes

Specific genotype-phenotype associations in LQTS have emerged, suggesting relatively gene-specific

triggers, ECG patterns, and response to therapy[1] (**Fig. 33.3**). Swimming- and exertion-induced cardiac events are strongly associated with mutations in *KCNQ1* (LQT1), whereas auditory triggers and events occurring during the postpartum period most often occur in patients with LQT2. Exertion- or emotional stress–induced events are most common in LQT1, and events occurring during periods of sleep/rest are most common in LQT3. Using a study population of 721 LQT1 and 634 LQT2 genetically confirmed patients from the U.S. portion of the international LQTS registry, a multivariate analysis was used to assess the independent contribution of clinical and mutation-specific factors to the occurrence of a first triggered event associated with exercise, arousal, or sleep/rest.[12,13] Among the 221 symptomatic LQT1 patients, their first cardiac event was most often associated with exercise (55%), followed by sleep/rest (21%), arousal (14%), and nonspecific (10%) triggers, whereas the 204 symptomatic LQT2 patients most often had their first event associated with either arousal triggers (44%) or nonexercise/nonarousal triggers (43%), and only 13% of the symptomatic LQT2 patients had an exercise-induced first event. In addition, LQT1 male patients younger than 13 years had an almost threefold increase in risk for exercise-triggered events, whereas LQT1 females age 13 and older had a 3.5-fold increase in risk for sleep/rest nonarousal events. For LQT2 patients, the rate of arousal-triggered events was similar between male and female children, whereas there was a significant higher rate in women than in men (26% versus 6%, at age 40) after the onset of adolescence. Characteristic gene-suggestive ECG patterns have been described previously. LQT1 is associated with a broad-based T wave LQT2 with a low-amplitude notched or biphasic T wave, and LQT3 with a long isoelectric segment followed by a narrow-based T wave.

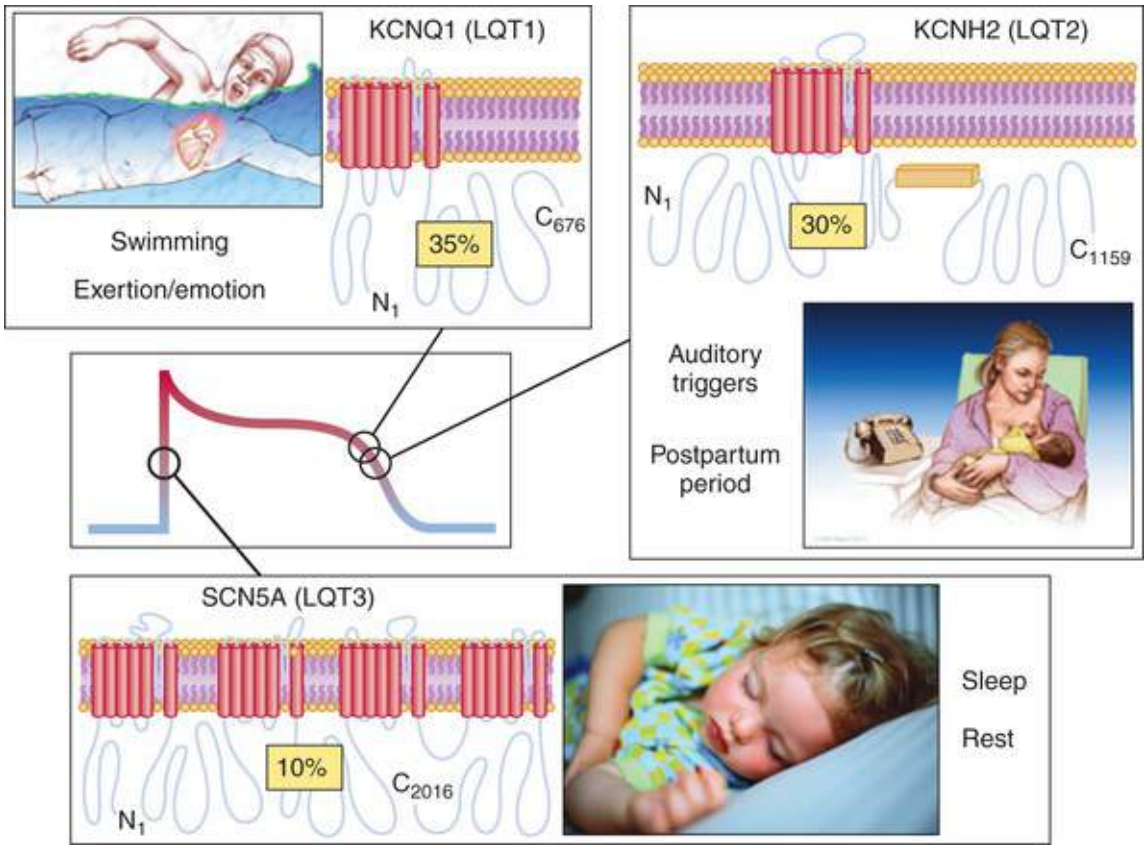

FIGURE 33.3 Genotype-phenotype correlations in LQTS. Seventy-five percent of clinically strong LQTS is caused by mutations in three genes (35% *KCNQ1*, 30% *KCNH2*, and 10% in *SCN5A*) encoding for ion channels that are critically responsible for the orchestration of the cardiac action potential. Genotype-phenotype correlations have been observed, including swimming/exertion/emotion and LQT1, auditory triggers/postpartum period and LQT2, and sleep/rest and LQT3.

However, exceptions to these relatively gene-specific T wave patterns exist, and due caution must be

exercised with making a pre–genetic test prediction of the particular LQTS subtype involved because the most common clinical mimicker of the LQT3-looking ECG is seen among patients with LQT1. This is key to keep in mind because importantly, the underlying genetic basis heavily influences the response to standard LQTS pharmacotherapy with beta blockers, which are extremely protective in LQT1 patients and moderately protective for patients with LQT2 and LQT3. Additionally, targeting the pathologic LQT3-associated late sodium current with agents such as mexiletine, flecainide, and ranolazine may represent a gene-specific therapeutic option for LQT3.[14,15] Attenuation in repolarization with clinically apparent shortening in the QTc has been demonstrated with such a strategy, with a reduction in LQT3-triggered events using this strategy.[14-16] The generalization that beta-blocker efficacy is genotype dependent has been well accepted, whereas the effectiveness of beta-blocker therapy may be largely trigger specific. For both LQT1 and LQT2 patients, beta blockade was associated with a pronounced 71% (LQT2 patients) to 78% (LQT1 patients) reduction in the risk for exercise-triggered cardiac events, but had no statistically significant effect on the apparent risk for arousal- or sleep/rest-triggered events.[12,13] However, many symptomatic LQT1 and LQT2 patients experience a subsequent cardiac event associated with a different trigger. For example, an LQT2 patient first presenting with an arousal event or event during sleep may present subsequently with an exercise-triggered event. Therefore beta-blocker therapy still remains first-line therapy even for patients experiencing a non–exercise-associated first event.

In addition, intragenotype risk stratification has been realized for the two most common subtypes of LQTS based on mutation type, mutation location, and cellular function.[1] Patients with LQT1 secondary to K_v7.1 missense mutations localizing to the transmembrane-spanning domains clinically have a twofold greater risk of a LQT1-triggered cardiac event than LQT1 patients with mutations localizing to the C-terminal region. In addition, missense mutations localizing to the so-called cytoplasmic loops (C-loops) within the transmembrane-spanning domains, an area of the protein involved in adrenergic channel regulation, are associated with the highest rate of both exercise- and arousal-triggered events, but were not associated with an increase rate of sleep/rest-associated events.[13] C-loop K_v7.1 missense mutations were consistently associated with a greater than sixfold increase in risk for exercise-triggered events compared to nonmissense mutations and a nearly threefold increase compared to N- and C-terminal missense mutations.[13]

Patients with mutations resulting in a greater degree of K_v7.1 loss of function at the cellular in vitro level (i.e., dominant negative) have a twofold greater clinical risk than those mutations that damage the biology of the K_v7.1 channel less severely (haploinsufficiency). Adding to the traditional clinical risk factors, molecular location and cellular function are independent risk factors used in the evaluation of patients with LQTS.[1]

Similar to molecular risk stratification in LQT1, patients with LQT2 secondary to K_v11.1 pore region mutations have a longer QTc and more severe clinical manifestation of the disorder and experience significantly more arrhythmia-related cardiac events at a younger age than LQT2 patients with non–pore-related mutations in K_v11.1. Similarly, in a Japanese cohort of LQT2 patients, those with pore mutations had a longer QTc, and although not significant among probands, nonprobands with pore mutations experienced their first cardiac event at an earlier age than those with a non–pore-related mutation. Most recently, additional information suggests that LQT2 patients with mutations involving the transmembrane pore region had the greatest risk for cardiac events, those with frameshift or nonsense mutations in any region had an intermediate risk, and those with missense mutations in the C terminus had the lowest risk for cardiac events. Interestingly, LQT2 patients with mutations in the pore loop region of the K_v11.1

channel have a greater than twofold increased risk for arousal-triggered events, and LQT2 patients with non–pore loop TM region mutations have an almost sevenfold increase in the risk for exercise-triggered cardiac events compared with patients with N-terminal or C-terminal (non-PAS domain) mutations.[12]

Incomplete penetrance and variable expressivity are clinical hallmark features of LQTS and it has been long thought that co-inheritance of a true disease-causing mutation and either a common or rare channel genetic variant may determine the expressed severity of the disorder. For example, the coexistence of the common K897T-KCNH2 polymorphism and the A1116V-KCNH2 mutation (on opposite alleles) led to a more severe clinical course in a single Italian LQTS family. The A1116V mutation by itself produced a subclinical phenotype of mild QT prolongation and an asymptomatic course, while the proband hosting both variants had clinically overt disease consisting of a diagnostic QT prolongation, presyncopal episodes, and cardiac arrest. Besides cardiac ion channels, SNPs of non–ion channel genes such as *NOS1AP* (the gene encoding the nitric oxide synthase 1 adapter protein), *ADRA2C* ($alpha_{2C}$-adrenergic receptor), and *ADRB1* ($beta_1$-adrenergic receptor) may modify disease severity in LQTS.[1]

In 2012, Amin and colleagues[17] provided compelling evidence for a strong, disease-modifying effect of a 3′ untranslated region (3′UTR) KCNQ1 allele–specific haplotype in LQT1 mutation–positive pedigrees; the magnitude of the effect on the QTc and the symptomatology go well beyond any other currently described genetic modifiers. The *KCNQ1* gene encodes for a single $K_v7.1$ ion channel alpha subunit. Following *KCNQ1* gene expression and post-translational modifications, four alpha subunits are assembled to create a pore-forming $K_v7.1$ tetrameric channel. Therefore, if a patient had a heterozygous *KCNQ1* mutation (i.e., one normal *KCNQ1* gene allele and one mutant allele), one would expect that if both the normal and the mutant gene alleles were expressed in equal amounts, $1/16$ of the channels would be a normal homomeric tetramer and $1/16$ of the channels would be mutant homomeric tetramer. The remaining channels would be hybrids containing both normal and mutant alpha subunits. One would predict that if the normal *KCNQ1* gene allele expression was somehow suppressed, there would be relatively more KCNQ1 mutant alpha subunits translated and ultimately assembled to provide more dysfunctional KCNQ1 channels, thus leading to a more severe manifestation of the disorder (**Fig. 33.4**). Simply put, there would be far more bad (mutant) channels than good (healthy) channels created. The opposite would be true if the mutation containing the *KCNQ1* allele were suppressed.

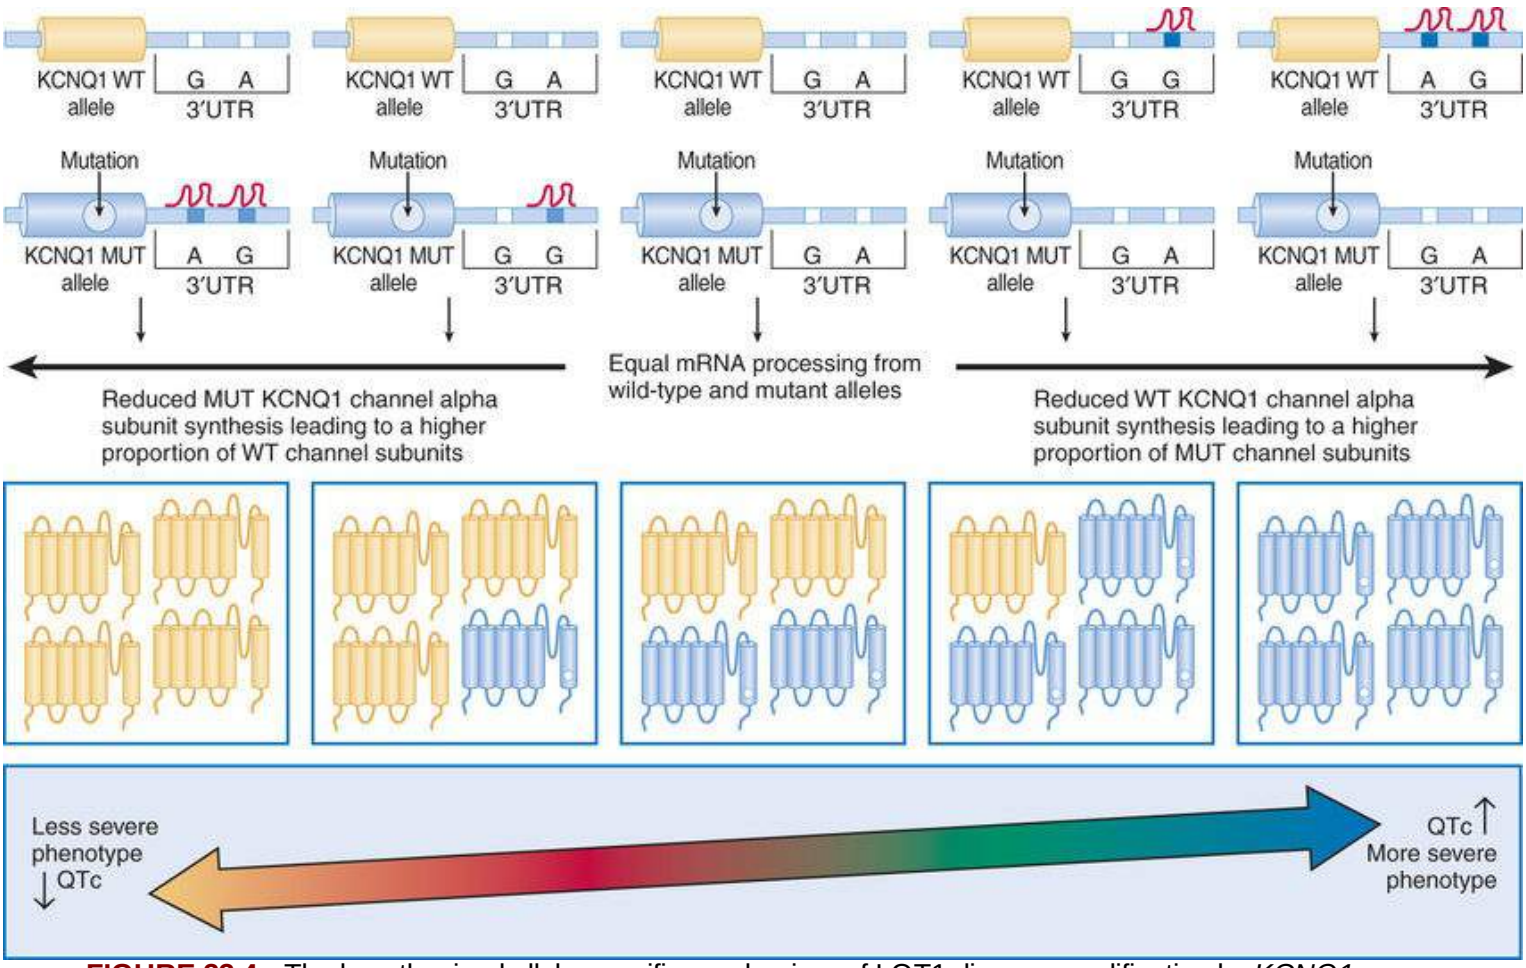

FIGURE 33.4 The hypothesized allele-specific mechanism of LQT1 disease modification by *KCNQ1* 3′UTR single-nucleotide polymorphisms (SNPs). Illustrated is the proposed microRNA-mediated allele-specific *KCNQ1* gene transcript–"suppressing" mechanism, supported by the existence of naturally occurring SNPs within the *KCNQ1* 3′UTR. Presence of the SNPs' minor alleles (A, G; *dark squares*) creates a "suppressive" haplotype by forming new microRNA (shown in *red*) binding sites that suppress the expression of the *KCNQ1* allele in which they reside, thus altering the stoichiometric assembly of wild-type (i.e., normal, shown in *yellow*) and mutant (shown in *gray*) $K_V7.1$ alpha subunits. (Modified from Amin AS, Giudicessi JR, Tijsen AJ, et al. Variants in the 3′ untranslated region of the KCNQ1-encoded Kv7.1 potassium channel modify disease severity in patients with type 1 long QT syndrome in an allele-specific manner. Eur Heart J 2012;33:714-23.)

Most genes have a 3′UTR that produces a messenger RNA (mRNA) transcript containing regions of *cis*-regulatory binding sites for small, noncoding microRNAs (miRNAs) that bind to the transcript and ultimately inhibit that gene's expression. Naturally occurring genetic variation within these 3′UTRs (miR-SNPs) can either abolish existing or create new miRNA-binding sites. Amin and colleagues[17] identified three naturally occurring, single-nucleotide polymorphisms (SNPs; rs2519184, rs8234, and rs10798) within the *KCNQ1* 3′UTR, whereby the presence of their minor alleles (A, G, G) create a "suppressive" haplotype by creating new miRNA-binding sites that suppress the expression of the *KCNQ1* gene allele in which they reside. In a cohort of 168 *KCNQ1* (LQT1) mutation–positive individuals from 41 families, the inheritance of the "suppressive" haplotype residing on the normal "healthy" allele produced a more severe LQT1 phenotype in regard to QTc and symptomatology, whereas the inheritance of the "suppressive" haplotype residing on the same allele as the *KCNQ1* mutation gave a less severe LQT1 phenotype (shorter QTc and fewer symptoms).[17] This intriguing discovery not only may explain a significant component of reduced penetrance and variable expressivity that is a common feature of arrhythmia syndromes, but also may represent a paradigm shift in our thinking about disease-modifying genetic-drivers of mendelian disorders, because one of the most important genetic determinants of disease severity in LQT1 appears to be the 3′UTR *KCNQ1* haplotype on the allele inherited from the unaffected

“non-LQTS” parent.

In 2011 the Heart Rhythm Society (HRS) and European Heart Rhythm Association (EHRA) released the first HRS/EHRA-sponsored guidelines for clinical genetic testing for LQTS and the other channelopathies.[18]

Triadin Knockout Syndrome

Recently, Altmann and colleagues[19] discovered *TRDN*-encoded triadin (Trdn) as a novel genetic basis for recessively inherited LQTS that they termed triadin knockout (TKO) syndrome. Almost 15% of their genetically elusive LQTS cohort overall and 50% of the children (≤10 years) with genetically elusive LQTS hosted homozygous or compound heterozygous *TRDN* frameshift mutations. However, because the cohort was small, the prevalence in this study may not be reflective of the general population of genetically elusive LQTS cases. A homozygous p.D18fs*13 mutation was identified in an African American girl; the same homozygous p.K147fs0* mutation was identified in three unrelated patients of either Indian or Arabic decent; and one Caucasian male was found to be compound heterozygous for two frameshift mutations (p.N9fs*5 and p.K147fs*0). Since frameshift mutations often result in nonfunctional proteins or immediate nonsense-mediated RNA decay, these patients are expectantly triadin null. Remarkably, all five triadin null children displayed the common electrocardiographic phenotype of extensive T wave inversions in precordial leads V_1 to V_4, with persistent or transient QT prolongation, severe disease expression of exercise-induced cardiac arrest in early childhood, and a recessive inheritance pattern, and required aggressive therapy. Patients often presented with sudden cardiac arrest (SCA) before age 5 years, and current therapeutic strategies (beta blockers and left cardiac sympathetic denervation [LCSD] surgery) have not been effective.[19] Importantly, the parents of these children, who are all heterozygous for a triadin null allele (i.e., triadin haploinsufficient), do not have an overt abnormal cardiac phenotype. Whether they may be predisposed to an environmentally induced and acquired ventricular arrhythmia is currently unknown.

In addition, *TRDN* mutations have been implicated previously in recessively inherited catecholaminergic polymorphic ventricular tachycardia (CPVT), as identified in 2 of 97 (2%) patients diagnosed with CPVT who were genotype negative for *RYR2* or *CASQ2* mutations.[20] Specifically, a homozygous p.D18fs*13 mutation was identified in a 2-year-old boy who experienced exertion-induced SCA, and compound heterozygous triadin null mutations (p.T59R and p.Q205X) were identified in a 26-year-old man who experienced recurrent exertion-induced syncope since infancy. Most recently, two additional case reports described children with compound triadin null alleles (p.N9fs*5/p.Q205X and p.D18fs*13/p.E168X).[21,22] Similar to previous observations, three of the six children described in these two case reports experienced SCA before age 5 years.

Triadin is a critical component of the cardiac calcium release unit (CRU), which mediates its calcium-sensing properties and governs excitation-contraction coupling (ECC) in the heart.[23,24] Specifically, cardiac triadin is responsible for stabilization of the T tubule junctional sarcoplasmic reticulum (jSR) association by linking calsequestrin 2 (Casq2), ryanodine receptor 2 (RyR2), and junctophilin-2 (JPH2) proteins together in proximity to the L-type calcium channel (LTCC), thus facilitating a proper negative feedback loop for Ca^{2+} handling. Ablation of cardiac triadin results in cardiac dyad structural remodeling and Ca^{2+} overload as a result of slower Ca^{2+}-dependent inactivation of the LTCC. Slower LTCC inactivation could lengthen the cardiac action potential and manifest as QT prolongation on the ECG.

Andersen-Tawil Syndrome

Clinical Description and Manifestations

Andersen-Tawil Syndrome (ATS), first described in 1971 in a case report by Andersen and later described by Tawil in 1994, is now recognized as a rare, multisystem disorder characterized by a triad of clinical features: periodic paralysis, dysmorphic features, and ventricular arrhythmias. ATS is a heterogeneous disorder that is either sporadically or autosomal dominantly derived and has a high degree of variable phenotypic expression and incomplete penetrance, with as much as 20% of mutation-positive patients being nonpenetrant. The mean age of onset for periodic paralysis has been reported to be 5 years (ranging from 8 months to 15 years) and slightly older, 13 years (range, 4 to 25 years), for cardiac symptoms.[1]

Electrocardiographic (ECG) abnormalities of ATS may include pronounced QTU prolongation, prominent U waves, and ventricular ectopy, including polymorphic ventricular tachycardia (VT), bigeminy, and bidirectional VT. Although ventricular ectopy is common and the ectopic density can be high in some patients, the majority of ATS patients are asymptomatic, and SCD is extremely rare. ATS1 was initially proposed as type 7 LQTS (LQT7) due to the observation of extreme prolongation of the QT interval; however, these measurements included the prominent U wave. As such, this complex clinical disorder, manifesting at times with only a modest prolongation of the QT interval, is probably best considered as its own clinical entity, referred to as ATS1, rather than as part of the LQTS regime. However, given the potential for false interpretation of the QT interval because of the prominent U wave and the probability of phenotypic expression of only cardiac-derived symptomatology (syncope, palpitations, ventricular rhythm disturbances), a considerable number of ATS patients are misdiagnosed, conceivably with classic LQTS. Similarly, the presence of bidirectional VT, an accepted hallmark of CPVT (see later), often leads to a misdiagnosis of ATS as the potentially lethal CPVT. Correctly distinguishing between ATS and CPVT is critical because the treatment strategies are quite different.[1]

Genetic Basis.

To date, more than 40 unique mutations in *KCNJ2* have been described as causative for ATS1. Mutations in *KCNJ2* account for approximately two thirds of ATS cases, while the molecular basis of the remaining third remains genetically and mechanistically elusive. However, the prevalence of *KCNJ2* mutations may be as high as 75% to 80% for patients with at least two ATS phenotypic features (i.e., typical ATS).[25,26] Most ATS-associated mutations in *KCNJ2* are inherited in an autosomal dominant inheritance pattern, but as many as one third of mutations in *KCNJ2* could be sporadic, de novo occurrences. In addition, somatic mosaicism has also been described in at least one *KCNJ2*-associated ATS family.[26] Localized to chromosome 17q23, *KCNJ2* encodes for Kir2.1, a small potassium channel alpha subunit expressed in brain, skeletal muscle, and heart, that is critically responsible for the inward rectifying cardiac I_{K1} current (**see Table 33.1 and Fig. 33.1**). In the heart, I_{K1} plays an important role in setting the heart's resting membrane potential, buffering extracellular potassium, and modulating the action potential waveform. Most *KCNJ2* mutations described in ATS are missense mutations that cause a loss of function of I_{K1} either through a dominant negative effect on Kir2.1 subunit assembly or through haploinsufficiency as a result of protein-trafficking defects.

Phenotypic Correlates in *KCNJ2*-Mediated Andersen-Tawil Syndrome

(ATS1)

Genotype-specific ECG features of ATS have emerged. Zhang and colleagues[27] examined the ECG T-U morphology and found that 91% of *KCNJ2* mutation–positive ATS1 patients had characteristic T-U wave patterns (including prolonged terminal T wave downslope, a wide T-U junction, and biphasic enlarged U waves), compared to none of the 61 unaffected family members or 29 genotype-negative ATS patients. In 2012, Kimura and associates[25] found that 88% of *KCNJ2* mutation–positive ATS patients had an abnormal U wave. Additionally, whereas the U wave is greatly abnormal in ATS1, it is typically normal in LQTS. Consequently, this *KCNJ2* gene–specific ECG feature of T-U morphology can be useful in differentiating ATS1 patients from *KCNJ2* mutation–negative ATS and LQT1 to LQT3 patients and may facilitate a cost-effective approach toward genetic testing of the appropriate disorder.[27] Interestingly, topologic location of *KCNJ2* mutations may influence the phenotypic expression of ATS features. The vast majority (approximately 90%) of *KCNJ2* mutations reside in either the N or the C terminus of this two-transmembrane single-pore channel. C-terminal mutations appear to be more often associated with typical ATS (more than two ATS features), dysmorphism, and periodic paralysis, whereas N-terminal mutations were more often observed in atypical ATS (only one ATS feature, predominately a cardiac phenotype only).[25]

Timothy Syndrome

Clinical Description and Manifestations

Timothy syndrome (TS, LQT8) is an extremely rare (<30 patients described worldwide), multisystem, highly lethal arrhythmia disorder associated with both cardiac and extracardiac abnormalities. The typical cardiac manifestations of TS include fetal bradycardia, extreme prolongation of the QT interval (QTc >500 msec) often with macroscopic T wave alternans and 2 : 1 AV block at birth.[28] These abnormalities often coincide with congenital heart defects or cardiomyopathies. Extracardiac abnormalities often consist of simple syndactyly (webbing of toes and fingers), dysmorphic facial features, abnormal dentition, immune deficiency, severe hypoglycemia, and developmental delay (including autism). Currently, the majority of TS patients die before reaching puberty. Although the majority of TS cases have been described as sporadic de novo occurrences, there have now been a few cases described with somatic mosaicism that is associated with a less severe phenotype.[1] For example, the *CACNA1C* mutation may be present in the patient's skeletal muscle, but only in minuscule amounts, or may even be completely absent, in other cell types of the human body (absent in heart, blood lymphocytes, etc.), and the patient may present with simple syndactyly but not an overt cardiac phenotype.

Genetic Basis.

In 2004, Splawski and colleagues[28] identified the molecular basis for this highly lethal arrhythmia disorder and named it Timothy syndrome after Katherine Timothy, Drs. Keating and Splawski's study coordinator, who meticulously phenotyped these cases. Remarkably, in all 13 unrelated patients where DNA was available, Splawski identified the same recurrent sporadic de novo missense mutation, G406R, in the alternatively spliced exon 8A of the *CACNA1C*-encoded LTCC ($Ca_v1.2$), which is important for excitation-contraction coupling in the heart and, as with the cardiac sodium channel *SCN5A*, mediates an inward depolarizing current in cardiomyocytes[28] (**see Table 33.1 and Fig. 33.1**). Through the mechanism of alternative splicing, the human LTCC consists of two mutually exclusive isoforms, one

containing exon 8A and the other exon 8. In 2005, Splawski and coworkers[29] described two cases of atypical TS (TS2) with similar features of TS but without syndactyly. As with other TS cases, these two atypical cases were identified as having sporadic de novo *CACNA1C* mutations not in exon 8A, but rather in exon 8. One case hosted a mutation analogous to the classic TS mutation, G406R, whereas the other case hosted a G402R missense mutation. All three mutations confer gain of function to the LTCCs through impaired channel inactivation[28,29] and reside near the end of the S6 transmembrane segment of domain 1 in the beginning of the intracellular loop between domains I and II of the Cav1.2 alpha subunit.

In 2012, Gillis and colleagues[30] identified a novel *CACNA1C* mutation A1473G in a single patient with a prolonged QT interval, dysmorphic facial features, syndactyly, and joint contractures consistent with TS. In 2015, Boczek and colleagues[31] identified a novel *CACNA1C* mutation I1166T in a patient exhibiting a TS phenotype with QT prolongation, patent ductus arteriosus, seizures, facial dysmorphism, joint hypermobility, hypotonia, hand anomalies, intellectual impairment, and tooth decay. Patch-clamp analysis of I1166T demonstrated a novel electrophysiologic phenotype distinct from the loss of inactivation seen with the previously established TS mutations. Instead, I1166T electrophysiologic studies illustrated a loss of current density and a gain-of-function shift in activation, leading to an increase in window current.[31] Interestingly, the topologic position of both I1166T and A1473G (a few amino acids away from the S6 transmembrane segment of domain III and IV, respectively) in the channel architecture is similar to that of the three original TS mutations (S6 segment of domain I).

Cardiac-Only Timothy Syndrome

In 2015, Boczek and colleagues[32] used whole-exome sequencing to identify a novel *CACNA1C* mutation R518C that was most likely responsible for the observed phenotype in a large pedigree with concomitant LQTS, hypertrophic cardiomyopathy (HCM), congenital heart defects, and SCD. None of the patients had extracardiac phenotypes, such as those observed with TS. A subsequent *CACNA1C* exon 12–specific analysis in five additional unrelated index cases with a similar phenotype of LQTS and a personal or family history of HCM identified two additional pedigrees with mutations at the same amino acid position, either R518C or R518H. Patch-clamp studies on both R518C and R518H revealed a complex $Ca_v1.2$ electrophysiologic phenotype consisting of loss of current density and inactivation in combination with increased window and late current. All three pedigrees hosting R518C/H–*CACNA1C* presented with this unique and atypical phenotypic sequela consistent with cardiac-only Timothy syndrome (COTS).[32]

Short-QT Syndrome

Clinical Description and Manifestations

Short-QT syndrome (SQTS), first described in 2000 by Gussak and associates, is associated with a short QT interval (usually ≤320 msec) on a 12-lead ECG, paroxysmal atrial fibrillation, syncope, and an increased risk for SCD. Giustetto and colleagues[33] analyzed the clinical presentation of 53 patients with SQTS from 29 families, the largest cohort studied to date, and found that 62% were symptomatic, with cardiac arrest being the most common symptom (31% of patients) and frequently the first manifestation of the disorder. One fourth of the patients had a history of syncope, and almost 30% had a family history of SCD. Symptoms, including syncope and cardiac arrest, most often occurred during periods of rest or sleep. Almost one-third presented with atrial fibrillation.[34] SCD was observed during infancy, suggesting the potential role for SQTS as a rare pathogenic basis for some cases of SIDS.[1,34,35]

Genetic Basis.
SQTS is most often inherited in an autosomal dominant manner; however, some de novo sporadic cases have been described. To date, mutations in six genes have been implicated in the pathogenesis of SQTS, including gain-of-function mutations in the potassium channel encoding genes *KCNH2* (SQT1), *KCNQ1* (SQT2), and *KCNJ2* (SQT3) and loss-of-function mutations in *CACNA1C* (SQT4), *CACNB2b* (SQT5), and *CACNA2D1* (SQT6) encoding for LTCC alpha, beta, and delta subunits, respectively (**see Table 33.1 and Fig. 33.1**). However, despite the identification of these six SQTS susceptibility genes, it remains unknown as to what proportion of SQTS is expected to be SQT1 to SQT6 genotype positive and what proportion awaits genetic elucidation. More than 75% of SQTS cases remain elusive genetically.

Genotype-Phenotype Correlates

Insufficient data exist to define genotype-phenotype correlations clearly in SQTS, since probably less than 60 cases have been described in the literature to date, but gene-specific ECG patterns have emerged. The typical ECG pattern consists of a QT interval of 320 milliseconds or less (QTc ≤340 msec) and tall, peaked T waves in the precordial leads with either no or a short ST segment present. The T waves tend to be symmetric in SQT1 but asymmetric in SQT2 to SQT4. In SQT2, inverted T waves can be observed. In SQT5, a Brugada syndrome–like ST elevation in the right precordial lead may be seen.[34]

Although perhaps premature because of a small sample size, a recent report has suggested that SQTS patients with *KCNH2* mutations have a shorter QT and a greater response to hydroquinidine therapy than patients with a non–*KCNH2*-mediated SQTS.[36] Based on a clinical variable analysis of 65 mutation-positive SQTS patients among 132 SQTS cases previously reported in the literature, Harrell and colleagues[37] indicated that patients with *KCNH2*-mediated SQTS (SQT1) exhibit a later age of onset of manifestation, whereas patients with *KCNQ1*-mediated SQTS (SQT2) have a higher prevalence of bradyarrhythmias and atrial fibrillation.

Drug-Induced Torsade de Pointes

Clinical Description and Manifestations

Drug-induced QT prolongation or drug-induced torsades de pointes (DI-TdP) is a constant concern for physicians prescribing particular drugs with the capacity for producing such unwanted and potentially life-threatening side effects (**see Chapters 8, 37, and 39**). The estimated incidence of antiarrhythmic drug–induced TdP has ranged from 1% to 8% depending on the drug and dose.[38] DI-TdP and subsequent sudden death are rare events, but the list of potential "QT liability" or "torsadegenic" drugs is extensive and includes not only antiarrhythmic drugs such as quinidine, sotalol, and dofetilide, but also many noncardiac medications, such as antipsychotics, methadone, antimicrobials, antihistamines, and the gastrointestinal stimulant cisapride[39] (see www.qtdrugs.org for a comprehensive list).

I_{Kr} Channel Blockers and the "Repolarization Reserve"

Besides their intended function and their intended target of action, the vast majority of medications with a potential unwanted TdP-predisposing side effect are $I_{Kr}/K_v11.1$ channel blockers (also referred to as HERG channel blockers). In effect, QT-prolonging drugs create an "LQT2-like" phenotype through reduced repolarization efficiency and subsequent lengthening of the cardiac action potential. However, I_{Kr}

drug blockade alone does not appear sufficient to provide the potentially lethal TdP substrate. One particular thesis centers on the observation that cardiac repolarization relies on the interaction of several ion currents that provide some level of redundancy in order to protect against extreme QT prolongation by "QT liability" drugs. This "repolarization reserve" may be reduced through anomalies in the repolarization machinery, as a result of common or rare genetic variants in critical ion channels that produce a subclinical loss of the repolarizing currents I_{Ks} and I_{Kr}.[38] In fact, studies revealed that 10% to 15% of patients with DI-TdP hosted rare ion channel mutations.[1] A recent smaller study found potential LQTS susceptibility mutations in 40% of cases of seemingly isolated, drug-induced LQTS.[40] Further, functional characterization suggested that these mutations were somewhat "weaker" than the loss-of-function mutations associated with classic, autosomal dominant LQTS, supporting the multihit hypothesis that underlies "reduced repolarization reserve."

Common Ion Channel Polymorphisms.

Among the common polymorphisms of the *KCNH2*-encoding I_{Kr} potassium channel, the K897T and R1047L polymorphisms have received the most attention (**see Chapter 8**). As reviewed by Fitzgerald and Ackerman,[39] Paavonen and coworkers observed that T897-KCNH2 channels exhibit slower activation kinetics with a higher degree of inactivation, an alteration expected to decrease channel function and perhaps alter drug sensitivity, since several common drugs inhibiting I_{Kr} channel function bind preferentially to the inactivated state of the channel. These data suggest that T897 channels may genetically "reduce repolarization reserve" and facilitate a proarrhythmic response that may be enhanced in the setting of I_{Kr} channel–blocking drugs, compared to wild-type K897 channels. In fact, K897T appears to affect the QTc response to ibutilide in a gender specific manner. In a study by Sun and colleagues reviewed by Schulze-Bahr,[11] among 105 atrial fibrillation patients treated with dofetilide, R1047L was overrepresented among those patients who developed drug-induced TdP compared with patients who were free of TdP. In addition to these common potassium channel alpha subunit polymorphisms, three common polymorphisms (D85N-KCNE1, T8A-KCNE2, and Q9E-KCNE2) involving auxiliary beta subunits have been implicated in drug-induced arrhythmia susceptibility.[39]

Along with genetic variants in major repolarizing channels, variants of the major depolarizing channel, Nav1.5, may provide a substrate for a proarrhythmic response in the setting of I_{Kr} channel–blocking drugs or in patients with other risk factors for DI-TdP. The most prominent channel polymorphism to confer arrhythmia susceptibility in an ethnic-specific manner is S1103Y-SCN5A (originally annotated as the Y1102 variant). This polymorphism, seen in 13% of African Americans but not observed in any Caucasian or Asian controls (>1000), was overrepresented in arrhythmia cases (56.5%) compared to controls (13%) involving African-Americans (odds ratio, 8.7).[38,39] S1103Y has very subtle alterations in channel kinetics in heterologous expression studies under basal conditions. However, functional and modeling studies supported the potential for QT prolongation, reactivation of calcium channels, early afterdepolarizations, and arrhythmias, particularly in the setting of concomitant exposure to I_{Kr}-blocking drugs.

Recent genome-wide association studies (GWAS) have associated common variants of the *NOS1AP*-encoded nitric oxide synthase 1 adapter protein with QT interval duration. NOS1AP is a regulator of the neuronal nitric oxide synthase (nNOS), which regulates intracellular calcium levels and myocyte contraction through its effect on the LTCCs. Common SNPs in the *NOS1AP* appear associated with drug-induced QT prolongation and ventricular arrhythmia.[41] This association was most pronounced in patients

taking amiodarone, currently one of the most common antiarrhythmic drugs. It has been hypothesized that genetic variants in *NOS1AP* that suppress the gene's expression may in turn result in increased LTCC currents and subsequent QT prolongation, and such individuals may be at increased arrhythmogenic risk while taking amiodarone.[41] However, although QT prolongation is observed routinely with amiodarone, DI-TdP attributed to amiodarone is exceedingly rare.

Additionally, genetic variation or individual differences in drug elimination or metabolism may contribute to individual risk for DI-TdP. For example, patients with genetically mediated reduction in cytochrome P-450 (CYP) 3A enzymatic activity could be vulnerable to DI-TdP in the setting of I_{Kr} blockers that depend on CYP3A for its metabolism.[11,39]

The Other Channelopathies

Catecholaminergic Polymorphic Ventricular Tachycardia

Clinical Description and Manifestations

Catecholaminergic polymorphic ventricular tachycardia (CPVT) is a heritable arrhythmia syndrome that classically manifests with exercise-induced syncope or sudden death, is predominantly expressed in young persons, and closely mimics the phenotypic byline of LQT1 but appears to be much more lethal.[42,43] As with LQT1, swimming is a potentially lethal arrhythmia-precipitating trigger in CPVT. In fact, both LQT1 and CPVT have been shown to underlie several cases of unexplained drowning or near-drowning in young, healthy swimmers. However, CPVT is associated with a completely normal resting ECG (perhaps bradycardia and mild U waves) and is suspected on ECG after exercise or catecholamine stress testing that demonstrates significant ventricular ectopy, occasionally with CPVT's pathognomonic arrhythmia of bidirectional VT.[1]

Clinically, a presentation of exercise-induced syncope and a QTc less than 460 milliseconds should always prompt first consideration of and need to rule out CPVT rather than “concealed” or “normal QT interval” LQT1. Further, exercise-induced premature ventricular complexes in bigeminy is much more likely than the more specific but less sensitive finding of bidirectional VT.[44] CPVT is associated with a structurally normal heart. Once thought to manifest only during childhood, more recent studies have suggested that the age of first presentation can range from infancy to 40 years. CPVT's potential lethality is illustrated by mortality rates of 30% to 50% by age 35 and the presence of a positive family history of young (<40 years) SCD for more than one third of CPVT individuals and in as many as 60% of families hosting *RYR2* mutations.[43] Moreover, approximately 15% of autopsy-negative SUD in young persons and some cases of SIDS have been attributed to CPVT.[1,45,46]

Genetic Basis.

Perturbations in key components of intracellular calcium–induced calcium release from the sarcoplasmic reticulum serve as the pathogenic basis for CPVT (**see Chapter 34**). Inherited in an autosomal dominant manner, mutations in the *RYR2*-encoded cardiac ryanodine receptor/calcium release channel represent the most common genetic subtype of CPVT (CPVT1), accounting for 60% of clinically “strong” cases of CPVT (**Fig. 33.5; see Table 33.1**). Gain-of-function mutations in *RYR2* lead to leaky calcium release channels and excessive calcium release, particularly during sympathetic stimulation that can precipitate calcium overload, delayed depolarizations, and ventricular arrhythmias.[42] Again, most unrelated CPVT

families are identified with their own unique *RYR2* mutation, and about 5% of unrelated mutation-positive patients host multiple putative pathogenic mutations.[47]

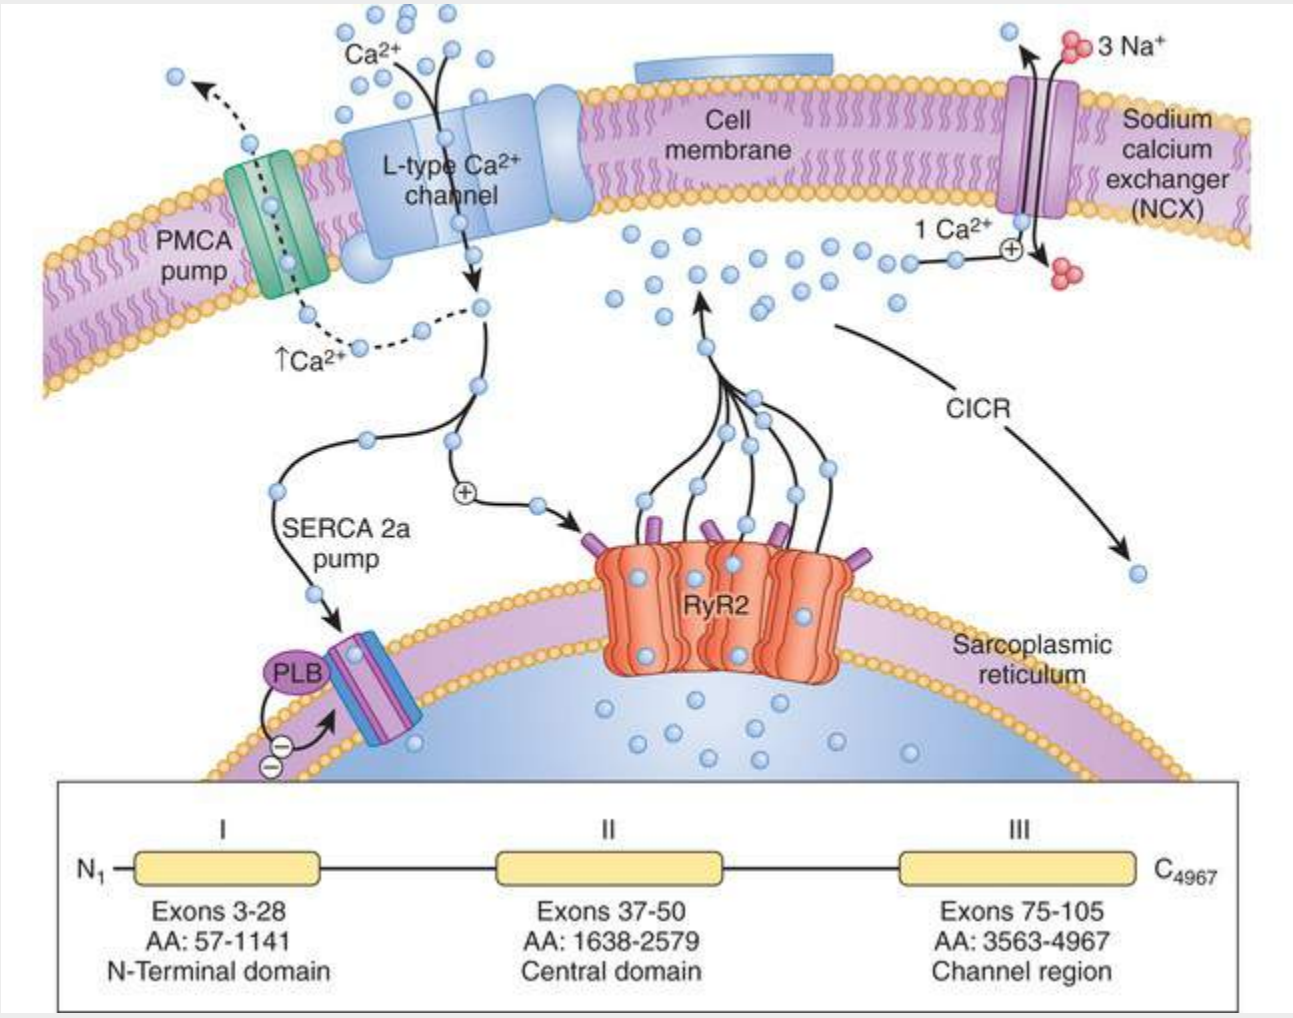

FIGURE 33.5 Catecholaminergic polymorphic ventricular tachycardia (CPVT), a disorder of intracellular calcium handling. Perturbations in key components of the calcium-induced calcium release (*CICR*) mechanism responsible for cardiac excitation-contraction coupling is the pathogenic basis for CPVT. At the center of this mechanism is the *RYR2*-encoded cardiac ryanodine receptor (RyR2)/calcium release channel located in sarcoplasmic reticulum membrane. Mutations in *RYR2* are clustered and distributed in three "hot spot" regions of this 4967–amino acid (*AA*) protein: domain I, or the N-terminal domain (AA: 57-1141); domain II, or the central domain (AA: 1638-2579); and domain III, or the channel region (AA: 3563-4967).

RYR2 is one of the largest genes in the human genome, with 105 exons that transcribe/translate one of the largest cardiac ion channel proteins comprising 4967–amino acid residues. There apparently are no specific mutation "hot spots," but there are three regional hot spots or "domains" where unique mutations reside (**Fig. 33.5**). Greater than 90% of *RYR2* mutations discovered to date represent missense mutations. However, as many as 5% of unrelated CPVT patients may host large gene rearrangements consistent with large whole-exon deletions, similar to that observed in LQTS.[47] Although genotype-phenotype correlations have been limited, a more recent study has suggested that family members hosting C-terminal (ion channel–forming domain) *RYR2* mutations may have a higher ventricular arrhythmia burden of nonsustained ventricular tachycardia (NSVT) than individuals hosting N-terminal or central domain *RYR2*-localizing mutations.[48]

Strikingly, almost one third of patients with "possible/atypical" LQTS (QTc <480 msec) who have exertion-induced syncope have also been identified as *RYR2* mutation positive.[47] In fact, almost 30% of

patients with CPVT have been misdiagnosed as having “LQTS with normal QT intervals” or “concealed LQTS,” indicating the critical importance of properly distinguishing between CPVT and LQTS at the clinical level, because risk assessment and treatment strategies of these unique disorders may vary. Similarly, some patients diagnosed with CPVT based on the presence of bidirectional VT on exercise have been identified with *KCNJ2* mutations, which are associated with the rarely lethal ATS.[1] The misdiagnosis of ATS as the potentially lethal disorder CPVT may lead to more aggressive prophylactic therapy (i.e., ICD implantation) than necessary. Two autosomal recessive forms of CPVT have been identified involving mutations in either *CASQ2*-encoded calsequestrin-2 protein or *TRDN*-encoded triadin.[1,21] Recently, mutations in *CALM1* and *CALM3* have been implicated as a cause of autosomal dominant CPVT[49,50] (**see Table 33.1**).

Brugada Syndrome

Clinical Description and Manifestations

Brugada syndrome (BrS) is an heritable arrhythmia syndrome characterized by an ECG pattern consisting of coved-type ST-segment elevation (≥2 mm) followed by a negative T wave in the right precordial leads V_1 through V_3 (often referred to as type 1 Brugada ECG pattern) and an increased risk for SCD resulting from episodes of polymorphic ventricular tachyarrhythmias.[51] The penetrance and expressivity of the disorder are highly variable, ranging from lifelong asymptomatic individuals to SCD during the first year of life. BrS is generally considered a disorder involving young male adults, perhaps greatest among Southeast Asian men, with arrhythmogenic manifestation first occurring at an average age of 40 years, with SCD typically occurring during sleep. However, BrS has been demonstrated in children and infants. In a 2007 population study of 30 children (<16 years) affected by BrS from 26 families, fever represented the most common precipitating factor for arrhythmic cardiac events, including syncope and SCD.[1]

Genetic Basis.

BrS is inherited as an autosomal dominant trait, although more than half of BrS cases may be sporadic. Approximately 20% to 30% of BrS cases result from loss-of-function mutations in the *SCN5A*-encoded cardiac sodium channel (**see Table 33.1 and Fig. 33.1**) and are classified as Brugada syndrome type 1 (BrS1). In 2009 an international compendium of *SCN5A* mutations in patients referred for BrS genetic testing reported almost 300 distinct mutations in 438 of 2111 (21%) unrelated patients, and the mutation detection yield ranged from 11% to 28% across nine centers.[52] The yield of mutation detection may be significantly higher among familial forms than in sporadic cases. Schulze-Bahr and colleagues[53] identified *SCN5A* mutations in 38% of their familial BrS cases, compared to none in 27 sporadic cases ($P = 0.001$). The majority of the mutations were missense (66%), followed by frameshift (13%), nonsense, (11%), splice site (7%), and in-frame deletions/insertions (3%). Approximately 3% of the genotype-positive patients host multiple putative pathogenic *SCN5A* mutations, and as in the genotype-phenotype observations in LQTS, patients hosting multiple *SCN5A* mutations tend to be younger at diagnosis (29.7 ±16 years) than those with a single mutation (39.2 ±14.4 years).[52] Again, as in LQTS, there is no particular mutational “hot spot” because almost 80% of the BrS-related *SCN5A* mutations occur as “private,” single-family mutations.

However, almost 10% of the 438 unrelated, *SCN5A* mutation–positive patients hosted one of four mutations: E1784K (14 patients), F861WfsX90 (11 patients), D356N (8 patients), and G1408R (7

patients).[52] Interestingly, the most common BrS1 mutation, E1784K, has also been reported as the most frequently seen LQT3-associated *SCN5A* mutation, illustrating how the same DNA alteration in a given gene can lead to two distinct cardiac arrhythmia syndromes, most likely as a result of other environmental or genetic modifying factors. In fact, E1784K represents the quintessential example of a cardiac sodium channel mutation with the capacity to provide for a mixed clinical phenotype of LQT3, BrS, and conduction disorders.[54]

In addition to pathogenic mutations in *SCN5A*, common polymorphisms may have a modifying effect on the disorder. Bezzina and others described an Asian-specific haplotype of six *SCN5A* promoter polymorphisms in near-complete linkage disequilibrium that occurred with an allelic frequency of 22% and was comparatively absent in Caucasians and blacks.[1] These promoter region polymorphisms may modulate the variability in cardiac conduction and in part contribute to the observed higher prevalence of BrS in the Asian population. Brugada and colleagues[55] provided data supporting the common polymorphism H558R as a modulator of the BrS phenotype, where the minor allele R558 provided a less severe clinical course in their 75 genotyped Brugada patients. Patients homozygous for H558 had longer QRS complex duration in lead II, higher J point elevation in lead V_2, higher "aVR sign," and trended toward more symptoms than H558R heterozygotes or R558 homozygotes. In 2013, Bezzina and associates[56] conducted a GWAS of 312 individuals with BrS and 1115 controls and detected three common genetic variants at three loci within or near the *SCN5A*, *SCN10A*, and *HEY2* genes that had a significant association with the BrS phenotype. These three loci had a cumulative dose-dependent, oligogenetic effect on disease risk, with an estimated odds ratio reaching 21.5 in the presence of more than four risk alleles compared to less than two alleles.

In addition to *SCN5A*, mutations have now been discovered in 17 other BrS susceptibility genes (**see Table 33.1**). Mechanistically, either decreases in the inward sodium or calcium currents or increases in the outward $K_v4.3$ potassium current produce the BrS phenotype through perturbations of the respective channel alpha subunits or channel interacting proteins[51] (**see Fig. 33.1**). For example, mutations in the glycerol-3-phosphate dehydrogenase 1–like protein encoded by *GPD1L* affect trafficking of the sodium channel to the plasma membrane, thus reducing overall sodium current and giving rise to the BrS phenotype, whereas mutations involving the LTCC alpha and beta subunits encoded by the *CACNA1C* and *CACNB2b* genes, respectively, were implicated in approximately 10% of BrS cases. However, on closer examination of this seminal discovery, a tight link between calcium channel–mediated disease and the clinical phenotype of BrS with concomitant short QT interval is evident, in which 50% of patients with BrS/short QT interval hosted a mutation in the LTCC subunit. In fact, in 2012, Crotti and associates[57] performed the first comprehensive mutational analysis in a large cohort of unrelated BrS patients. They identified *SCN5A* mutations in 16% of their cohort, but only 1.5% of their BrS cases had a mutation in one of the LTCC subunit genes, in the absence of a short QT interval.

To date, 18 genes have been implicated in BrS pathogenicity, but only *SCN5A* shows a significant contribution to the disease. In fact, extreme caution must be used when interpreting rare genetic variants identified within the minor BrS genes.[58,59] Importantly, the genetic cause of more than two thirds of clinically diagnosed BrS remains elusive, suggesting a high degree of genetic heterogeneity. This degree of genetic elusiveness also begs the question of whether most BrS is a genetically heterogeneous monogenic disorder or in fact a congenital heart defect or developmental disorder involving the epicardial right ventricular outflow tract,[60] or as anticipated, a mixture of monogenic-mediated BrS, oligogenic-mediated BrS, and non–genetic-mediated BrS.[56]

Phenotypic Correlates of *SCN5A*-Mediated Brugada Syndrome (BrS1)

Because the majority of BrS cases are elusive genetically, genotype-phenotype correlations in BrS have not been analyzed to the same degree as in LQTS. *SCN5A* mutations are associated with a higher incidence of conduction abnormalities in BrS patients, and the presence of a long PQ interval may be indicative of *SCN5A*-mediated BrS1, whereas the presence of a short QT interval (QTc <350 msec) may be indicative of LTCC-mediated BrS pathology. Crotti and colleagues[57] reported that compared to a less than 10% yield for a positive *SCN5A* genetic test in patients with a PQ interval shorter than 200 milliseconds, the yield was almost 40% among patients with a PQ interval of 200 milliseconds or longer.[57] Interestingly, young BrS males (<20 years, 83%) had a significantly higher *SCN5A* mutation detection rate than men age 20 to 40 (21%) and those over 40 (11%; $P < 0.0001$). In addition, BrS1 patients with nonsense, frameshift, or premature truncation–inducing mutations exhibit a more severe phenotype.[61] Unlike LQTS genetic testing, in which the triad of diagnostic, prognostic, and therapeutic impact has been fulfilled, BrS genetic testing is currently limited by its lower yield (25%, versus 75% for LQTS) and relative absence of a therapeutic contribution from knowing the genotype.[1,18,51,62]

Early Repolarization Syndrome

Clinical Description and Manifestations

The early repolarization (ER) pattern is characterized by the ECG finding of an elevation (≥1 mm above baseline) of the QRS-ST junction (the "J point") manifesting as QRS slurring (at transition of QRS to ST segment) or notching (positive deflection inscribed on terminal S wave), ST-segment elevation with upper concavity, and prominent T waves in two or more contiguous leads. The prevalence of the ER pattern in the general population has been reported to range from less than 1% to 13%, depending on age, sex, race, and the criteria for J point elevation.[63] This ECG phenomenon has long been considered an innocuous variant in healthy individuals. However, Haissaguerre and colleagues[64] have noted that J point elevation (≥1 mm above baseline) on inferolateral ECG leads was overrepresented significantly (31%) and was greater in magnitude among 206 case participants who experienced cardiac arrest caused by idiopathic ventricular fibrillation (IVF) than in 412 controls (5%; $P < 0.001$) matched for age, sex, race, and level of physical activity. Those patients with ER were more often males and have a personal history of syncope or cardiac arrest during sleep than those without ER pattern. Similarly, Rosso and colleagues[65] noted an overrepresentation of J point elevation in their 45 IVF patients compared to controls (45% versus 13%; $P = 0.001$), with the same observation of male predominance among those with ER. Therefore, according to the 2016 J wave syndromes expert consensus conference report, early repolarization syndrome (ERS) is typically diagnosed in patients who display ER in the inferior and/or lateral leads and present with aborted cardiac arrest, documented ventricular fibrillation, or polymorphic ventricular tachycardia. The Proposed Shanghai Scoring System for the diagnosis of ERS was presented in the 2016 consensus document.[51]

In community-based general population of 10,864 middle-aged (30 to 59 years 52% male) Finnish individuals, Tikkanen and colleagues[66] identified 630 persons overall (5.8%) with a J point elevation of at least 0.1 mV. This overall prevalence of ER pattern was reduced to only 0.33% when considering a J point elevation of 0.2 mV or greater. A 30-year follow-up with the endpoint of cardiac death showed that compared to participants without a J point elevation, those with ER (J point ≥0.1 mV) in the inferior leads had an increased risk of both cardiac death (adjusted relative risk [ARR] = 1.28; 95% confidence interval [CI] = 1.04 to 1.59; $P = 0.03$) and arrhythmias (ARR = 1.43; 95% CI = 1.06 to 1.94; $P = 0.03$), and this

risk was further increased (cardiac death ARR = 2.98; 95% CI = 1.85 to 4.92; $P < 0.001$; arrhythmia ARR = 2.92; 95% CI = 1.45 to 5.89; $P < 0.001$) with increasing elevation (≥0.2 mV) of the J point. However, an ER pattern localizing to only the lateral leads did not show a statistically significant association with increased risk for arrhythmic cardiac death.[66] The clinical conundrum with respect to this inferolateral ERS is distinguishing the potentially lethal ERS from the frequently observed juvenile ER pattern seen in healthy individuals, particularly healthy athletes.

Genetic Basis.

The indication for a genetic basis of ERS stems from the observation that 16% of IVF patients with an ER pattern had a family history of unexplained sudden death.[64] In 2009, Haissaguerre and colleagues[67] described the first gene to be implicated in ERS, a rare, functionally uncharacterized, missense mutation (S422L) in the *KCNJ8*-encoding pore-forming subunit Kir6.1 of the adenosine triphosphate (ATP)–sensitive potassium channel in a 14-year-old girl with IVF. Since then, this same mutation has been described in additional cases of BrS and ERS and has been shown to have a gain of function in electrophysiologic phenotype.[68,69] However, despite its abnormal in vitro functional phenotype, it is now appreciated that S422L-*KCNJ8* is far more common than once thought, thus questioning its pathogenic status. In fact, since its implication in disease, S422L-*KCNJ8* is now known to have heterozygous frequency of 0.5% (168 of 33,363) among European Caucasians in the Exome Aggregation Consortium (ExAC) and as high as 4% among the Ashkenazi Jewish population, thus suggesting that this variant may be a functional polymorphism rather than a pathogenic mutation.[70] In 2010, Burashnikov and colleagues[71] implicated the LTCC alpha$_1$ (*CACNA1C*), beta$_2$ (*CACNB2b*), and alpha$_2$delta (*CACNA2D1*) subunit encoding genes in the pathogenesis of ERS with their identification of mutations in 4 of 24 (16.6%) ERS index cases.[71] However, not all these genetic variants have been characterized functionally, and some may represent rare variants of uncertain significance. In addition, rare variants in *ABCC9*, *SCN5A*, and *SCN10A* have been implicated in ERS.[51]

Idiopathic Ventricular Fibrillation

Clinical Description and Manifestations

Ventricular fibrillation (VF) is a major cause of SCD and ultimately is the “final common arrhythmic pathway” for all the aforementioned channelopathies. In the absence of identifying structural or genetic abnormalities to explain the VF or the out-of-hospital cardiac arrest, the VF is termed “idiopathic” ventricular fibrillation (IVF). In essence, as in SIDS, IVF is a diagnosis of exclusion and can stem from several underlying mechanisms. IVF may account for up to 10% of sudden deaths, especially in the younger population. About 30% of IVF-labeled individuals will have recurrent episodes of VF. About 20% have a family history of sudden death or IVF, suggesting a hereditary component in some cases.[72] Unfortunately, most IVF cases are often only recognized after their first out-of-hospital cardiac arrest.

Genetic Basis.

IVF may be clinically, genetically, and mechanistically related most closely to BrS. As many as 20% of IVF patients have been diagnosed subsequently with BrS, depending on the criteria used.[1] As with BrS,

loss-of-function *SCN5A* mutations have been identified in IVF patients who have no ECG stigmata at rest, or with provocation for BrS. However, some case reports of IVF have identified mutations in other arrhythmia susceptibility genes, such as *ANK2*, which encodes for ankyrin B; *RYR2*, which encodes for the cardiac ryanodine receptor; and *CALM1*, which encodes for calmodulin 1.[35,73] These particular IVF cases ultimately represented atypical presentations of LQTS or CPVT. For most IVF cases, a genetic mechanism remains undefined.

However, Alders and associates[72] embarked on a genome-wide haplotype-sharing analysis involving three distantly related IVF pedigrees and identified a haplotype on chromosome 7q36 that was conserved among all affected individuals and in 7 of 42 independent IVF patients, suggesting a risk locus for IVF. This chromosome segment contains part of the *DPP6* gene, which encodes for dipeptidyl-peptidase-6, a putative component of the transient outward current (Ito, Kv4.3) in the heart. Further, the investigators showed a 20-fold increase in *DPP6* mRNA expression in the myocardium of haplotype carriers compared to controls, suggesting that *DPP6* may be a candidate gene for IVF. To date, however, no IVF-associated coding-region mutations have been identified in *DPP6*. Valdivia and colleagues[74] identified a mutation in the *SCN3B*-encoded sodium channel Na_v $beta_3$ subunit that precipitates intracellular retention of $Na_v1.5$, functionally mimicking a trafficking-defective *SCN5A* loss of function, in a 20-year-old man with IVF.

Progressive Cardiac Conduction Disease (Defect)

Clinical Description and Manifestations

Cardiac conduction disease (CCD) causes a potentially life-threatening alteration in normal impulse propagation through the cardiac conduction system. CCD can result from a number of physiologic mechanisms, ranging from acquired to congenital, and with or without structural heart disease. Progressive cardiac conduction disease or defect (PCCD), also known as *Lev-Lenègre disease*, is one of the most common cardiac conduction disturbances in the absence of structural heart disease. It is characterized by progressive (age-related) alteration of impulse propagation through the His-Purkinje system, with right or left bundle branch block and widening of the QRS complex, leading to complete AV block, syncope, and occasionally sudden death.[75]

Genetic Basis.

In 1999, Schott and colleagues further expanded the spectrum of loss-of-function *SCN5A* disease with the inclusion of familial PCCD, identifying a splice-site *SCN5A* mutation (c.3963+2 T>C) associated with an autosomal dominant inheritance pattern in a large French family, as reviewed by Ruan and associates.[75] Since then, investigators have identified more than 30 PCCD-associated mutations in *SCN5A*. In addition to *SCN5A*, mutations in *SCN1B* can cause BrS with conduction disease. These mutations present with a loss-of-function phenotype through reduced current density and enhanced slow inactivation of the channel. As with most loss-of-function *SCN5A* diseases, the phenotypic expression of PCCD can be complex and is often present with a concomitant BrS or BrS-like phenotype. In fact, Probst and associates[76] showed that PCCD is the prevailing phenotype in BrS-associated *SCN5A* mutation carriers, in whom the penetrance of conduction defects was 76%.

In 2009, Meregalli and colleagues[61] demonstrated that the *SCN5A* mutation type can have a profound effect on the severity of PCCD and BrS. Studying 147 individuals hosting one of 32 different *SCN5A*

mutations, they found that patients with either a premature truncation mutation (M_T; i.e., nonsense or frameshift) or a severe loss-of-function missense mutation ($M_{inactive}$, >90% reduction in peak I_{Na}) had a significantly longer PR interval compared with patients with missense mutations having less impairment to the sodium current (M_{active}, ≤90% reduction). Further, those patients with a truncation mutation had significantly more episodes of syncope than those with an "active" mutation (M_{active}). These data suggest that mutations with a more deleterious loss of sodium current produce a more severe phenotype of syncope and conduction defect, providing the first evidence for intragenotype risk stratification associated with *SCN5A* loss-of-function disease.

Most recently, gain-of-function mutations (E7K, R164W, A432T, and G844D) in the *TRPM4*-encoded transient receptor potential melastatin type 4 ion channel have been implicated as a cause of autosomal dominant, isolated cardiac conduction disease and progressive familial heart block type 1 (PFHBI) following linkage analysis and subsequent mutational analysis of *TRPM4* in four different large, multigenerational pedigrees, thus identifying an essential role for calcium-activated nonselective cation channel activity in the cardiac conduction system.[77,78]

When CCD is associated with concomitant phenotype of LQTS, the QRS is usually narrow, and the conduction defect is typically an intermittent 2 : 1 AV block. Patients with LQT2, TS1, or ATS1 may also have dysfunctional AV conduction.

Sick Sinus Syndrome

Clinical Description and Manifestations

Sinus node dysfunction (SND) or sick sinus syndrome (SSS), manifesting as inappropriate sinus bradycardia, sinus arrest, atrial standstill, tachycardia-bradycardia syndrome, or chronotropic incompetence, is the leading reason for pacemaker implantation and has been attributed to dysfunction of the sinoatrial (SA) node.[1] SSS usually occurs in the elderly population (1 in 600 cardiac patients over age 65) with acquired cardiac conditions, including cardiomyopathy, congestive heart failure, ischemic heart disease, and metabolic disease. However, a significant number of patients show no identifiable cardiac anomalies or cardiac conditions underlying SND ("idiopathic" SND), which can occur at any age, including in utero. Additionally, familial forms of idiopathic SND consistent with autosomal dominant inheritance with reduced penetrance and recessive forms with complete penetrance have been reported.[75]

Genetic Basis.

Mutational analysis of small cohorts and case reports of patients with idiopathic SSS have thus far implicated four genes: *SCN5A*, *HCN4*, *ANK2*, and *MYH6* (**see Table 33.1**). To date, 15 SSS-associated mutations have been reported in *SCN5A*.[75,79] The mutations either produced nonfunctional sodium channels through loss of expression or channels with mild to severe loss of function through an altered biophysical mechanism of the channel.[79] In 2003, based on prior observations of arrhythmias and conduction disturbances, Benson and coworkers examined *SCN5A* as a candidate gene for congenital SSS in 10 pediatric patients from seven families who were diagnosed during the first decade of life and identified compound heterozygote mutations (T220I + R1623X, P1298L + G1408R, and delF1617 + R1632H) in five individuals from three of the seven families, implicating *SCN5A* in autosomal recessive SSS.[75] Not surprisingly, many of the *SCN5A*-positive patients displayed a mixed phenotype consisting of SSS, BrS, and/or CCD. The expressivity of the mixed phenotype can be highly variable within affected

families. In 2007 a 12-year-old boy with SSS, CCD, and recurrent VT was identified with an L1821fsX10 frameshift mutation that displayed a unique channel phenotype of 90% reduced current density (consistent with BrS/SSS/CCD), but an increase in late sodium current relative to the peak current (consistent with LQT3) for those channels expressed. As illustrated by this family, in whom the mutation was present in six asymptomatic members, with two displaying only mild ECG phenotypes, this disorder is often associated with incomplete or low penetrance.

Two loss-of-function mutations in hyperpolarization-activated cyclic nucleotide-gated channel 4 gene, *HCN4*, have been identified in two cases of idiopathic SND. The *HCN4* gene encodes the so-called I_f or pacemaker current and plays a key role in automaticity of the sinus node. In one study a heterozygous single-nucleotide deletion (c.1631delC) creating a frameshift mutation (P544fsX30) with early truncation of the protein was identified in an idiopathic SND patient, and in a second study, another patient with idiopathic SND had a missense mutation (D553N) that resulted in abnormal trafficking of the pacemaker channel.[80] Interestingly, the frameshift mutation identified in a 66-year-old woman produced a mild phenotype associated with sinus rhythm during exercise, whereas the D553N missense mutation identified in a 43-year-old woman was associated with severe bradycardia, recurrent syncope, QT prolongation, and polymorphic ventricular tachycardia (torsade de pointes), suggesting the potential for lethality in *HCN4*-mediated disease. Whether or not the preliminary 10% to 15% yield for defective *HCN4*-encoded pacemaker channels in idiopathic SND is durable, as derived from the two small cohorts, will require further studies involving much larger cohorts.

In 2008, Le Scouarnec and colleagues[81] reported the genetic and molecular mechanism involving *ANK2* (also known as *ANKB*)-encoded ankyrin B in two large families with high-penetrant and severe SND. Ankyrin B is essential for normal membrane organization of the ion channels and transporters in the cardiocytes within the SA node and is required for proper physiologic cardiac pacing. Dysfunction of ankyrin B-based trafficking pathway causes abnormal electrical activity in the SA node and SND. As in the sodium channel, variants in *ANK2* cause a variety of cardiac dysfunctions.

In 2011, Holm and colleagues,[82] using a GWAS on 792 Icelandic individuals with SSS and 37,592 Icelandic population controls, identified a rare missense variant (c.2161C>T, p.R721W) in MYH6-encoded alpha heavy-chain 6 subunit of cardiac myosin that was significantly associated with SSS. Moreover, the lifetime risk of being diagnosed with SSS was only 6% for noncarriers of c.2161C>T compared to 50% for carriers of the *MYH6* variant. In 2015, Ishikawa and associates[83] identified a three–base pair in-frame deletion resulting in a single–amino acid deletion (p.delE933) in one of nine unrelated genotype-negative probands with SSS. The mutant slowed down action potential propagation when heterologously expressed in atrial myocardial HL-1 cells. Moreover, morpholino knockdown of *MYH6* in zebrafish lead to a reduced heart rate that could be restored when coexpressed with wild-type *MYH6*, but not when coexpressed with dE933-*MYH6*.

“Ankyrin-B Syndrome”

The *ANK2* gene encodes ankyrin B protein, a member of a large family of proteins that anchors various integral membrane proteins to the spectrin-based cytoskeleton. Specifically, ankyrin B is involved in anchoring the Na^+,K^+-ATPase, Na^+/Ca^+ exchanger, and InsP3 receptor to specialized microdomains in the cardiomyocyte transverse tubules. Loss-of-function mutations of *ANK2* were shown originally to cause a dominantly inherited cardiac arrhythmia, with an increased risk for SCD associated with a prolonged QT interval, and subsequently the label “type 4 long QT syndrome” (LQT4) was assigned to this *ANK2* pedigree. Since then, this disorder has been more correctly renamed “sick sinus syndrome with

bradycardia," or the "ankyrin-B syndrome."[84]

In 2007, Mohler and colleagues[84] described the first human *ANK2* mutation (E1425G) identified in a large, multigenerational French kindred presenting with "atypical LQTS" displaying a phenotype of prolonged QT interval, severe sinus bradycardia, polyphasic T waves, and atrial fibrillation. Following this sentinel discovery, significant loss-of-function ankyrin B variants of differing degrees of functionality have been identified in patients with various arrhythmia phenotypes, including bradycardia, SND, delayed cardiac conduction/conduction block, IVF, atrial fibrillation, drug-induced LQTS, exercise-induced VT, and even a CPVT phenotype. In addition, 2% to 4% of ostensibly healthy white controls and 8% to 10% of black controls (including the most common "black"-specific variant L1622I) also host rare variants in *ANK2,* underscoring the challenge in distinguishing pathogenic mutations that truly mediate an "ankyrin-B syndrome" from rare *ANK2* variants of uncertain significance. Individuals hosting *ANK2* variants displaying a more severe loss of function in vitro tend to have a more severe cardiac phenotype and may be at increased risk for SCD.[84]

Familial Atrial Fibrillation

Clinical Description and Manifestations

Atrial fibrillation (AF) is the most common cardiac arrhythmia, with a prevalence of about 1% in the general population and 6% in people over age 65 years[85] (**see Chapter 38**). Most often, AF is associated with underlying cardiac pathology, including cardiomyopathy, valvular disease, hypertension, and atherosclerotic cardiovascular disease, and is responsible for more than one third of cardioembolic episodes. However, AF can present even at an early age without any identifiable cardiac anomalies and is termed *lone* AF, accounting for 2% to 16% of all AF cases.[85] Further, approximately one third of lone AF patients have a family history of AF, suggesting familial forms of the disease.[86]

Genetic Basis.

Although the majority of familial atrial fibrillation (FAF) cases remain genetically elusive, several genetic loci and causative genes have been described over the past decade. In 1996, Brugada and colleagues identified three families with autosomal dominant AF. The age of onset ranged from in utero to 45 years. Genetic linkage analysis of these families revealed a novel locus for AF on chromosome 10 (10q22). In 2003 a second locus was identified at 6q14-16, again associated with autosomal dominant inheritance. To date, the underlying causative genes for both loci remain unknown.

In 2003, however, an AF-associated locus on chromosome 11 in a large four-generation family and subsequent identification of a SQTS-like gain-of-function mutation, S140G-*KCNQ1*, in $K_v7.1$ (I_{Ks}) was identified, thus providing for the first time a causal link between a cardiac potassium ion channel mutation and FAF. Interestingly, a second de novo mutation involving codon 141 of *KCNQ1* was identified in a patient with a severe form of AF and SQTS presenting in utero.[85] An R27C mutation in *KCNE2,* which encodes for a $K_v7.1$ and $K_v11.1$ interacting protein, was discovered in two AF families and produced an I_{Ks} gain-of-function phenotype when coexpressed with wild-type *KCNQ1.* In 2005 a V93I mutation in *KCNJ2* in 1 of 30 unrelated Chinese AF families was identified. Whereas loss-of-function *KCNJ2* mutations yield ATS1, the AF-associated V93I mutation conferred gain-of-function biophysical properties to the Kir2.1 channels. Lastly, in 2006, a loss-of-function mutation in *KCNA5* responsible for the $K_v1.5$ potassium channel I_{Kur} was discovered in a family with AF.

Beside these potassium channels, $Na_v1.5$ has been implicated in lone and familial AF. In fact, AF is a fairly common arrhythmia among patients with loss-of-function *SCN5A*-opathies; in particular, up to 15% to 20% of BrS cases develop AF.[76] In 2008 a novel *SCN5A* mutation (M1875T) was described in a family characterized by juvenile-onset atrial arrhythmias that progressed to AF in the absence of structural heart disease or ventricular arrhythmias. Functional studies of this mutant channel produced an increased peak current density and a depolarizing shift of activation (gain of function). Additionally, Darbar[86] identified *SCN5A* channel mutations in approximately 3% of AF cases. In 2014, Hasegawa and colleagues[87] performed a mutational analysis of AF-related genes (*KCNQ1*, *KCNH2*, *KCNE1-3*, *KCNJ2*, and *SCN5*A) and identified three missense variants (*SCN5A*-M1875T, *KCNJ2*-M301K, and *KCNQ1*-G229D) in 3 of 30 (10%) consecutive patients with juvenile-onset AF.

Non–ion channel genes also have been implicated in familial and lone AF.[85] In 2008, Hodgson-Zingman and colleagues identified a frameshift mutation in the *NPPA* gene in a large pedigree with FAF.[88] *NPPA* encodes for the atrial natriuretic peptide, which modulates ionic currents in myocardial cells and may shorten atrial conduction time. The clinical phenotype of neonatal onset of AF, with an autosomal recessive inheritance pattern, was recently linked to a mutation in *NUP155*, which encodes for a member of the nucleoporins family of proteins. In 2006, Gollob and colleagues identified four heterozygote *GJA5* missense mutations in 4 of 15 patients with early-onset idiopathic AF.[89] Most interestingly, three of the four mutations were shown to be in cardiac tissue only (somatic) and not germline in origin. *GJA5* encodes for the cardiac gap-junction protein connexin 40, which is selectively expressed in atrial myocytes and mediates the finely orchestrated electrical activation of the atria. Most recently, Yang and colleagues[90,91] have identified either a *GATA4* (S70T and S160T) or *GATA5* (G184V, K218T, and A266P) missense mutation in 5 or 130 (3.8%) unrelated Han Chinese individuals with familial AF. *GATA4* and *GATA5* belong to a family of cardiac transcription factors critical for cardiogenesis.

Future Perspectives

The comparatively young discipline of the heritable arrhythmia syndromes and cardiac channelopathies has exploded over the past decade. The pathogenic insights into the molecular underpinnings for nearly all these syndromes have matured through the entire continuum of research from discovery, translation, and most recently, incorporation into clinical practice. This bench-to-bedside maturation now requires the learned interpretation of the available genetic tests for these syndromes, with a clear understanding of the diagnostic, prognostic, and therapeutic implications associated with genetic testing for these channelopathies.

The emergence of next-generation sequencing platforms and systems biology bioinformatics algorithms are providing new tools to efficiently interrogate an individual's entire genome or exome (entire amino acid–encoding region of the genome) in a single reaction. This highly proficient technology effectively provides a list of every single-nucleotide substitution and small insertion/deletion (common or rare, benign or pathogenic) for every gene in a patient's genome and is crucial to the current and next phase of new gene discovery. Current and forthcoming advanced sequencing technologies and systems biology bioinformatics algorithms will soon allow us to close the genetic gap in our understanding of these potentially lethal yet highly treatable cardiac arrhythmia syndromes. This will not only foster new disease-causing gene discovery, but also reveal novel genetic variants that may in part explain reduced penetrance and variable expressivity and help identify patients at greatest risk for a potentially tragic cardiac event. Continued exploration into the underlying genetic and molecular basis of these arrhythmia

syndromes will open the door for novel approaches to genotype-specific pharmacologic therapeutics.

In addition, recent advances in cellular programming have provided new avenues for understanding the etiology of complex diseases. The biomedical promise of human induced pluripotent stem (iPS) cell–generated cardiomyocytes, derived from a patient's own skin biopsy (fibroblast), venipuncture (lymphocytes), or urine sample, is enormous for cardiac research into disease models, personalized drug development, and key questions about the reduced penetrance and variable expressivity common among these cardiac channelopathies.

Despite that pharmacologic and invasive therapies for inherited cardiac arrhythmia disorders often achieve symptom reduction, there is still an urgent need for alternative therapeutics to effectively treat or even cure the most severe forms. With continued understanding of the genetic and molecular basis of these syndromes, as well as of “gene silencing” based on small interfering RNA (siRNA), microRNA (miRNA), and small hairpin RNA (shRNA), together with the development of novel RNA-guided nuclease-mediated CRISPER/Cas9 genome editing, sophisticated viral vectors such as adeno-associated virus 9 (AAV9), and novel gene delivery strategies, gene therapy may become a feasible option for some patients with difficult-to-manage, potentially life-threatening cardiac arrhythmias.[92]

Mechanisms of Cardiac Arrhythmias

Gordon F. Tomaselli, Michael Rubart, Douglas P. Zipes

Foundations of Cardiac Electrophysiology

Physiology of Ion Channels

Electrical signaling in the heart involves the passage of ions through ionic channels. The sodium, potassium, calcium, and chloride (Na^+, K^+, Ca^{2+}, and Cl^-) ions are the major charge carriers, and their movement across the cell membrane through channel pores creates a flow of current that generates excitation and signals in cardiac myocytes. Opening of ion channels allows selected ions to flow passively down the electrochemical activity gradient at a very high rate (>10^6 ions per second). The high transfer rates and restriction to “downhill” fluxes not stoichiometrically coupled to the hydrolysis of

energy-rich phosphates distinguish ionic channel mechanisms from those of other ion-transporting structures (pumps and exchangers), such as sarcolemmal Na^+,K^+–adenosine triphosphatase (ATPase), sarcoendoplasmic reticulum Ca^{2+}-ATPase (SERCA) or the Na^+/Ca^{2+} exchanger (NCX). Ion channels may be induced to open or close (gated) by extracellular and intracellular ligands, changes in transmembrane voltage, or mechanical stress (**Table 34.1**). Gating of single ion channels can best be studied by means of the patch-clamp technique.

TABLE 34.1

Synopsis of Transsarcolemmal Ionic Currents in Mammalian Cardiac Myocytes

CURRENT	SUBUNIT	FUNCTIONAL PROPERTIES
I_{Na}	Nav1.5, Nav1.1, Nav1.3, Nav1.6, Nav1.8 (alpha subunits)	TTX-resistant (Nav1.5, Nav1.8) and TTX-sensitive (Nav1.1, Nav1.3, Nav1.6) voltage-gated currents; Nav1.5 is the major cardiac isoform; neuronal Na^+ channel isoforms contribute to SA node pacemaking and ventricular repolarization
$I_{Ca.L}$	Cav1.2 (alpha subunit)	L-type (*l*ong lasting, *l*arge conductance) Ca^{2+} currents through voltage-gated Ca^{2+} (Cav) channels blocked by dihydropyridine antagonists (e.g., nifedipine), phenylalkylamines (e.g., verapamil), benzodiazepines (e.g., diltiazem), and various divalent ions (e.g., Cd^{2+}); activated by dihydropyridine agonists (e.g., Bay K 8644); responsible for phase 0 depolarization and propagation in SA and AV nodal tissue and contributing to the plateau of atrial, His-Purkinje, and ventricular cells; main trigger of Ca^{2+} release from the sarcoplasmic reticulum (Ca^{2+}-induced Ca^{2+} release); the noninactivating or "window" component underlies EADs
$I_{Ca.T}$	Cav3.1/alpha$_{1G}$ (alpha subunit)	T-type (*t*ransient current, *t*iny conductance) Ca^{2+} currents through Cav channels blocked by mibefradil and efonidipine but insensitive to dihydropyridines; may contribute an inward current to the later phase of phase 4 depolarization in pacemaker cells and action potential propagation in AV nodal cells; role in triggering Ca^{2+}-induced Ca^{2+} release uncertain
I_f	HCN4 (alpha subunit)	Hyperpolarization-activated "funny" current carried by Na^+ and K^+ in SA and AV nodal cells and His-Purkinje cells; involved in generating phase 4 depolarization; increases the rate of impulse initiation in pacemaker cells
I_{K1}	Kir2.1 (alpha subunit)	K^+ current through inwardly rectifying K^+ (Kir) channels, voltage-dependent block by Ba^{2+} at micromolar concentrations; responsible for maintaining resting the membrane potential in atrial, His-Purkinje, and ventricular cells; channel activity is a function of both membrane potential and $[K^+]_o$; inward rectification appears to result from depolarization-induced internal block by Mg^{2+} and neutral or positively charged amino acid residues in the cytoplasmic channel pore
$I_{K.G}$ ($I_{K.ACh}$, $I_{K.Ade}$)	Kir3.1/Kir3.4 (alpha subunit)	Inwardly rectifying K^+ current activated by muscarinic (M_2) and purinergic (type 1) receptor stimulation via GTP regulatory (G) protein signal transduction; expressed in SA and AV nodal cells and atrial cells, where it causes hyperpolarization and action potential shortening; activation causes negative chronotropic and dromotropic effects
I_{Ks}	KvLQT1 (alpha subunit)/minK (beta subunit)	K^+ current carried by a voltage-gated K^+ (Kv) channel (delayed rectifier K^+ channel); plays a major role in determining phase 3 of the action potential
I_{Kr}	hERG (alpha subunit)/MiRP1 (beta subunit)	Rapidly activating component of delayed rectifier K^+ current; I_{Kr} specifically blocked by dofetilide and sotalol in a reverse use–dependent manner; inward rectification of I_{Kr} results from depolarization-induced fast inactivation; plays a major role in determining the APD
I_{Kur}	Kv1.5 (alpha subunit)	K^+ current through a Kv channel with ultrarapid activation but ultraslow inactivation kinetics; expressed in atrial myocytes; determines the APD
$I_{K.Ca}$	SK2 (alpha subunit)	K^+ current through small-conductance Ca^{2+}-activated channels; blocked by apamin and expressed in human atrial and ventricular myocytes; determines the APD; upregulated in failing cardiomyocytes
I_{to} (I_{to1}, I_A)	Kv4.3 (alpha subunit)/KChIP2 (beta subunit)	Transient outward K^+ current through voltage-gated (Kv) channels; exhibits fast activation and inactivation and recovery kinetics; blocked by 4-aminopyridine in a reverse use–dependent manner; contributes to the time course of phase 1 repolarization; transmural differences in I_{to} properties contribute to regional differences in early repolarization
$I_{Cl.Ca}$ (I_{to2})	?	4-Aminopyridine–resistant transient outward current carried by Cl^- ions; activated by an increase in intracellular calcium level; blocked by stilbene derivatives (SITS, DIDS); contributes to the time course of phase 1 repolarization; may underlie spontaneous transient inward currents under conditions of Ca^{2+} overload; molecular correlate uncertain
$I_{Cl.cAMP}$	?	Time-independent chloride current regulated by the cAMP/adenylate cyclase pathway; slightly depolarizes resting membrane potential and significantly shortens the APD; antagonizes action potential prolongation associated with beta-adrenergic stimulation of $I_{Ca.L}$
$I_{Cl.swell}$ or $I_{Cl.vol}$	?	Outwardly rectifying, swelling-activated Cl^- current; inhibited by 9-anthracene carboxylic acid; activation causes resting membrane depolarization and action potential shortening
$I_{K.ATP}$	Kir6.2 (alpha subunit)/SUR	Time-independent K^+ current through Kir channels activated by a fall in intracellular ATP concentration; inhibited by sulfonylurea drugs, such as glibenclamide; activated by pinacidil, nicorandil, cromakalim; causes shortening of the APD during myocardial ischemia or hypoxia
$I_{Cir.swell}$	?	Inwardly rectifying, swelling-activated cation current; permeable to Na^+ and K^+; inhibited by Gd^{3+}; depolarizes resting membrane potential and prolongs terminal (phase 3) repolarization
$I_{Na/Ca}$	NCX1.1	Current carried by Na^+/Ca^{2+} exchanger; causes net Na^+ outward current and Ca^{2+} inward current (reverse mode) or net Na^+ inward and Ca^{2+} outward current (3 Na^+ for 1 Ca^{2+}); direction of Na^+ flux depends on membrane potential and intracellular and extracellular concentrations of Na^+ and Ca^{2+}; Ca^{2+} influx mediated by $I_{Na/Ca}$ can trigger SR Ca^{2+} release; underlies I_{ti} (transient inward current) under conditions of intracellular Ca^{2+} overload
$I_{Na/K}$	Alpha subunit/beta subunit	Na^+ outward current generated by Na^+,K^+-ATPase (stoichiometry: 3 Na^+ leave and 2 K^+ enter); inhibited by digitalis
I_{ti}	?	Transient inward current activated by Ca^{2+} waves; I_{ti} possibly reflects 3 Ca^{2+}-dependent components: I_{NCX}, $I_{Cl.Ca}$, and a *TRPM4* (transient receptor potential cation channel, member 4 gene)–mediated current
Electroneutral Ion-Exchanging Proteins		
Ca^{2+}-ATPase	SERCA2	Extrudes cytosolic calcium
Na/H	Cardiac myocytes express isoform NHE1	Exchanges intracellular H^+ for extracellular Na^+; specifically inhibited by the benzoylguanidine derivatives HOE 694 and HOE 642; inhibition causes intracellular acidification
Cl^--HCO_3^-		Exchanges intracellular HCO_3^- for external Cl^-; inhibited by SITS
Na^+-K^+-$2Cl^-$	Na-K-Cl NKCC1	Cotransporter blocked by amiloride

APD, Action potential duration; *AV,* atrioventricular; *DIDS,* 4,4′-diisothiocyanatostilbene-2,2′-disulfonic acid; *EADs,* early afterdepolarizations; *GTP,* guanosine triphosphate; *SA,* sinoatrial; *SITS,* 4-acetamido-4′-isothiocyanatostilbene-2,2′-disulfonic acid; *TTX,* tetrodotoxin.

The *permeability ratio* is a commonly used index of a channel's ionic selectivity, defined as the ratio of

the permeability of one ion type to that of the main permeant ion type. Permeability ratios of voltage-gated K^+ and Na^+ channels for monovalent and divalent (e.g., Ca^{2+}) cations are usually less than 1 : 10. Voltage-gated Ca^{2+} channels exhibit a more than 1000-fold discrimination against Na^+ and K^+ ions (e.g., P_K / P_{Ca} = 1/3000) and are impermeable to anions.

Because ions are charged, net ionic flux through an open channel is determined by both the concentration and the electrical gradients across the membrane (electrodiffusion). The potential at which the passive flux of ions resulting from the chemical driving force is exactly balanced by the electrical driving force is called the *equilibrium, reversal,* or *Nernst potential* of the channel. In a channel that is perfectly selective for one ion species, the reversal potential equals the thermodynamic equilibrium potential of that ion, E_S, which is given by the Nernst equation in the form:

$$E_S = (RT/zF) \ln([S_o]/[S_i])$$

where $[S_i]$ and $[S_o]$ are the intracellular and extracellular concentrations of the permeant ion, respectively, z is the valence of the ion, R is the gas constant, F is the Faraday constant, T is the temperature (kelvin), and ln is the natural logarithm. At membrane voltages more positive than the reversal potential of the channel, passive cation movement is outward, whereas it is inward at membrane potentials more negative than the Nernst potential of that channel. If the current through an open channel is carried by more than one permeant ion, the reversal potential becomes a weighted mean of all Nernst potentials.

Membrane voltages during a cardiac action potential vary over the range of approximately −90 to +30 mV (**eTable 34.1**). With physiologic external K^+ (4 mM), E_K is approximately −91 mV, and passive movement of K^+ during an action potential is out of the cell. On the other hand, because the calculated reversal potential of a cardiac Ca^{2+} channel is +64 mV (assuming that P_K/P_{Ca} = 1/3000, K_i = 150 mM, K_o = 4 mM, Ca_i = 100 nM, and Ca_o = 2 mM), passive Ca^{2+} flux is into the cell. With physiologic internal and external chloride concentrations, E_{Cl} is −83 to −36 mV, and passive movement of Cl^- ions through open chloride channels can be both inward and outward at membrane potentials typically occurring during a cardiac action potential. In more general terms, the direction and magnitude of passive ion flux through a single open channel at any given transmembrane voltage are governed by the reversal potential of that ion and its concentration gradient across the membrane.

ETABLE 34.1

Ion Concentrations and Reversal Potentials in Cardiac Muscle

ION	EXTRACELLULAR CONCENTRATION $[S]_o$ (mM)	INTRACELLULAR CONCENTRATION $[S]_i$ (mM)	RATIO $[S]_o/[S]_i$	E_S (mV)
Na^+	145	15	9.7	+60
K^+	4	150	0.027	−94
Cl^-	120	5-30	4-24	−83 to −36
Ca^{2+}	2	10^{-4}	2×10^4	+129

Ion Flux Through Voltage-Gated Channels.

Changes in transmembrane potential determine ion flux through voltage-gated channels, not only through

the voltage dependence of the electrochemical driving force on the permeant ion, but also through the voltage dependence of channel activation. The fraction of time that a channel is open and allows ionic flux is determined by the membrane voltage. Activation of cardiac Na^+ channels or voltage-dependent K^+ channels (see later discussions) increases with membrane depolarization. Note that channels do not have a sharp voltage threshold for opening. Rather, the dependence of channel activation on membrane potential is a continuous function of voltage and follows a sigmoidal curve (**Fig. 34.1A**, *blue curve*). The potential at which activation is half-maximal and the steepness of the activation curve determine the channel's activity during changes in membrane potential. Shifting the activation curve to potentials positive to the midpoint of activation and reducing the steepness of the channel's activation curve are two possible mechanisms by which ion channel blockers can inhibit ion channel activity.

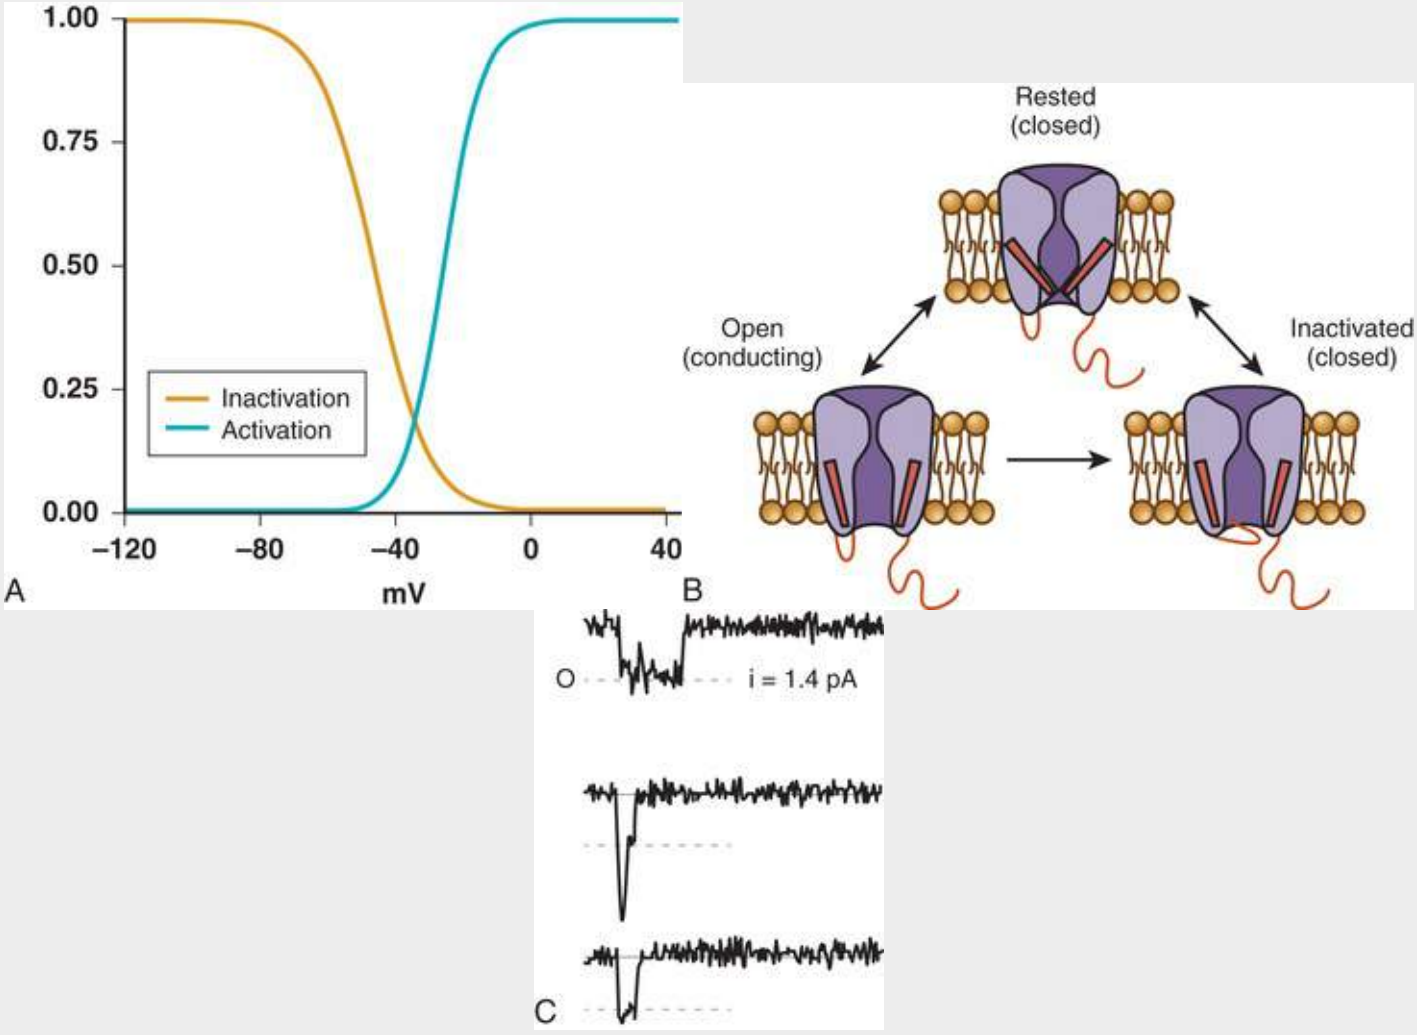

FIGURE 34.1 **A,** Curves that describe the voltage dependence of channel opening or the transition from the rested, closed to the open, conducting state (activation curve, *blue*) and channel availability (inactivation, *orange*). The inactivation or availability curve describes the voltage dependence of the occupancy of the inactivated state, and channels may transition to the inactivated state by way of the open or the rested, closed state. Generally, an inactivated channel must first return to the closed state in order to be available to open again. **B,** Schematic of the principal conformations of voltage-dependent channels. The position of the activation gate changes with the transition from closed to open, and the transition to the inactivated state is determined by the position of the inactivation gate. **C,** Single-channel current recordings showing the opening of sodium (Na) channels in response to a step change in voltage. The *middle tracing* reflects the activity of two channels, each with a single-channel amplitude of 1.4 pA.

As indicated in **Fig. 34.1B**, open channels enter a nonconducting conformation after a depolarizing change in membrane potential, a process termed *inactivation*. If membrane depolarization persists, the

channel remains inactivated and cannot reopen. This steady-state inactivation increases with membrane depolarization in a sigmoidal fashion (**see Fig. 34.1A**, *gold curve*). Inactivation curves of the various voltage-gated ion channels in the heart differ in their slopes and midpoints of inactivation. For example, sustained membrane depolarization to −50 mV (as may occur in acutely ischemic myocardium) causes almost complete inactivation of the fast voltage-gated Na^+ channel, whereas the L-type Ca^{2+} channel (see Voltage-Gated Ca^{2+} Channels) exhibits only little inactivation at this membrane potential. Activation and inactivation curves can overlap, in which case a steady-state or noninactivating current flows. The existence of such a "window" current has been verified for both the voltage-gated Na^+ and the L-type Ca^{2+} currents. The L-type Ca^{2+} current and the fast Na^+ window currents have been implicated in the genesis of triggered activity arising from early afterdepolarizations (EAD) and delayed afterdepolarizations (DAD).[1]

Channels recover from inactivation and then enter the closed state, from which they can be reactivated and open again (**see Fig. 34.1B**). Rates of recovery from inactivation vary among the different types of voltage-dependent channels and usually follow monoexponential or multiexponential time courses, with the longest time constants ranging from a few milliseconds, for example, as for the fast sodium current, to several seconds, as for some subtypes of K^+ currents. Together, the activity of voltage-dependent ion channels in cardiomyocytes over the course of an action potential is tightly regulated by the orchestrated interplay of a number of time- and voltage-dependent gating mechanisms, including activation, inactivation, and recovery from inactivation. All these mechanisms represent potential targets for pharmacologic intervention.

Principles of Ionic Current Modulation.

The whole-cell current amplitude I is the product of the number of functional channels in the membrane available for opening (N), the probability that a channel will open (P_o), and the single-channel current amplitude (i), or $I = N \cdot P_o \cdot i$. Modulation of current amplitudes in single cardiomyocytes therefore results from alterations in N, P_o, i, or any combination of these factors. Changes in the number of available channels in the cell membrane may result from alterations in the expression of ion channel–encoding genes. The magnitude of the single-channel current amplitude is dependent, among other factors, on the ionic concentration gradient across the membrane. Changes in channel activation (i.e., P_o) can result from phosphorylation or dephosphorylation of the channel protein. The channel's phosphorylation state may cause a shift in the membrane potential dependence of a channel's activation or availability curve, or both, or modification of the sensitivity of channel activation or inactivation to changes in membrane potential.

Phases of the Cardiac Action Potential

The cardiac transmembrane action potential consists of five phases: *phase 0,* upstroke or rapid depolarization; *phase 1,* early rapid repolarization; *phase 2,* plateau; *phase 3,* final rapid repolarization; and *phase 4,* resting membrane potential and diastolic depolarization (**Fig. 34.2 and eFig. 34.1**). These phases are the result of passive ion fluxes moving down their electrochemical gradients established by active ion pumps and exchange mechanisms. Each ion moves primarily through its own ion-specific channel. The following discussion explains the electrogenesis of each of these phases.

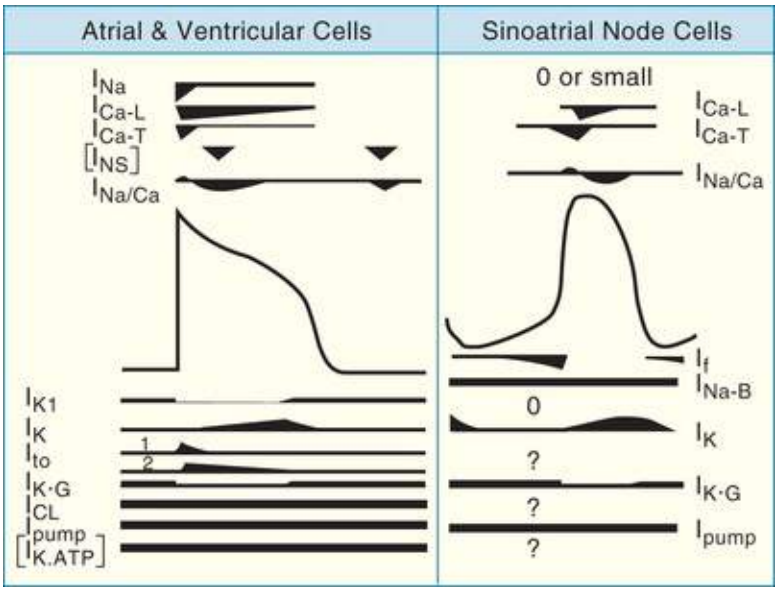

FIGURE 34.2 Currents and channels involved in generating resting membrane and action potentials. The time course of a stylized action potential of atrial and ventricular cells is shown on the **left,** and that of sinoatrial node (SAN) cells is on the **right.** Above and below are the various channels and pumps that contribute the currents underlying the electrical events. See **Table 34.1** for identification of the symbols and description of the channels or currents. Where possible, the approximate time courses of the currents associated with the channels or pumps are shown symbolically, without trying to represent their magnitudes relative to each other. I_K incorporates at least two currents, I_{Kr} and I_{Ks}. There appears to be an ultrarapid component as well, designated I_{Kur}. The *heavy bars* for I_{Cl}, I_{pump}, and $I_{K.ATP}$ indicate only the presence of these channels or pump, without implying magnitude of currents, because the magnitude would vary with physiologic and pathophysiologic conditions. The channels identified by *brackets* (I_{NS} and $I_{K.ATP}$) are active only under pathologic conditions. I_{NS} may represent a swelling-activated cation current. For the SAN cells, I_{NS} and I_{K1} are small or absent. *Question marks* indicate that experimental evidence is not yet available to determine the presence of these channels in SAN cell membranes. Although it is likely that other ionic current mechanisms exist, they are not shown here because their roles in electrogenesis are not sufficiently well defined. (From Members of the Sicilian Gambit. Antiarrhythmic Therapy: a Pathophysiologic Approach. Mount Kisco, NY: Futura; 1994, p 13.)

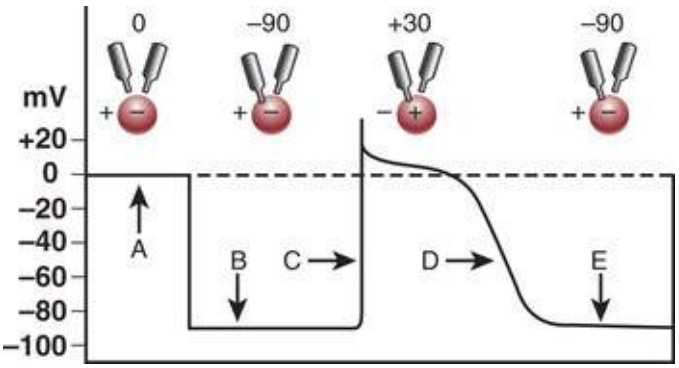

EFIGURE 34.1 Demonstration of action potentials recorded during impalement of a cardiac cell. **Upper row,** Shown are a cell (*circle*), two microelectrodes, and stages during impalement of the cell and its activation and recovery. Both microelectrodes are extracellular (*A*), and no difference in potential exists between them (0 potential). The environment inside the cell is negative, and the outside is positive, because the cell is polarized. One microelectrode has pierced the cell membrane (*B*) to record the intracellular resting membrane potential, which is −90 mV with respect to the outside of the cell. The cell has depolarized (*C*), and the upstroke of the action potential is recorded. At its peak voltage, the inside of the cell is approximately +30 mV with respect to the outside of the cell. The repolarization phase (*D*) is shown, with the membrane returning to its former resting potential (*E*).

General Considerations.

Ionic fluxes regulate membrane potential in cardiac myocytes in the following fashion. When only one type of ion channel opens, assuming that this channel is perfectly selective for that ion, the membrane potential of the entire cell would equal the Nernst potential of the permeant ion. By solving the Nernst equation for the four major ions across the plasma membrane, the following equilibrium potentials are obtained: sodium, +60 mV; potassium, −94 mV; calcium, +129 mV; and chloride, −83 to −36 mV (**Table 34.2**). Therefore, if K^+-selective channels open, such as the inwardly rectifying K^+ (Kir) channel (see later), the membrane potential approaches E_K (−94 mV). If Na^+-selective channels open, the transmembrane potential becomes E_{Na} (+60 mV). A quiescent cardiac myocyte (phase 4) has many more open potassium than sodium channels, and the cell's transmembrane potential is close to E_K. When two or more types of ion channels open simultaneously, each channel moves the membrane potential to the equilibrium potential of their respective permeant ions. The contribution of each ion type to the overall membrane potential at any given moment is determined by the instantaneous permeability of the plasma membrane to that ion. For example, deviation of the measured resting membrane potential from E_K (**see Table 34.2**) would predict that other ion types with equilibrium potentials positive to E_K are contributing to the resting membrane potential in cardiac myocytes. If it is assumed that Na^+, K^+, and Cl^- are the permeant ions at resting potential, their individual contributions to the resting membrane potential (V) can be quantified by the Goldman-Hodgkin-Katz (GHK) voltage equation:

TABLE 34.2

Properties of Transmembrane Potentials in Heart Cells

PROPERTY	SA NODAL CELL	ATRIAL MYOCYTE	AV NODAL CELL	HIS PURKINJE CELL	VENTRICULAR MYOCYTE
Resting potential (mV)	−50 to −60	−80 to −90	−60 to −70	−90 to −95	−80 to −90
Action Potential Features					
Amplitude (mV)	60-70	110-120	70-80	120	110-120
Overshoot (mV)	0-10	30	5-15	30	30
Duration (msec)	100-300	100-300	100-300	300-500	200-300
Vmax (V/sec)	1-10	100-200	5-15	500-700	100-200
Propagation velocity (m/sec)	<0.05	0.3-0.4	0.1	2-3	0.3-0.4
Fiber diameter (μm)	5-10	10-15	1-10	100	10-15

AV, Atrioventricular; *SA,* sinoatrial; *Vmax,* maximal rise of membrane potential.

Modified from Sperelakis N. Origin of the cardiac resting potential. In Berne RM, Sperelakis N, Geiger SR, editors. Handbook of Physiology: The Cardiovascular System. Bethesda, Md: American Physiological Society; 1979, p 190.

$$V = (RT/F)\ln[(P_K[Na]_o + P_{Cl}[Cl]_i)/P_K[K]_i + P_{Na}[Na]_P_c[Cl]_o$$

where the symbols have the meanings outlined previously. With only one permeant ion, V approximates the Nernst potential for that ion. With several permeant ion types, V is a weighted mean of all the Nernst potentials.

Resting Membrane Potential.

The intracellular potential during electrical quiescence in diastole is −50 to −95 mV, depending on the type of cell (**Table 34.2**). Therefore the inside of the cell is 50 to 95 mV negative relative to the outside of the cell because of the transmembrane gradients of ions such as K^+, Na^+, and Cl^-.

Because cardiac myocytes have an abundance of open K^+ channels at rest, the cardiac transmembrane potential (in phase 4) is close to $E_{K.}$ Outward potassium current through open, inwardly rectifying K^+ channels (I_{K1}) under normal conditions contributes to the resting membrane potential mainly in atrial and ventricular myocytes, as well as in Purkinje cells. Deviation of the resting membrane potential from E_K is the result of movement of ions with an equilibrium potential greater than the E_K, for example, Cl^- efflux through activated chloride channels, such as $I_{Cl.cAMP}$, $I_{Cl.Ca}$, and $I_{Cl.swell}$. Calcium does not contribute directly to the resting membrane potential, but changes in intracellular free calcium concentration $[Ca^{2+}]_i$ can affect other membrane conductance values. For example, an increase in sarcoplasmic reticulum (SR) Ca^{2+} load can cause spontaneous intracellular Ca^{2+} waves, which in turn activate the Ca^{2+} -dependent chloride conductance $I_{Cl.Ca}$ and thereby lead to spontaneous transient inward currents and concomitant membrane depolarization. Increases in $[Ca^{2+}]_i$ can also stimulate the Na^+/Ca^{2+} exchanger $I_{Na/Ca}$. This protein exchanges three Na^+ ions for one Ca^{2+} ion and thus generates a current; the direction depends on the $[Na^+]$ and $[Ca^{2+}]$ on the two sides of the membrane and the transmembrane potential difference (see Electrogenic Transporters). At the resting membrane potential and during a spontaneous SR Ca^{2+}-release event, this exchanger would generate a net Na^+ influx, possibly causing transient membrane depolarization.[2] Another transporter, the Na-K pump, electrogenically pumps Na^+ out of the cell and simultaneously pumps K^+ into the cell (three Na^+ outward and two K^+ inward) against their respective chemical gradients, keeping the intracellular K^+ concentration high and the intracellular Na^+ concentration low. The rate of Na^+-K^+ pumping to maintain the same ionic gradients must increase as the heart rate increases because the cell gains a small amount of Na^+ and loses a small amount of K^+ with each depolarization. Cardiac glycoside block of Na^+,K^+-ATPase increases contractility through an increase in intracellular Na^+ concentration $[Na^+]_i$, which in turn reduces Ca^{2+} extrusion through the Na^+/Ca^{2+} exchanger and thereby increases myocyte contractility.[3]

Phase 0: Upstroke or Rapid Depolarization.

A stimulus delivered to excitable tissues can evoke an action potential characterized by a sudden change in voltage caused by transient depolarization followed by repolarization. The action potential is conducted throughout the heart and is responsible for initiating each heartbeat. Electrical changes in the action potential follow a relatively fixed time and voltage relationship that differs according to specific cell types (**Fig. 34.3**). In neurons, the entire process takes several milliseconds, whereas action potentials in human cardiac fibers last several hundred milliseconds. Normally, the action potential is independent of the size of the depolarizing stimulus if the latter exceeds a certain threshold potential. Small, subthreshold depolarizing stimuli depolarize the membrane in proportion to the strength of the stimulus. However, when the stimulus is sufficiently intense to reduce membrane potential to a threshold value in the range of −70 to −65 mV for normal Purkinje fibers, an “all-or-none” response results. More intense depolarizing stimuli do not produce larger action potential responses; in contrast, hyperpolarizing pulses, or stimuli that render the membrane potential more negative, elicit a response proportional to the strength of the stimulus.

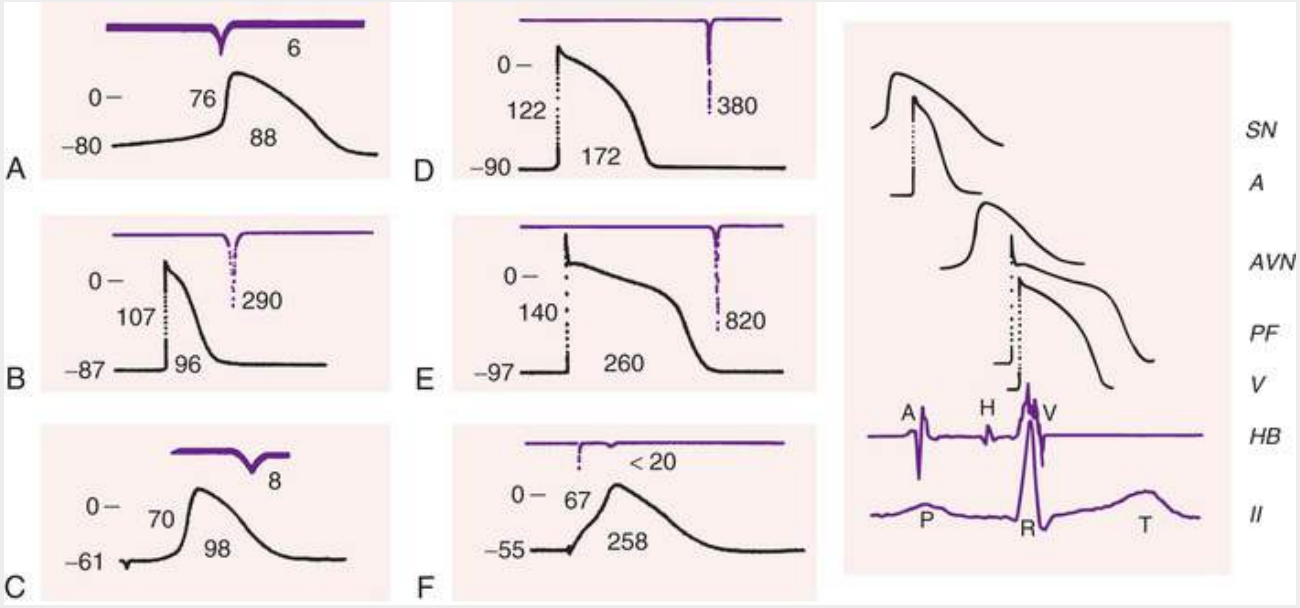

FIGURE 34.3 Action potentials recorded from different tissues in the heart **(left)** remounted along with a His bundle recording and scalar electrocardiogram from a patient **(right)** to illustrate the timing during a single cardiac cycle. In panels **A** to **F,** the top tracing is dV/dt of phase 0, and the second tracing is the action potential. For each panel, the numbers (from *left to right*) indicate maximum diastolic potential (mV), action potential amplitude (mV), action potential duration at 90% of repolarization (milliseconds), and rate of depolarization of phase 0 (V/sec). Zero potential is indicated by the *short horizontal line* next to the zero on the upper left of each action potential. **A,** Rabbit sinoatrial node. **B,** Canine atrial muscle. **C,** Rabbit AV node. **D,** Canine ventricular muscle. **E,** Canine Purkinje fiber. **F,** Diseased human ventricle. Note that the action potentials recorded in **A, C,** and **F** have reduced resting membrane potentials and amplitudes relative to the other action potentials. In the right panel, *A,* Atrial muscle potential; *AVN,* atrioventricular nodal potential; *HB,* His bundle recording; *II,* lead II; *PF,* Purkinje fiber potential; *SN,* sinus nodal potential; *V,* ventricular muscle potential. Horizontal calibration on the left: 50 milliseconds for **A** and **C,** 100 milliseconds for **B, D, E,** and **F;** 200 milliseconds on the right. Vertical calibration on the left: 50 mV; horizontal calibration on the right: 200 milliseconds. (Modified from Gilmour RF Jr, Zipes DP. Basic electrophysiology of the slow inward current. In Antman E, Stone PH, editors. Calcium Blocking Agents in the Treatment of Cardiovascular Disorders. Mount Kisco, NY: Futura; 1983, pp 1-37.)

Mechanism of Phase 0.

The upstroke of the cardiac action potential in atrial and ventricular muscle and His-Purkinje fibers is the result of a sudden increase in membrane conductance of Na^+. An externally applied stimulus or a spontaneously generated local membrane circuit current in advance of a propagating action potential depolarizes a sufficiently large area of membrane at an adequately rapid rate to open the Na^+ channels and depolarize the membrane further. When the stimulus activates enough Na^+ channels, Na^+ ions enter the cell down their electrochemical gradient. The excited membrane no longer behaves like a K^+ electrode, that is, exclusively permeable to K^+, but more closely approximates an Na^+ electrode, and the membrane voltage moves toward the Na^+ equilibrium potential (+60 mV).

The rate at which depolarization occurs during phase 0, that is, the maximum rate of change in voltage over time, is indicated by the expression dV/dt_{max} or Vmax (**see Table 34.2**), which is an approximation of the rate and magnitude of Na^+ entry into the cell and a determinant of conduction velocity for the propagated action potential. The transient increase in sodium conductance lasts 1 to 2 milliseconds. The action potential, or more properly the Na^+ current (I_{Na}), is said to be regenerative; that is, intracellular movement of a little Na^+ depolarizes the membrane more, which increases conductance of Na^+ more and allows more Na^+ to enter, and so on. As this process is occurring, however, $[Na^+]_i$ and positive intracellular charges increase and reduce the driving force for Na^+ flux into the cell. When the equilibrium potential for Na^+ (E_{Na}) is reached, the driving force acting on the ion to enter the cell

balances the driving force acting on the ion to exit the cell, and no current flows. Importantly, Na^+ conductance is time dependent, so when the membrane spends some time at voltages less negative than the resting potential, Na^+ conductance decreases (inactivation). Therefore an intervention that reduces membrane potential for a time (acute myocardial ischemia), but not to threshold, partially inactivates Na^+ channels, and if the threshold is now achieved, the magnitude and rate of Na^+ influx are reduced, which causes conduction velocity to slow.

In cardiac Purkinje fibers, sinoatrial cells, and to a lesser extent, ventricular muscle, different populations of Na^+ channels exist: the tetrodotoxin (TTX)-sensitive, neuronal Na^+ channel isoforms and the TTX-resistant Nav1.5 isoform, the latter being the predominant isoform in cardiac muscle.[4] Although the precise roles of TTX-sensitive Na^+ channels in ventricular or atrial cardiomyocytes have not been defined, these channels may be important modulators of sinoatrial node pacemaking, Purkinje myocyte action potential duration, and in arrhythmia production in some situations.[5] Neuronal Nav channels in the heart have been identified as regulators of contractility.[6]

Normal atrial and ventricular muscle cells and fibers in the His-Purkinje system exhibit action potentials with very rapid, large-amplitude upstrokes called *fast responses*. Action potentials in the normal sinoatrial (SA) and atrioventricular (AV) nodes and many types of diseased tissue have very slow, reduced-amplitude upstrokes and are called *slow responses* (**see Table 34.1 and Figs. 34.2 and 34.3**). Upstrokes of slow responses are mediated by a slow inward, predominantly L-type voltage-gated (Cav) Ca^{2+} current ($I_{Ca.L}$) rather than by the fast inward I_{Na} and are referred to as *slow response potentials* because the time required for activation and inactivation of $I_{Ca.L}$ is approximately an order of magnitude slower than that for the fast I_{Na}. The recovery of slow responses is delayed because of slow recovery of $I_{Ca,L}$ from inactivation. Recovery of $I_{Ca,L}$ slow-response channel requires establishment of the maximal diastolic potential (i.e., is voltage dependent) and more time before the channel can be activated again (i.e., time dependent), a phenomenon termed *postrepolarization refractoriness*. Moreover, calcium entry and $[Ca^{2+}]_i$ promote inactivation and delay recovery of slow-response channels.

The prolonged time for reactivation of $I_{Ca.L}$ probably accounts for the fact that SA and AV nodal cells remain refractory longer than the time that it takes for full voltage repolarization to occur. Thus, premature stimulation immediately after the membrane potential reaches full repolarization leads to action potentials with reduced amplitudes and upstroke velocities. Therefore, slow conduction and prolonged refractoriness are characteristic features of nodal cells. These cells also have a reduced "safety factor for conduction," which means that the stimulating efficacy of the propagating impulse is low, and conduction block occurs easily. The electrophysiologic changes accompanying acute myocardial ischemia may represent a depressed form of a fast response in the center of the ischemic zone and a slow response in the border area.

The threshold for activation of $I_{Ca.L}$ is about −30 to −40 mV. In fibers of the fast-response type, $I_{Ca.L}$ is normally activated during phase 0 by the regenerative depolarization caused by the fast I_{Na}. Current flows through both fast and slow channels during the latter part of the action potential upstroke. However, $I_{Ca.L}$ is much smaller than the peak I_{Na} and therefore contributes little to the action potential until the fast I_{Na} is inactivated after completion of phase 0. Thus, $I_{Ca.L}$ affects mainly the plateau of action potentials recorded in atrial and ventricular muscle and His-Purkinje fibers. In addition, $I_{Ca.L}$ may play a prominent role in partially depolarized cells in which fast I_{Na} has been inactivated, if conditions are appropriate for slow-channel activation.

Ca^{2+} entry through activated L-type Cav channels triggers release of Ca^{2+} from SR stores and is an

essential component of cardiac excitation-contraction coupling in atrial and ventricular myocardium (**see Chapter 22**). L-type Cav channels are expressed in SA and AV nodal cells, where they play a role in controlling automaticity and action potential propagation, respectively. Although T-type Cav channels have not been detected in human myocardium, experimental evidence in animals has suggested that these channels play an important role in determining SA node automaticity and AV nodal conduction.[7]

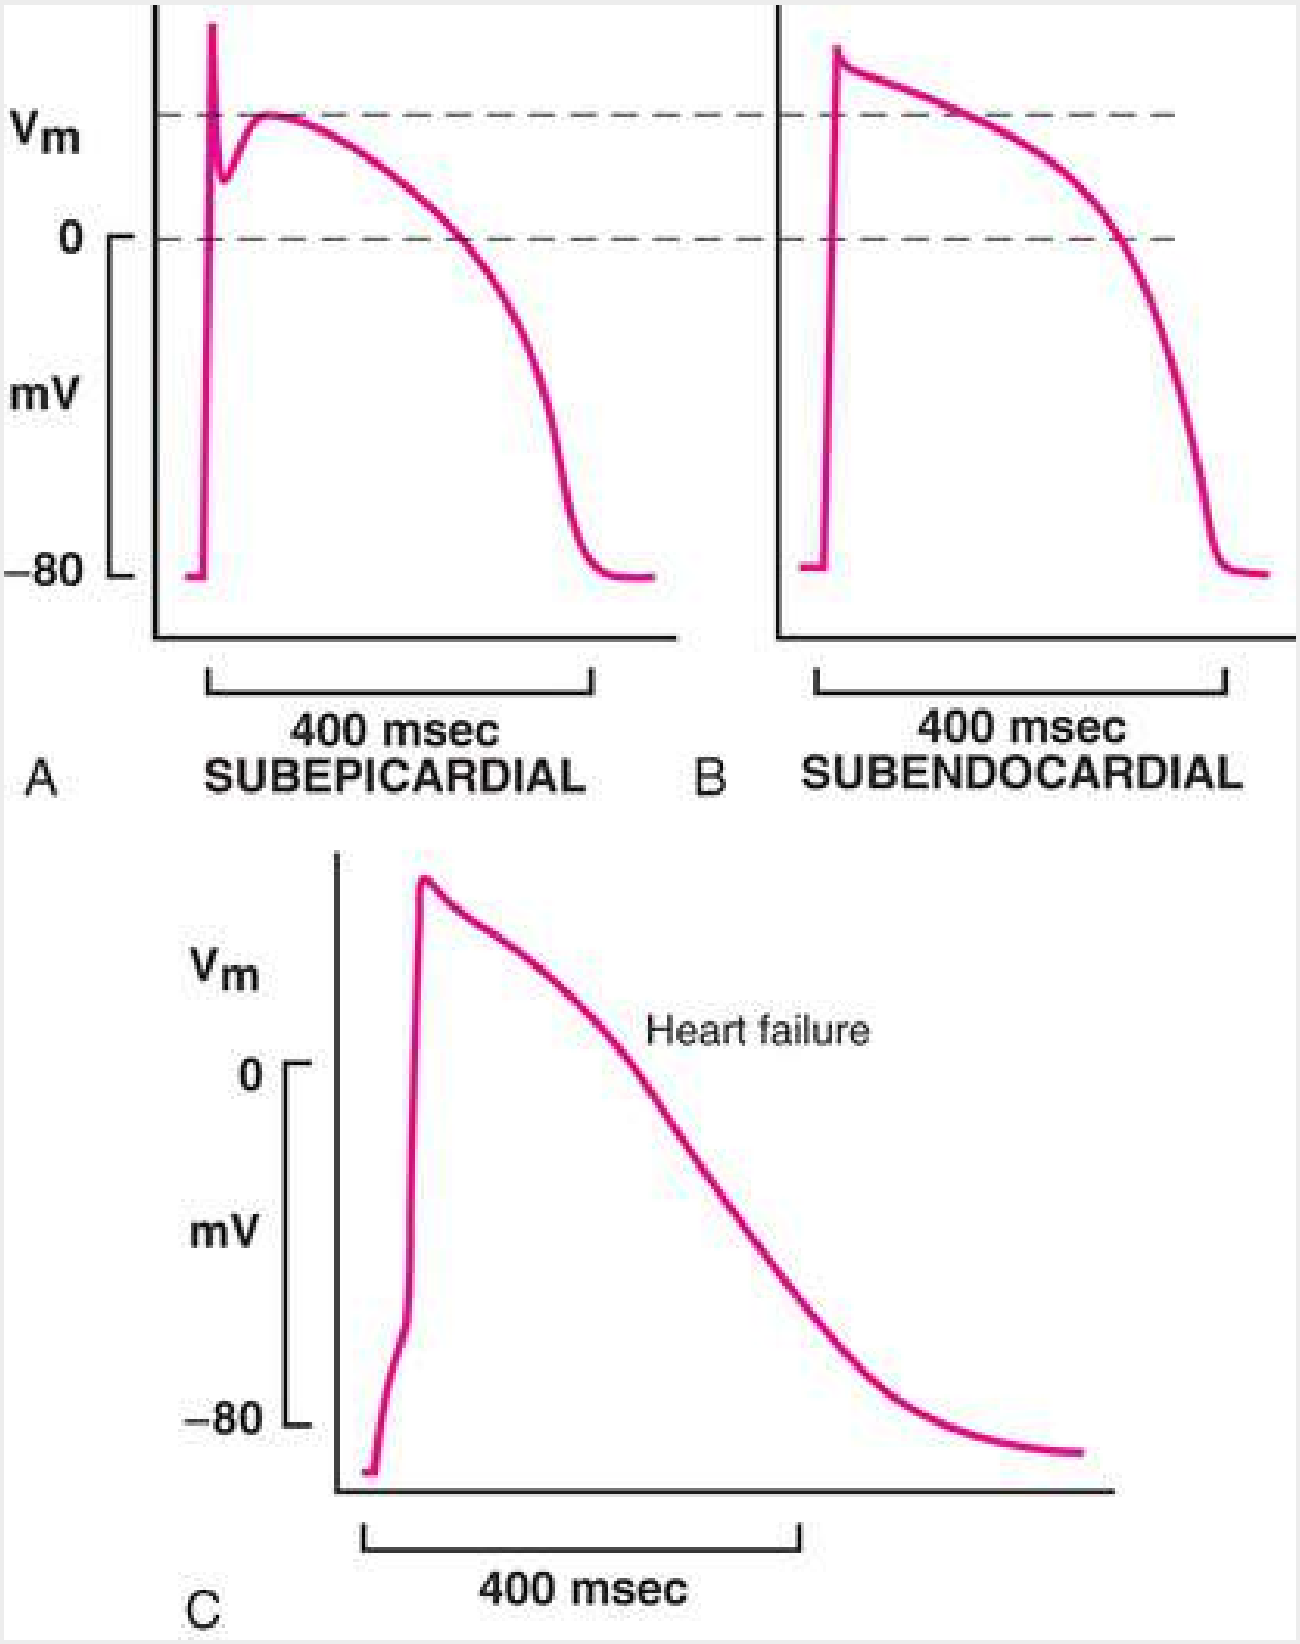
Other significant differences exist between the fast and slow channels. Drugs that elevate cyclic adenosine monophosphate (cAMP) levels, such as beta-adrenoceptor agonists, phosphodiesterase inhibitors such as theophylline, and the lipid-soluble derivative of cAMP, dibutyryl cAMP, increase $I_{Ca.L}$. Although Nav channels are sensitive to increases in cAMP, the net effect (decrease versus increase) appears to be species and condition dependent. Acetylcholine reduces $I_{Ca.L}$ by decreasing adenylate cyclase activity. However, acetylcholine stimulates the accumulation of cyclic guanosine monophosphate (cGMP). cGMP has negligible effects on basal $I_{Ca.L}$ but decreases the $I_{Ca.L}$ levels that have been elevated by beta-adrenoceptor agonists. This effect is mediated by cAMP hydrolysis through a cGMP-stimulated cyclic nucleotide phosphodiesterase.

Fast and slow channels can be differentiated on the basis of their pharmacologic sensitivity. Calcium channel antagonists that block the slow channel with a fair degree of specificity include verapamil, nifedipine, diltiazem, and D-600 (a methoxy derivative of verapamil). Antiarrhythmic agents such as lidocaine, quinidine, procainamide, and disopyramide affect the fast channel and not the slow channel (**see Chapter 36**).

Phase 1: Early Rapid Repolarization.

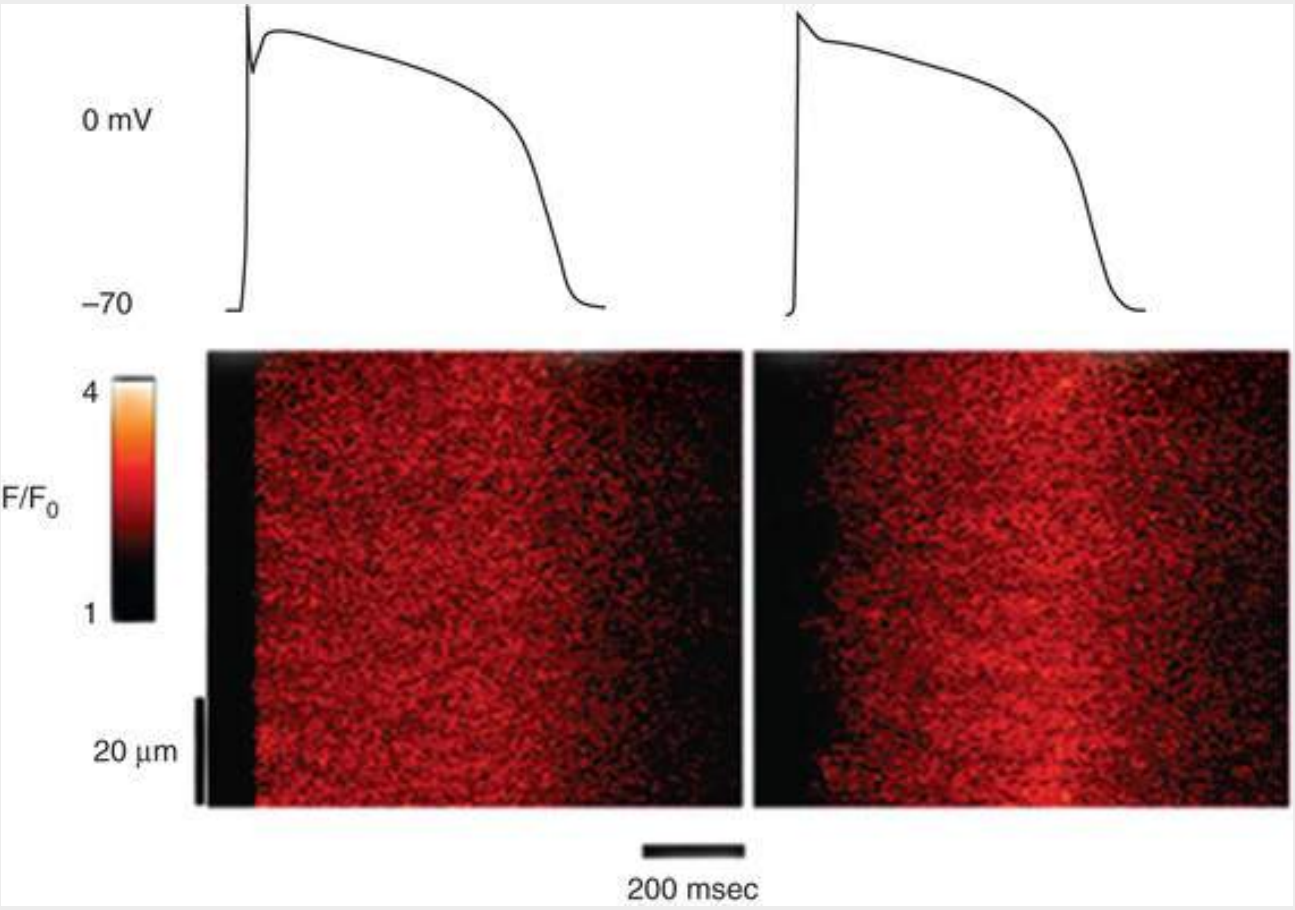
Following phase 0, the membrane repolarizes rapidly and transiently to almost 0 mV (early notch), partly because of inactivation of I_{Na} and concomitant activation of several outward currents.

The 4-aminopyridine–sensitive transient outward K^+ current, commonly termed I_{to} (or I_{to1}), is turned on rapidly by depolarization and then rapidly inactivates. Both the density and the recovery of I_{to} from inactivation exhibit transmural gradients in the left and right ventricular free wall, with the density decreasing and reactivation becoming progressively prolonged from epicardium to endocardium. Transmural differences in the expression of KChIP2, the auxiliary subunit to Kv4.3 pore-forming alpha subunits, may also contribute to the transmural gradient in I_{to} properties and densities in the human heart.[8] This gradient gives rise to regional differences in action potential shape, with increasingly slower phase 1 restitution kinetics and diminution of the notch along the transmural axis (**eFig. 34.2**).



EFIGURE 34.2 Action potential recordings demonstrating differences in the action potential shape of human ventricular myocytes of subepicardial **(A)** and subendocardial **(B)** origin. Subepicardial myocytes present a prominent notch during phase 1 repolarization of the action potential, most likely caused by a larger I_{to} in these cells. The notch is absent in subendocardial cells. The peak plateau potential is higher in subendocardial than in subepicardial myocytes, and the action potential duration tends to be shorter in subepicardial cells. **C,** Transmembrane action potential in a human ventricular cardiomyocyte from a failing heart. Note loss of the prominent phase 1 notch and delayed repolarization. Recording temperature = 35°C; $V_{m,}$ membrane potential. (**A, B,** From Näbauer M et al. Regional differences in current density and rate-dependent properties of the transient outward current in subepicardial and subendocardial myocytes of human left ventricle. Circulation 1996;93:168; **C,** from Priebe L, Beuckelmann DJ. Simulation studies of cellular electrical properties in heart failure. Circ Res 1998;82:1206.)

These regional differences might create transmural voltage gradients, thereby increasing dispersion of repolarization, a putative arrhythmogenic factor (Brugada syndrome; **see Chapters 33 and 39**). However, elimination of the physiologic repolarization gradient appears to be similarly arrhythmogenic. Downregulation of I_{to} is at least partially responsible for slowing of phase 1 repolarization in failing human myocytes. Studies have demonstrated that these changes in the phase 1 notch of the cardiac action potential cause a reduction in the kinetics and peak amplitude of the action potential–evoked intracellular Ca^{2+} transient because of failed recruitment and synchronization of SR Ca^{2+} release through $I_{Ca.L}$ (**eFig. 34.3**). Thus, modulation of I_{to} appears to play a significant physiologic role in controlling cardiac excitation-contraction coupling, and it remains to be determined whether transmural differences in phase 1 repolarization translate into similar differences in regional contractility.



EFIGURE 34.3 Diminution of phase 1 amplitude ("notch") causes asynchronous sarcoplasmic reticulum (SR) Ca^{2+} release. Normal cardiomyocytes were voltage-clamped, with action potential profiles having a normal or heart failure wave shape **(top),** and local changes in intracellular calcium were recorded simultaneously. When the myocyte was clamped with a normal action potential profile having the early phase 1 repolarization notch **(left),** there was uniform Ca^{2+} release, reflected in the rapid and synchronous increase in fluorescence. However, when a congestive heart failure action potential profile without early rapid phase 1 repolarization was used **(right),** Ca^{2+} release was dyssynchronous. This dyssynchrony causes slowing in the rate of rise of the Ca^{2+} transient and loss of spatial and temporal release uniformity. F/F_0, Fluorescence of the Ca^{2+} indicator normalized to its baseline fluorescence. (From Harris DM et al. Alterations in early action potential repolarization causes localized failure of sarcoplasmic reticulum Ca^{2+} release. Circ Res 2005;96:543. By permission of the American Heart Association.)

The 4-aminopyridine–resistant, Ca^{2+} -activated chloride current $I_{Cl.Ca}$ (or I_{to2}) also contributes a significant outward current during phase 1 repolarization.[1] This current is activated by the action potential–evoked intracellular Ca^{2+} transient. Therefore, interventions that augment the amplitude of the

Ca^{2+} transient associated with the twitch (e.g., beta-adrenergic receptor stimulation) also enhance outward $I_{Cl.Ca}$. It is not currently known whether human cardiac myocytes express Ca^{2+}-activated chloride channels. Other, time-independent chloride currents may also play a role in determining the time course of early repolarization, such as the cAMP- or swelling-activated chloride conductances $I_{Cl.cAMP}$ and $I_{Cl.swell}$.

A third current contributing to early repolarization is outward Na^+ movement through the Na^+/Ca^{2+} exchanger operating in reverse mode. Sometimes, a transient depolarization follows phase 1 repolarization altering the initial voltage of the plateau (**see eFig. 34.2**).

Phase 2: Plateau.

During the plateau phase, which may last several hundred milliseconds, membrane conductance of all ions falls to rather low values; this is a time of high membrane resistance. Less change in current is required near plateau voltages than near resting potential levels to produce the same changes in transmembrane potential. The plateau is maintained by competition between the outward current carried by K^+ and Cl^- ions and the inward current carried by Ca^{2+} moving through $I_{Ca,L}$ and Na^+ being exchanged for internal Ca^{2+} by the Na^+/Ca^{2+} exchanger operating in forward mode. After depolarization, I_{K1} conductance falls to plateau levels as a result of inward rectification, despite the large electrochemical driving force on K^+ ions.

Several potassium currents are activated during the plateau phase, including the rapid (I_{Kr}) and slow (I_{Ks}) delayed rectifier currents (see Voltage-Gated K^+ Channels). The mechanism underlying rectification of the rapid component of the delayed rectifier K^+ current (I_{Kr}) in cardiac cells is rapid inactivation that occurs during depolarizing pulses. More I_{Kr} channels enter the inactivated state with stronger depolarizations, thereby causing inward rectification. This fast inactivation mechanism is sensitive to changes in extracellular K^+ in the physiologic range, with inactivation being more accentuated at low extracellular K^+ concentrations. Thus, hypokalemia would decrease outward I_{Kr}, thereby prolonging the action potential duration (APD).

Outward K^+ movement carried by I_{Ks} also contributes to plateau duration. Mutations in the *KvLQT1* subunit, which in combination with the I_{Ks} ancillary subunit (*KCNE1* encoding minK) reconstitutes the cardiac I_{Ks} current, are associated with abnormally prolonged ventricular repolarization (LQTS type 1; **see Chapters 33 and 39**). Although I_{Ks} activates slowly compared to the APD, it is only slowly inactivated. Therefore, increases in heart rate can cause this activation to accumulate during successive depolarizations, increasing K^+ currents that are active during the plateau of the action potential and thus shortening the APD appropriately at higher heart rates.

In conditions of reduced intracellular adenosine triphosphate (ATP) concentration (e.g., hypoxia, ischemia), K^+ efflux through activated K_{ATP} channels is enhanced, thereby shortening the plateau phase of the action potential. Other ionic mechanisms that control plateau potential and duration include the kinetics of inactivation of the L-type Ca^{2+} current. Reduced efficiency of intracellular free Ca^{2+} in inducing Ca^{2+}-dependent inactivation, such as in myocytes from hypertrophic hearts, can result in delayed repolarization. Steady-state components of both I_{Na} and $I_{Ca.L}$ (window currents) also shape the plateau phase. Na^+,K^+ -ATPase generates a net outward current by electrogenic ion exchange. Noninactivating chloride currents, such as $I_{Cl.swell}$ and $I_{Cl.cAMP}$, may produce significant outward currents during the plateau phase under certain conditions, thereby significantly shortening the APD. A nonselective, swelling-induced cation current has been shown to cause prolongation of action potentials in myocytes from failing ventricles.[1]

Phase 3: Final Rapid Repolarization.
Repolarization of the terminal portion of the action potential proceeds rapidly in part because of two currents: time-dependent inactivation of I_{CaL}, with a decrease in the intracellular movement of positive charges, and activation of repolarizing K^+ currents, including I_{Ks} and I_{Kr} and the inwardly rectifying K^+ currents I_{K1} and I_{KACh}, which all cause an increase in the movement of positive charges out of the cell. The net membrane current becomes more outward, and the membrane potential moves to the resting potential. A small-conductance Ca^{2+} -activated K^+ current, I_{KCa}, expressed in human atrial myocytes, controls the time course of phase 3 repolarization.[9]

Loss-of-function mutations in the human ether-a-go-go–related or hERG gene (*KCNH2*), which encodes the pore-forming subunit of I_{Kr}, prolong phase 3 repolarization, thereby predisposing to the development of torsades de pointes. Macrolide antibiotics such as erythromycin, antihistamines such as terfenadine, several neurologically active agents, and antifungal drugs such as ketoconazole inhibit I_{Kr} and have been implicated in acquired forms of LQTS (**see Chapters 33 and 39**). Similarly, mutations in *KVLQT1*, which encodes the pore-forming subunit of I_{Ks}, will prolong repolarization and predispose to lethal ventricular arrhythmias. A decrease in I_{K1} activity, as is the case in left ventricular myocytes from failing hearts, causes prolongation of the action potential by slowing of phase 3 repolarization and resting membrane depolarization. A reduction in the outward potassium current through open inwardly rectifying K^+ channels renders the failing cardiomyocyte more susceptible to the induction of delayed afterdepolarizations triggered by spontaneous intracellular Ca^{2+}-release events and therefore plays a major role in arrhythmogenesis in the failing heart.[1]

Phase 4: Diastolic Depolarization.
Under normal conditions, the membrane potential of atrial and ventricular muscle cells remains steady throughout diastole. I_{K1} is the current responsible for maintaining the resting potential near the K^+ equilibrium potential and shuts off during depolarization in atrial, His-Purkinje, and ventricular cells. In other fibers found in certain parts of the atria, in the muscle of the mitral and tricuspid valves, in His-Purkinje fibers, and in the SA node and portions of the AV nodal tract, the resting membrane potential does not remain constant in diastole but gradually depolarizes (**see Figs. 34.2 and 34.3**). The property possessed by spontaneously discharging cells is called phase 4 diastolic depolarization, which leads to initiation of action potentials resulting in automaticity. The discharge rate of the SA node normally exceeds the discharge rate of other potentially automatic pacemaker sites and thus maintains dominance of the cardiac rhythm. The discharge rate of the SA node is usually more sensitive than the discharge rate of other pacemaker sites to the effects of norepinephrine and acetylcholine. Normal or abnormal automaticity at other sites can cause discharge at rates faster than the SA nodal discharge rate and can thus usurp control of the cardiac rhythm for one cycle or many (**see Chapter 35**).

Normal Automaticity

Two models of sinoatrial node pacemaking have been proposed. In the first model, HCN channels (see Cardiac Pacemaker Channels and **Table 34.1**) are activated by hyperpolarizations in the normal range of diastolic membrane potentials. During the hyperpolarized diastolic interval between consecutive action potentials, the probability of HCN channels being open increases. Open HCN channels conduct both Na^+ and K^+, but at these negative membrane potentials, Na^+ entry predominates. It is this inward Na^+ current through HCN channels (together with inflow of Ca^{2+} through voltage-activated Ca^{2+} channels, inward currents through Na^+/Ca^{2+} exchangers, and decaying outward K^+ currents; **see Fig. 34.4**) at diastolic

membrane potentials that is thought to depolarize the pacemaker cells to threshold and thus trigger the next action potential and generate a periodically firing pacemaker.[1]

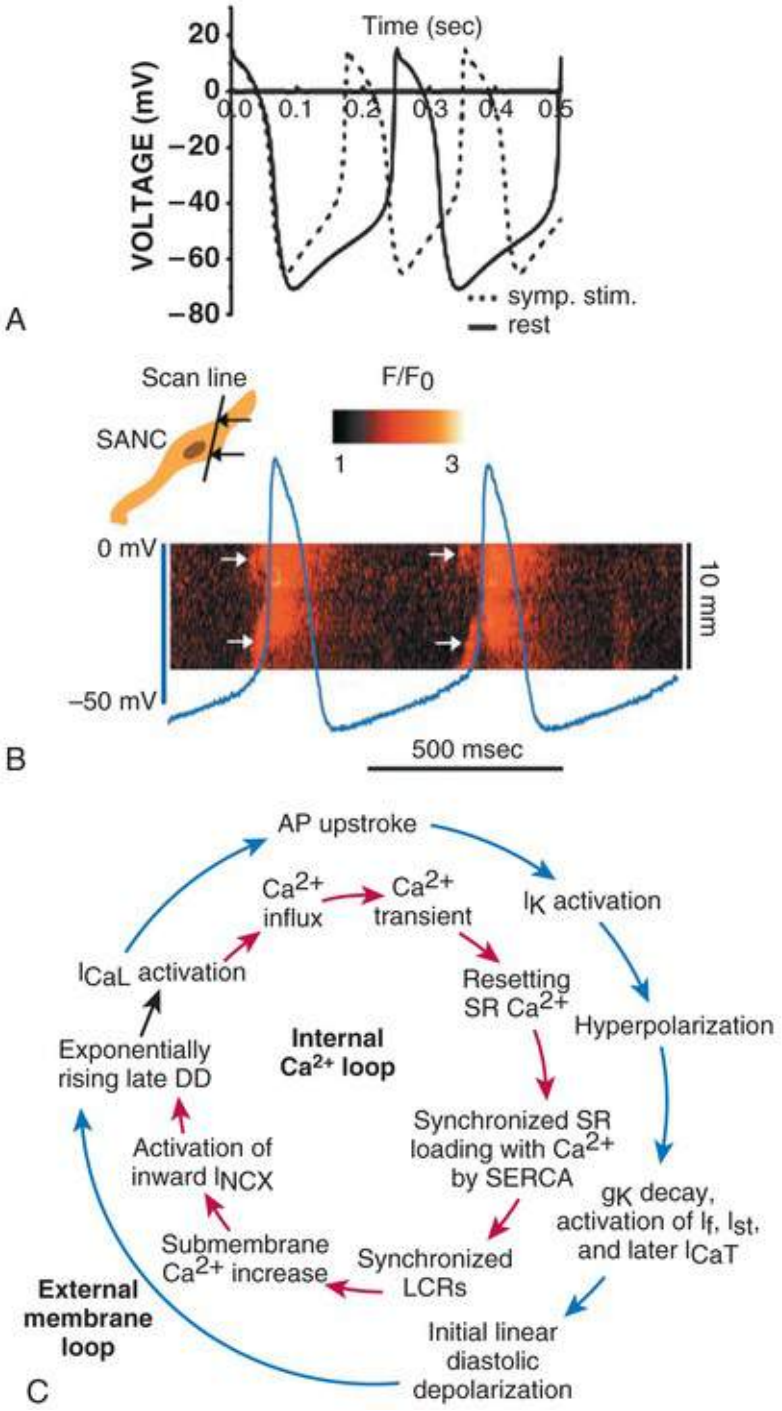


FIGURE 34.4 Sympathetic stimulation of heart rate in the sinoatrial node (SAN). **A,** Simulated SAN action potentials during baseline (*solid line*) and sympathetic stimulation (*dashed line*). Sympathetic stimulation increases the rate of diastolic depolarization and shifts the maximum diastolic potential to a less negative value, thereby accelerating action potential firing. **B, C,** Spontaneous sarcoplasmic reticulum (SR) Ca^{2+}-release events trigger membrane excitation in SAN myocytes. **B,** Confocal line scan images of Ca^{2+} signals measured in spontaneously beating rabbit sinoatrial node cells (SANC) with simultaneous recording (*blue lines*) of transmembrane action potentials; the orientation of the scan line is shown in the inset. *Arrows* in the confocal image show the local Ca^{2+} release in the submembrane space during late diastolic depolarization that precedes the rapid upstroke of the action potential. **C,** Model of sinoatrial node cell pacemaking, as suggested by Maltsev and coworkers. I_{NCX}, Na^+/Ca^{2+} exchange current; *DD,* diastolic depolarization; *LCR,* local Ca^{2+} release; *SERCA,* sarcoendoplasmic reticulum Ca^{2+}-ATPase. (**A,** From Larsson HP. How is the heart rate regulated in the sinoatrial node? Another piece to the puzzle. J Gen Physiol 2010;136:237; **B, C,** from Maltsev VA et al. The emergence of a general theory of the initiation and strength of the heartbeat. J Pharmacol Sci 2006;100:338.)

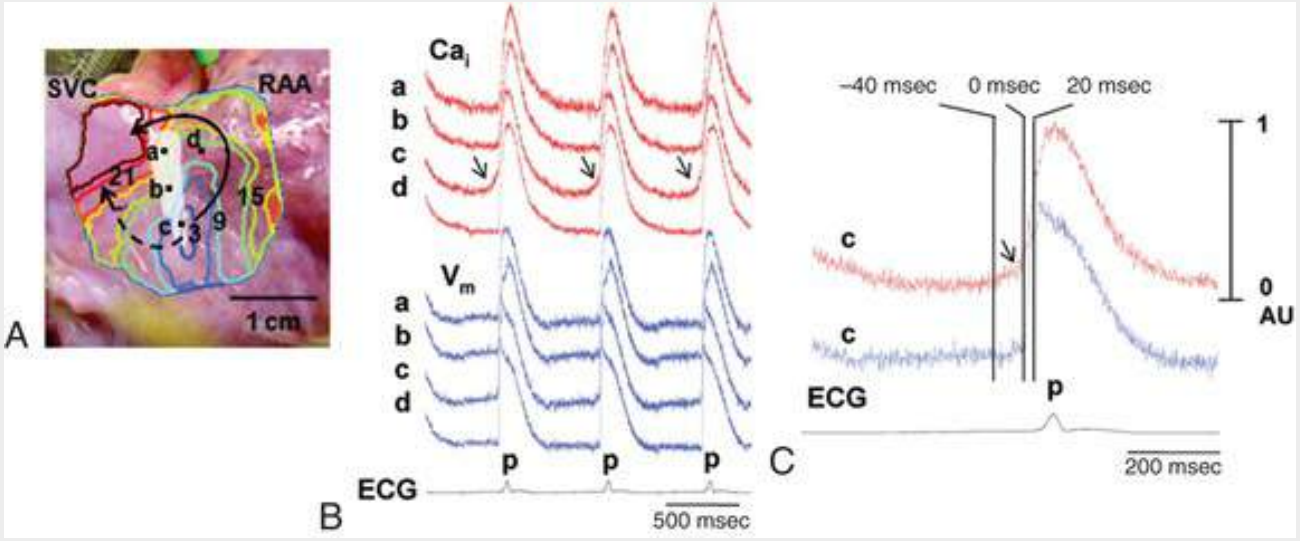
In the model proposed by proponents of Ca^{2+} oscillations operating as the primary pacemaking mechanism ("Ca^{2+} clock"), periodic increases in $[Ca^{2+}]_i$ serve as an internal generator ("calcium clock") of rhythmic signals that are transformed into changes in membrane voltage via modulation of calcium-sensitive ion channels and transporters in the outer membrane ("membrane clock"). This concept is illustrated in **Fig. 34.4**, in which simultaneous $[Ca^{2+}]_i$ and action potential measurements in isolated sinoatrial myocytes are used as an example. Local submembrane increases in $[Ca^{2+}]_i$ (denoted by the white arrows in **Fig. 34.4B**) occurring during the latter part of the spontaneous diastolic depolarization (transmembrane action potentials are shown in blue) precede the rapid upstroke of the action potential. The periodic SR Ca^{2+}-release events rhythmically activate the Na^+/Ca^{2+} exchange inward (i.e., depolarizing) current (I_{NCX}), which then results in an increase in membrane potential that prompts activation of surface membrane L-type Ca^{2+} channels to initiate an action potential. Thus the NCX operating in forward mode plays an essential role in converting the driver intracellular Ca^{2+} signals into membrane (i.e., voltage) signals. Once an action potential has been initiated, two highly interacting, concurrent series of events proceed during a normal SA node cell cycle (**Fig. 34.4C**). In a surface membrane delimited series of events, depolarization-induced activation of the delayed rectifier K^+ current I_K leads to membrane hyperpolarization, which is followed by slow diastolic depolarization via activation of a number of inward currents, including I_f and I_{CaT} (**see Table 34.1**). In a second, parallel cycle of events, action potential–induced SR Ca^{2+} release is followed by Ca^{2+} reuptake into the SR, which subsequently gives rise to multifocal, synchronized spontaneous Ca^{2+}-release events culminating in an increase in inward I_{NCX}. The role of late diastolic spontaneous SR Ca^{2+}-release events in triggering the SA node action potential has been demonstrated in canine hearts in situ (**eFig. 34.4**).



EFIGURE 34.4 Demonstration of late diastolic intracellular calcium elevations in the sinoatrial node in situ by simultaneous optical mapping of changes in intracellular calcium (Ca_i) and transmembrane voltage (V_m) in an isolated canine right atrial preparation. **A,** Isochronal map of atrial activation during sinus rhythm superimposed on a photograph of the endocardial surface of the sinoatrial node region. The number on each isochronal line indicates the time of activation in milliseconds. The *white shaded area* is the sinoatrial node. *SVC,* Superior vena cava; *RAA,* right atrial appendage. **B,** V_m (*blue*) and Ca_i (*red*) recordings from the superior (a), middle (b), and inferior (c) sinoatrial node, and right atrium (d). *Arrows* indicate late diastolic elevations in Ca_i. Note the presence of slow diastolic depolarization in the V_m tracings a through c, but not in d. **C,** Magnified views of Ca_i and V_m tracings of the inferior sinoatrial node. The late diastolic elevation in Ca_i (*arrow*) precedes rapid upstroke of the sinoatrial and atrial action potential and occurs much earlier than the P wave on the electrocardiogram (ECG). (From Joung B et al. Intracellular calcium dynamics and acceleration of sinus rhythm by β-adrenergic stimulation. Circulation 2009;119:788.)

The rate of SA node discharge can be varied by several mechanisms in response to autonomic or other influences. The pacemaker locus can shift within or outside the SA node to cells discharging faster or more slowly. If the pacemaker site remains the same, alterations in the slope of the diastolic depolarization, maximum diastolic potential, or threshold potential can speed or slow the discharge rate. For example, if the slope of diastolic depolarization steepens, and if the resting membrane potential becomes less negative or the threshold potential more negative (within limits), the discharge rate increases (e.g., **Fig. 34.4A**, dotted line). Opposite changes slow the discharge rate. The molecular mechanism that is primarily responsible for acceleration of the SA node discharge rate has been highly controversial. Proponents of the HCN pacemaker role consider an increase in inward HCN current via a shift of the HCN channel activation curve to more depolarized potentials as the primary regulatory mechanism.[1] In contrast, proponents of the Ca^{2+} clock model suggest protein kinase A (PKA)–mediated phosphorylation of Ca^{2+} -handling proteins (RyR, phospholamban [**see Chapter 22**], SERCA, voltage-gated Ca^{2+} channels) as the mechanism responsible for increased action potential firing: an increase in cAMP level (after beta-adrenergic receptor stimulation) augments PKA activity, which then increases the rate of spontaneous SR Ca^{2+} release and SR Ca^{2+} reuptake via synergistic activation of these proteins, whereas a reduction in cAMP levels (after muscarinic receptor stimulation) has the opposite effect. Acetylcholine (ACh) activates K^+ efflux through ACh-sensitive inward rectifier K^+ channels, which are expressed in both SA nodal and AV nodal cells, thereby shifting the maximum diastolic potential to more negative values. The same mechanism reduces input resistance at diastolic potentials, which means that a greater depolarizing current would be required to achieve the “threshold” for firing an action potential.

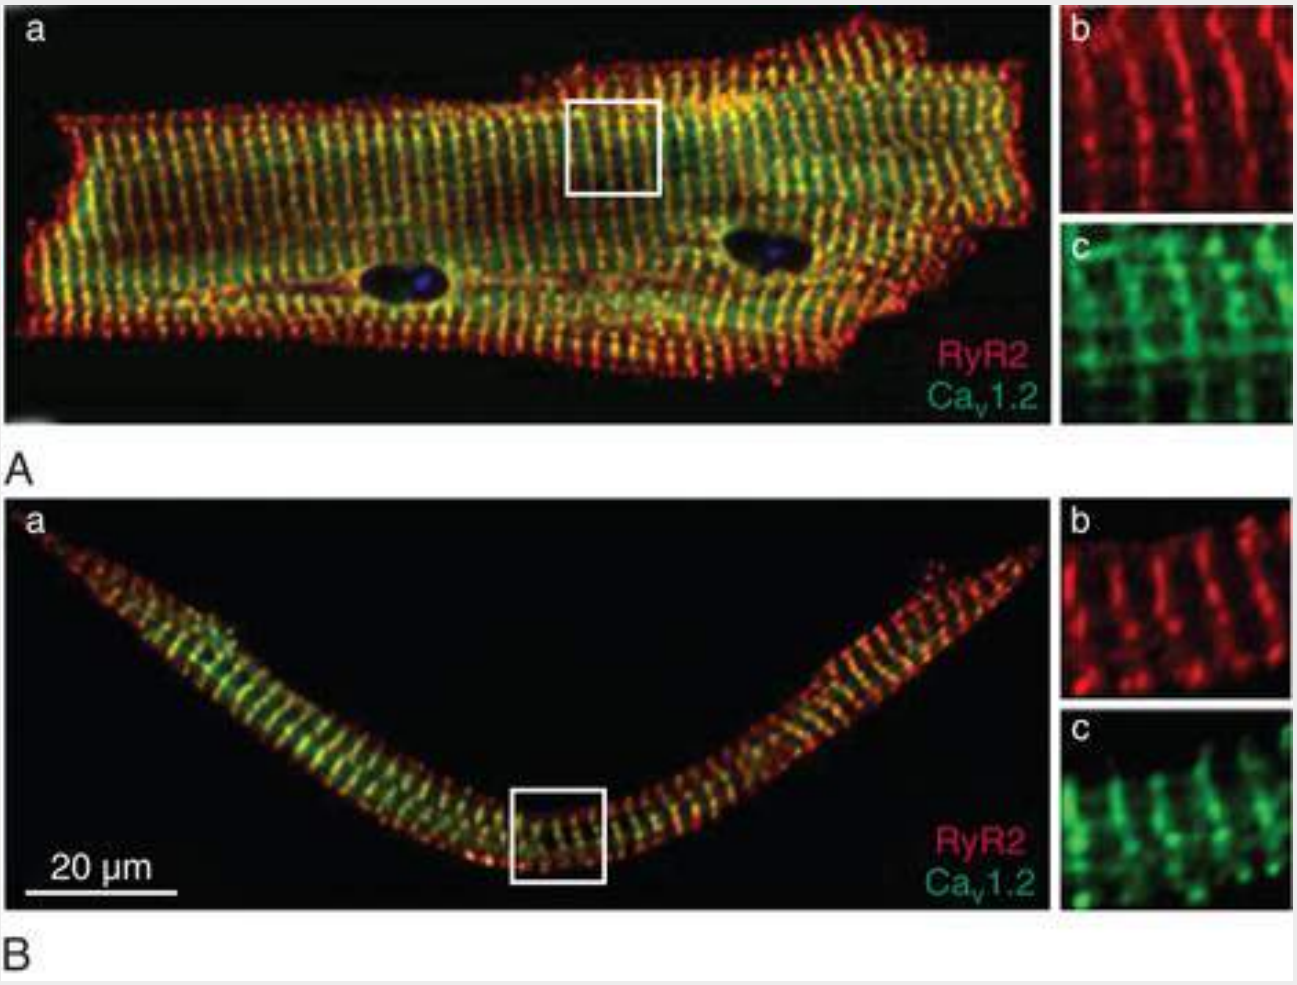
Passive Membrane Electrical Properties.

Passive membrane properties, including membrane resistance, capacitance, and cable properties, play an

important role in cardiac electrophysiology. Although the cardiac cell membrane is resistant to current flow, it also has capacitive properties, which means that it behaves like a battery and can store charges of opposite signs on its two sides—an excess of negative charges inside the membrane balanced by equivalent positive charges outside the membrane. These resistive and capacitive properties cause the membrane to take a certain amount of time to respond to an applied stimulus, rather than responding instantly, because the charges across the capacitive membrane must be altered first. A subthreshold rectangular current pulse applied to the membrane produces a slowly rising and decaying change in membrane voltage rather than a rectangular voltage change. A value called the *time constant* of the membrane reflects its capacitive property. The time constant tau (τ) is equal to the product of membrane resistance (R_m) and cell capacitance (C_m):

$$\tau = R_m \times C_m$$

This is the time taken by the membrane voltage to reach 63% of its final value after application of a steady current. The time course of changes in membrane potential after the application of a hyperpolarizing or depolarizing subthreshold current step is typically monoexponential in all myocyte types, thus indicating that the entire sarcolemma (including the T-tubular membrane; **see eFig. 34.5**) is generally charging uniformly.



EFIGURE 34.5 Subcellular colocalization of ryanodine receptors (RyR2) and L-type calcium channels ($Ca_V1.2$) in Purkinje cells (PCs) and ventricular myocytes (VMs). **A,** VM; **B,** PC; for each, subpanels (*b* and *c*) are enlarged regions of the boxed area. Colocalization RyR2 and $Ca_V1.2$ is shown in the T tubules and at the sarcolemma. T tubules are more heterogeneous and less well developed in PCs. *Red,* RyR2; *green,* $Ca_V1.2$. (From American Heart Association; Willis CB et al. Constitutive intracellular Na^+ excess in Purkinje cells promotes arrhythmogenesis at lower levels of stress than ventricular myocytes from mice with catecholaminergic polymorphic ventricular tachycardia. Circulation 2016;133:2348.)

When aligned end to end, cardiac cells, particularly the His-Purkinje system, behave similar to a long cable, in which current flows more easily inside the cell and to the adjacent cell across the gap junction than it does across the cell membrane to the outside. When current is injected at a point, most of it flows parallel to the long axis inside the cell, but some leaks out. Because of this loss of current, the change in voltage of a cell at a site distant from the point of applied current is less than the change in membrane voltage at the point where the stimulus was applied. A measure of this property of a cable is called the *space* or *length constant* lambda (λ), which is the distance along the cable from the point of stimulation at which the voltage at steady state is 1/e (37%) of its value at the point of stimulation.

Because the current loop in any circuit must be closed, current must flow back to its point of origin. Local circuit currents pass across gap junctions between cells and exit across the sarcolemmal membrane to close the loop and complete the circuit. Inward excitation currents in one area (carried by Na^+ in most regions) flow intracellularly along the length of the tissue (carried mostly by K^+), escape across the membrane, and flow extracellularly in a longitudinal direction. The outside local circuit current is the current recorded on an electrocardiogram (ECG). Through these local circuit currents, the transmembrane potential of each cell influences the transmembrane potential of its neighbor, because of the passive flow of current from one segment of the fiber to another across the low-resistance gap junctions (see Gap Junction Channels and Intercalated Discs and **Fig. 34.7**).

The speed of conduction in cardiac tissue depends on active membrane properties such as the magnitude of the Na^+ current, a measure of which is Vmax. Passive membrane properties also contribute to conduction velocity and include the *excitability threshold*, which influences the capability of cells adjacent to the one that has been discharged to reach threshold; the *intracellular resistance* of the cell, determined by free ions in the cytoplasm; the resistance of the gap junction; and the cross-sectional area of the cell. The direction of propagation is crucial because of the influence of *anisotropy*, in which conduction is faster parallel to the fiber axis compared to that across fibers.

Loss of Membrane Potential and Development of Arrhythmias

Many acquired abnormalities of cardiac muscle or specialized fibers that result in arrhythmias produce a loss of the resting membrane potential (less negative). This change should be viewed as a symptom of an underlying abnormality, analogous to fever or jaundice, rather than as a diagnosis in and of itself, because both the ionic changes resulting in cellular depolarization and the more fundamental biochemical or metabolic abnormalities responsible for the ionic alterations probably have a number of causative factors.

Cellular depolarization can result from elevated $[K^+]_o$ or decreased $[K^+]_i$, an increase in membrane permeability to Na^+ (P_{Na} increases), or a decrease in membrane permeability to K^+ (P_K decreases). Reference to the GHK equation for voltage (see earlier) illustrates that these changes alone or in combination make the transsarcolemmal diastolic voltage less negative.

Normal cells perfused by an abnormal milieu (e.g., hyperkalemia), abnormal cells perfused by a normal milieu (e.g., healed myocardial infarction), or abnormal cells perfused by an abnormal milieu (e.g., acute myocardial ischemia and infarction) can exist alone or in combination and reduce the resting membrane voltage. Each of these changes can have one or more biochemical or metabolic causes. For example, acute myocardial ischemia results in decreased $[K^+]_i$ and increased $[K^+]_o$, release of norepinephrine, and acidosis, which may be related to an increase in intracellular Ca^{2+} and Ca^{2+}-induced transient inward currents and accumulation of amphipathic lipid metabolites and oxygen free radicals. All these changes can contribute to the development of an abnormal electrophysiologic environment and arrhythmias during ischemia and reperfusion.

Effects of Reduced Resting Potential.

The reduced resting membrane potential alters the depolarization and repolarization phases of the cardiac action potential. For example, partial membrane depolarization causes a decrease in the steady-state availability of fast sodium channels, thereby reducing the magnitude of peak I_{Na} during phase 0 of the action potential. The subsequent reduction in action potential amplitude prolongs the conduction time of the propagated impulse, at times to the point of block.

Action potentials with reduced upstroke velocity resulting from partial inactivation of I_{Na} are called *depressed* fast responses. Their contours often resemble and can be difficult to distinguish from slow responses, in which upstrokes are caused by $I_{Ca.L}$ (**see Fig. 34.3F**). Membrane depolarization to levels of −60 to −70 mV can inactivate a substantial portion of the available voltage-gated Na^+ channels, and depolarization to −50 mV or less can almost completely inactivate all the Na^+ channels (**see Fig. 34.1A**). At membrane potentials positive to −50 mV, $I_{Ca.L}$ can be activated to generate phase 0 if conditions are appropriate. These changes in the action potential are likely to be heterogeneous, with unequal degrees of Na^+ inactivation that create areas with minimally reduced velocity, more severely depressed zones, and

areas of complete block. These inhomogeneous changes are conducive to the development of arrhythmias. Cells with reduced membrane potentials can exhibit postrepolarization refractoriness. Furthermore, if conduction block occurs in a fairly localized area without significant slowing of conduction proximal to the site of block, cells in this proximal zone exhibit short action potentials and refractory periods because unexcited cells distal to the block (still in a polarized state) electrotonically speed recovery in cells proximal to the site of block. If conduction slows gradually proximal to the site of block, the duration of these action potentials and their refractory periods can be prolonged.

Molecular Structure of Ion Channels

Ion channels are building blocks of biologic electricity in the heart, brain, skeletal muscle, and other excitable tissues. Ion channels are transmembrane glycoproteins that form ion-selective pores in cell membranes that open and close (*gating*) in response to an appropriate biologic signal. The most abundant ion channels in the heart gate in response to changes in transmembrane voltage. Other physiologically important channels respond to chemical ligands such as ACh, ATP, and calcium. Ion channels are typically named for the predominant permeant ion Na^+, Ca^{2+}, or K^+, and when appropriate, the ligand activator, ACh-dependent K channel. Electrophysiologic studies have detailed the functional properties of Na^+, Ca^{2+}, and K^+ currents in cardiomyocytes, and molecular cloning has revealed a large number of pore-forming (α) and auxiliary (β, γ, and δ) subunits thought to contribute to formation of ion channels. These studies have demonstrated that distinct molecular entities give rise to the various cardiac ion channels and shape the myocardial action potential. Mutations in the genes encoding subunits of cardiac ion channels are responsible for several inherited cardiac arrhythmias[10] (**see Chapter 33**). The expression and functional properties of myocardial ion channels also change in a number of acquired disease states, and these alterations can predispose to cardiac arrhythmias.[11]

Voltage-Gated Na^+ Channels.

Voltage-gated Na^+ (Nav) channel pore-forming (α) subunits have four homologous domains (I to IV), each of which contains six-transmembrane–spanning regions, and these four domains come together to form the Na^+-permeable pore[12] (**Fig. 34.5A**). Among the multiple Nav α subunits, Nav1.5 (which is encoded by the *SCN5A* gene) is the prominent one expressed in mammalian myocardium. The name of the voltage-gated sodium channel consists of the chemical symbol of the principal permeating ion (Na^+) and v, which indicates its principal physiologic regulator (voltage). The number following v indicates the gene subfamily (Nav1), and the number following the decimal point identifies the specific channel isoform (e.g., Nav1.1). An identical nomenclature applies to voltage-gated calcium and potassium channels. Mutations in *SCN5A*, which are associated with LQT3 syndrome, disrupt Nav channel inactivation and thereby give rise to a sustained inward Na^+ current during the plateau phase of the action potential and to prolongation of the action potential. Mutations in *SCN5A* are also linked to Brugada syndrome. Brugada syndrome mutations result in reduced Nav current amplitude, which leads to slowing of phase 0 action potential upstroke, reduced action potential amplitude, and altered phase 1 early repolarization.

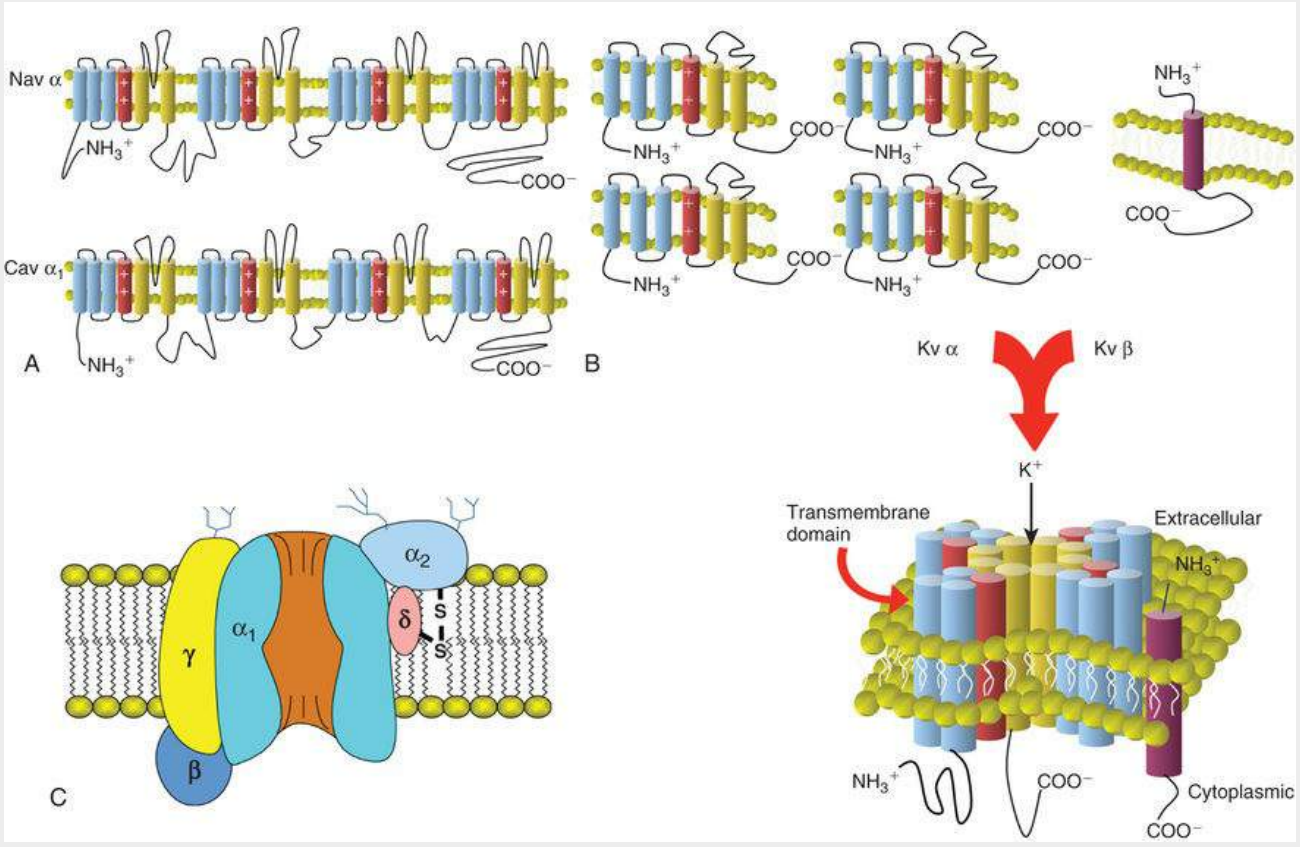


FIGURE 34.5 Transmembrane topology and schematic of the structure of ion channels. **A,** Voltage-gated Na^+ and Ca^{2+} channels are composed of a single tetramer consisting of four covalently linked repeats of the six-transmembrane–spanning motifs, whereas **B,** voltage-gated K^+ channels are composed of four separate subunits, each containing a single six-transmembrane–spanning motif. Inwardly rectifying K^+ channels are formed by inward rectifier K^+ channel pore-forming (alpha) subunits (Kir). In contrast to voltage-gated K^+ channel alpha subunits, the Kir alpha subunits have only two (not six) transmembrane domains. **C,** All ion channels are multisubunit proteins, as exemplified by the schematic subunit structure of L-type Ca channels.

Nav1.5 pore-forming α subunits coassemble with one to two auxiliary Nav β subunits to form functional cell surface Nav channels in cardiomyocytes. Nav β subunits appear to play an important role in anchoring ion channel proteins to the outer cell membrane. Subpopulations of Nav1.5 channels are present in different subcellular regions, such as the intercalated disc and T-tubular membranes.[13,14] As with many other ion channels, Nav1.5 channels are part of macromolecular complexes of channel and regulatory proteins.[15]

Voltage-Gated Ca^{2+} Channels.

As with Nav channels, cardiac voltage-gated Ca^{2+} (Cav) channels are assemblies of a pore-forming α_1 subunits and auxiliary Cav β or Cav α_2 -δ subunits (**Fig. 34.5C**). Among the various α subunits, Cav1.2, also known as α_{1C} encoded by the *CACNA1C* gene, is the prominent Cav α_1 subunit expressed in mammalian myocardium. Cav1.2 channels exhibit many of the time- and voltage-dependent properties and pharmacologic sensitivities of cardiac L-type Ca^{2+} currents (**see Table 34.1**). Accessory subunits modulate the functional properties of Cav channels.[16]

Cav3.1/α_1 G alpha subunits form a Ca^{2+} -selective channel with time- and voltage-dependent characteristics and pharmacologic sensitivities that resemble those of the low-voltage activated T-type Ca^{2+} channel. Disruption of the gene encoding Cav3.1 subunits (*CACNA1G*) in mice has been demonstrated to slow the sinus node rate and AV conduction, consistent with its role in SA and AV node function.[7]

Voltage-Gated K^+ Channels.

Voltage-gated K^+ channels (Kv) are the most diverse family of voltage-dependent channels in the heart. Kv channels are composed of four separate pore-forming (α) subunits, each containing six-membrane–spanning domains (S_1 through S_6)[17] (**see Fig. 34.5B**). Kv α subunits expressed in the human heart include members of the Kv1, Kv4, hERG (Kv7), and KvLQT (Kv11) subfamilies. In addition, Kv channel α subunit proteins interact with Kv channel accessory subunits, including minK, KChIP2, and MiRP1 (**see Table 34.1**), to form functional cell surface channels with distinct time- and voltage-dependent properties. Coassembly of the Kv4.3 α subunits and the accessory subunit KChIP2 gives rise to the cardiac transient outward Kv channel I_{to} (see Phase 1: Early Rapid Repolarization). hERG α subunits, together with MiRP1 accessory subunits, contribute to the generation of functional cardiac I_{Kr} channels. Mutations in the gene encoding hERG (*KCNH2*) have been shown to underlie congenital LQT2 syndrome. These LQT2 mutations are loss-of-function mutations that lead to reduced functional I_{Kr} channel expression or to alterations in channel processing or trafficking (**see Chapter 33**).

KvLQT1 α subunits associate with minK (encoded by *KCNE1*) accessory subunits to form functional channels that resemble slowly activating, noninactivating K^+ currents, referred to as I_{Ks}, in human myocardium. Mutations in the gene encoding KvLQT1 α subunits, *KCNQ1*, have been linked to LQT1 syndrome. Mutations in the minK-encoding gene *KCNE1* are associated with LQT5 syndrome. These mutations are all loss-of-function mutations that result in reduced expression of functional I_{Ks} channels in the outer membrane. Two missense mutations that cause familial atrial fibrillation (AF) are located on adjacent amino acid residues in the first membrane-spanning segment of *KCNQ1* and lead to altered physical interactions with the *KCNE1* subunits, which ultimately results in slowing of deactivation of I_{Ks} channels.[18]

Kv1.5 α subunits contribute to K^+-selective channels with time- and voltage-dependent characteristics that resemble the rapidly activating and slowly inactivating I_{Kur} in human atrial myocytes. I_{Kur} densities are greatly downregulated in the atria of patients with chronic AF.

Small-conductance, Ca^{2+}-sensitive K^+ channels are tetrameric assemblies of SK α subunits (encoded by *KCNN3*) and underlie a Ca^{2+}-activated K^+ current, $I_{KCa,}$ in human cardiomyocytes.[9] Common variants in *KCNN3* discovered in genome-wide analyses have been associated with AF.[19]

Inwardly Rectifying Cardiac K^+ Channels.

Kir channels in cardiac myocytes, as in other cells, conduct inward current at membrane potentials negative to E_K (see earlier, Physiology of Ion Channels) and smaller outward currents at membrane potentials positive to E_K. The activity of Kir channels is a function of both the membrane potential and the extracellular K^+ concentration ($[K^+]_o$) and are the major determinant of the resting membrane potential in working myocardium. As $[K^+]_o$ changes, the channel conducts inward current at potentials negative to the new E_K, whereas a small outward current within a certain potential range positive to the new E_K remains. Rectification simply means that membrane conductance changes with voltage. Specifically, inward rectification means that K^+ channels support ion flux at negative potentials but are closed or blocked at less negative or positive voltages. Membrane depolarization–induced internal block by intracellular magnesium and polyamine ions is thought to underlie inward rectification of cardiac I_{K1} channels.[17] Inwardly rectifying K^+ channels are formed by inward rectifier K^+ channel pore-forming α subunits. In contrast to Kv α subunits, Kir α subunits have only two (not six) transmembrane domains. Molecular studies have provided direct evidence that the α subunits Kir2.1 and Kir2.2 encoded by *KCNJ2* and *KCNJ3*, respectively, underlie the strongly inwardly rectifying Kir channel I_{K1} in

cardiomyocytes.

In cardiomyocytes, pore-forming Kir6.2 α subunits (encoded by *KCNJ11*) assemble with sulfonylurea receptor proteins (SUR1, SUR2 encoded by *ABCC8* and *ABCC9*, respectively) to form K^+-selective sarcolemmal $I_{K.ATP}$ channels. Kir6.1 protein (encoded by *KCNJ8*) also forms a channel, but its role in the heart is uncertain because sarcolemmal $I_{K.ATP}$ is abolished in SA nodal cells of Kir6.2 knockout mice. Based on activation of sarcolemmal $I_{K.ATP}$ by pinacidil and cromakalim, which are relatively specific for SUR2, the cardiac channel is suggested to be an octameric assembly of SUR2A/Kir6.2. However, different anatomic regions of the heart may express $I_{K.ATP}$ comprised of differing channel and SUR subunits. $I_{K.ATP}$ channels are thought to play a pivotal role in myocardial ischemia and preconditioning. For example, opening of cardiac sarcolemmal $I_{K.ATP}$ channels underlies electrocardiographic ST-segment elevation during acute myocardial ischemia. Drugs such as nicorandil and diazoxide open ATP-sensitive K^+ channels, whereas sulfonylurea compounds (e.g., glibenclamide) inhibit the activity of $I_{K.ATP}$.[20] Mutations in *ABCC9* have been associated with a rare multiorgan system disease, Cantu syndrome, characterized by craniofacial, dermal, and skeletal deformities, as well as congenital cardiac abnormalities such as bicuspid aortic valve, patent ductus arteriosus, biventricular hypertrophy pulmonary hypertension, and pericardial effusion.[21] It has been suggested that vasodilation by opening of vascular $I_{K.ATP}$ may be pathogenically involved.

In addition to the sarcolemmal channel an ATP-sensitive potassium conductance in mitochondrial (mitoK[ATP]) has been described that is involved in cardioprotection and arrhythmias. The molecular composition of this channel is uncertain but likely is composed of another type of inwardly rectifying K^+ channel.[22]

The molecular basis of the ACh-activated K^+ channel $I_{K.ACh}$ is a heteromultimer of two inwardly rectifying potassium channel subunits, Kir3.1 and Kir3.4.[17] Stimulation of $I_{K.ACh}$ by vagally secreted ACh decreases spontaneous depolarization in the SA node and slows conduction velocity in the AV node. Adenosine, through type 1 purinergic receptor–mediated G-protein activation, also increases $I_{K.ACh}$ activity (in this context referred to as $I_{K.Ado}$) in atrial, SA node, and AV node cells. Adenosine is useful for the acute termination of arrhythmias with the AV node as part of the reentry circuit, such as atrioventricular reentrant (AVRT) and atrioventricular nodal reentrant tachycardias (AVNRT) (see later, Mechanisms of Arrhythmogenesis).

Cardiac Pacemaker Channel.

The pacemaker (“funny”) current known as I_f of sinoatrial myocytes prominently contributes to diastolic depolarization. The current is found in many cell types but its features are variable. I_f activates slowly on hyperpolarization and deactivates rapidly with depolarization and supports a mixed monovalent cation (Na^+ and K^+) current. I_f is highly regulated; beta-adrenergic stimulation increases the probability of channel opening by shifting the channel's activation curve to more positive potentials, which leads to increased current availability for the generation of diastolic depolarization and thus steepens its rate. Cholinergic action, in general, exerts the opposite effect (see earlier). A family of genes topologically similar to voltage-dependent K^+ channels and related to cyclic nucleotide–gated channels in photoreceptors in the retina appears to encode I_f. Several isoforms of hyperpolarization-activated cyclic nucleotide–gated channels (HCN) have been cloned from heart. Of the four known HCN pore-forming α subunits, HCN4 is the most highly expressed in the mammalian myocardium. Mutation in the human *HCN4* gene has been linked to familial sinus bradycardia and inappropriate sinus tachycardia.[23,24]

Electrogenic Transporters

Na^+/Ca^{2+} Exchanger.

The NCX is an electrogenic ion transporter that exchanges three Na^+ ions for one Ca^{2+}, exhibiting the highest levels of activity in the mammalian heart. The cardiac NCX is a transmembrane glycoprotein proposed to have nine-transmembrane repeats based on hydropathy analysis (**Fig. 34.6A, B**). The intracellular loop contains domains that bind Ca^{2+} (CBD 1 and 2) and the endogenous NCX inhibitory domain, XIP.

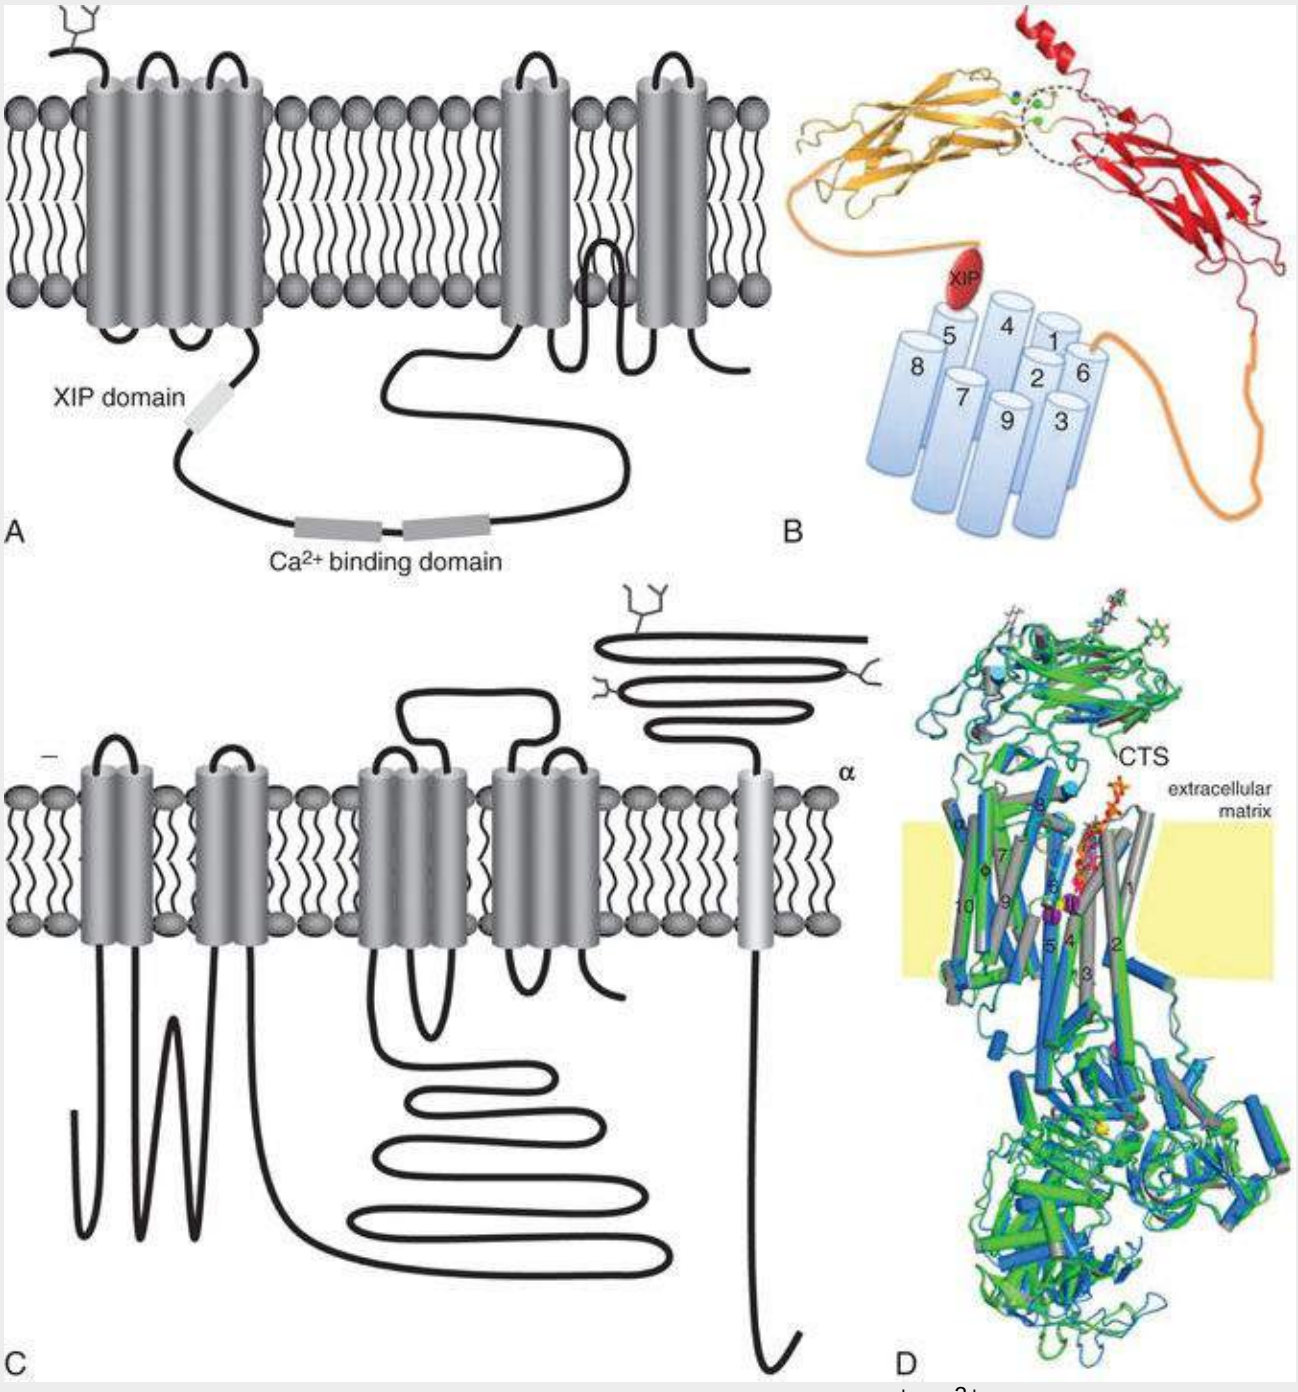

FIGURE 34.6 Transmembrane topology and predicted structures of Na^+/Ca^{2+} exchanger (NCX) and the Na^+,K^+-ATPase (Na pump). **A,** Predicted topology of NCX, the cytoplasmic segment includes an autoinhibitory domain (XIP) and two Ca^{2+}-binding domains. **B,** Predicted structure; the cytoplasmic surface is on top. **C,** Topologic structure of the α and β subunits of Na^+,K^+-ATPase. **D,** Overlapping structures of the Na pump bound to three different cardiotonic steroids. CTS, Cardiotonic steroid. (**B**, From Khaninshvilli. The SLC8 gene family of sodium-calcium exchangers (NCX) - structure, function, and regulation in health and disease. Mol Aspects Med 2013;34:220-35; **D,** from Laursen M et al. Structures and characterization of digoxin- and bufalin-bound Na^+,K^+-ATPase compared with the ouabain-bound complex. Proc Natl Acad Sci USA 2015;112:1755-60.)

Ion exchange through NCX can occur in either direction. With each heartbeat, cytosolic [Ca^{2+}] is released from SR stores primarily by the ryanodine release channel RyR2. Intracellular [Ca^{2+}] increases from the global resting level of less than 100 nM to approximately 1 μM with each cardiac cycle. Under normal physiologic conditions, outward Ca^{2+} flux through the NCX (generating an inward current) along with Ca^{2+} reuptake into the SR by the SR Ca^{2+}-ATPase (SERCA) are the major mechanisms of restoration of normal diastolic [Ca^{2+}]. NCX is sensitive to the cytoplasmic [Ca^{2+}] and [Na^+], which determine the exchanger activity and the membrane potential at which exchange current ($I_{Na/Ca}$) reverses direction. NCX

current is time independent and largely reflects changes in intracellular [Ca^{2+}] during the action potential. Thus, NCX plays an important role in determining the membrane voltage both at rest and during activation of the myocyte. At very depolarized potentials, reverse-mode Na^+/Ca^{2+} exchange (Ca^{2+} influx, net outward current) can occur; however, the role of reverse-mode exchange in initiating SR Ca^{2+} release and contraction is uncertain.[25]

NCX current may participate in the generation of arrhythmias in several ways. Increases in $[Ca^{2+}]_i$ shift the reversal potential of the NCX to more positive potentials and therefore increase the driving force for inward exchanger current. Inward NCX current will depolarize the membrane toward the threshold for firing an action potential and may be arrhythmogenic. NCX current is an important component of the inward current that underlies delayed afterdepolarizations (DADs). DADs are spontaneous membrane depolarizations from rest after complete repolarization of the action potential. DADs are usually not present under physiologic conditions but are favored by conditions that increase SR Ca^{2+} load, such as rapid firing rates, digitalis intoxication, and ischemia/reperfusion. Under these conditions, spontaneous SR Ca^{2+} release occurs, which then increases NCX and probably other Ca^{2+}-dependent currents, resulting in membrane depolarization.[2]

Na^+,K^+-*ATPase.*

Also called the Na pump, Na^+,K^+-ATPase establishes and maintains the major ionic gradients across the cardiac cell membrane. The Na pump belongs to the widely distributed class of P-type ATPases that transport a number of cations. The P-type designation refers to the formation of a phosphorylated aspartyl intermediate during the catalytic cycle. Na^+,K^+-ATPase hydrolyzes a molecule of ATP to transport two K^+ into the cell and three Na^+ out and thus is electrogenic, generating a time-independent outward current. The Na^+,K^+-ATPase is oligomeric, consisting of α and β subunits and a tissue-specific regulator phospholemman (PLM). PLM belongs to a family of single-membrane–spanning proteins called FXYD proteins, for a conserved FXYD motif in their extracellular domain. PLM (FXYD1) is expressed in heart and skeletal muscle. PLM in its unphosphorylated form inhibits Na^+,K^+-ATPase ion pumping.[26]

Na^+,K^+-ATPase isoforms are diverse and exhibit tissue-specific distributions. The structural diversity of the Na^+,K^+-ATPase comes from variations in α and β genes, splice variants of the α subunits and promiscuity of subunit associations, themes that also underlie the diversity of ion channels, particularly K channels. The α subunit is catalytic and binds digitalis glycosides in the extracellular linker between the first and second membrane-spanning region (**Fig. 34.6C, D**). In the heart, it has been suggested that the α_2 subunit preferentially regulates Na^+ in the dyadic cleft where α_1 seems to be engaged in regulating bulk $[Na^+]_i$.[3]

In heart failure, Na^+-K^+ ATPase function is compromised, and a number of studies have shown a reduction in expression in ventricular myocardium. The decrease occurs without a significant impact on the inotropic effect of digitalis glycosides, which exerts its predominant effect by blocking the Na pump. However, the reduction in the density of the Na pump may influence the electrophysiology of cardiac myocytes and their response to an extracellular K^+ load, as might occur in ischemia. The role of PLM in cardiac hypertrophy and failure has yet to be systematically characterized, and there is no consensus regarding the level of expression, phosphorylation, or functional role in the diseased heart.

Gap Junction Channels and Intercalated Discs

Another family of ion channel proteins is that containing the gap junctional channels. These dodecameric channels are found in the intercalated discs between adjacent cells (**Fig. 34.7A, B**). Three types of

specialized junctions make up each intercalated disc. The macula adherens or desmosome and the fascia adherens form areas of strong adhesion between cells and may provide a linkage for the transfer of mechanical energy from one cell to the next. The *nexus,* also called the tight or gap junction (**Fig. 34.7C-E**), is a region in the intercalated disc where cells are in functional contact with each other. Membranes at these junctions are separated by only about 10 to 20 Å and are connected by a series of hexagonally packed subunit bridges or gap junction channels that provide biochemical and low-resistance electrical coupling between adjacent cells, by establishing aqueous pores that directly link the cytoplasm of these adjacent cells. Gap junctions allow the movement of ions (e.g., Na^+, Cl^-, K^+, Ca^{2+}) and small molecules (e.g., cAMP, cGMP, inositol 1,4,5-triphosphate [IP_3]) between cells, thereby linking the interiors of adjacent cells.

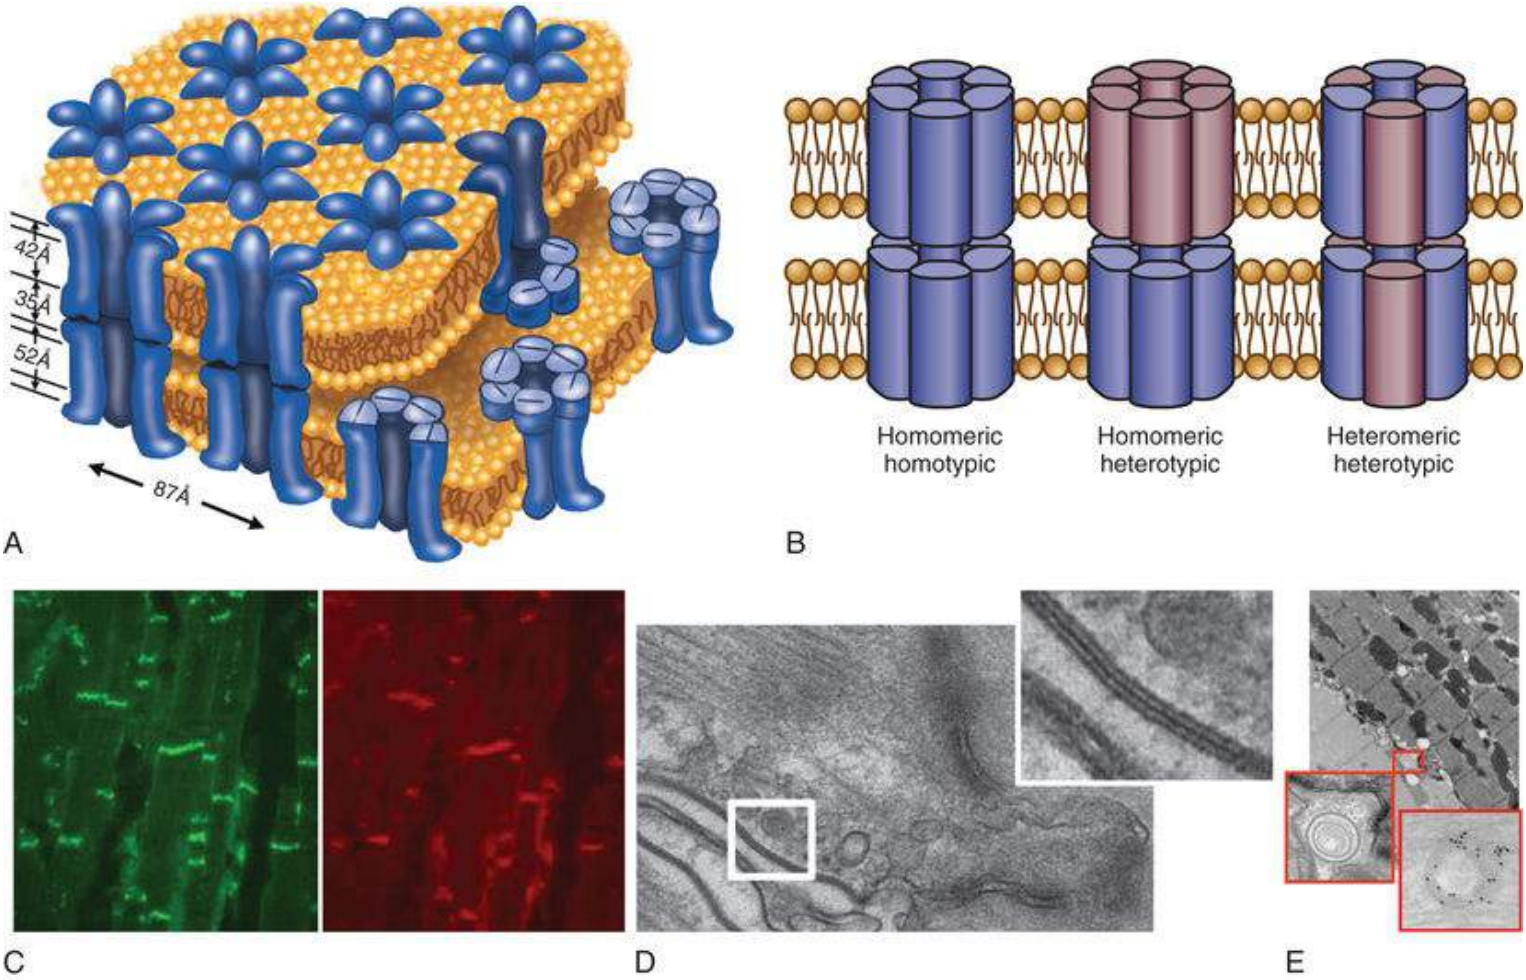

FIGURE 34.7 **A,** Model of the structure of a gap junction based on the results of x-ray diffraction studies. Individual channels are composed of paired hexamers that travel in the membranes of adjacent cells and adjoin in the extracellular gap to form an aqueous pore that provides continuity of the cytoplasm of the two cells; Å, ångstroms. **B**, Mixing of connexin subunits to form gap junction channels may occur at interfaces between tissue types in the heart. Homomeric, homotypic channels contain a single connexin isoform; homomeric heterotypic channels are composed of connexons (hemichannels) comprising a single connexin isoform; and heteromeric, heterotypic channels are made from connexons containing more than one connexin isoform. **C,** Connexin 43 (Cx43) is concentrated at the intercalated discs at cell ends in ventricular myocardium (*green*) and colocalizes with junctional proteins such as N-cadherin (*red*). **D,** Electron microscopic view of and intercalated from normal ventricular myocardium reveals a pentalaminar membrane (*inset*) characteristic of gap junctions. **E,** Remodeling of gap junctions in the failing heart. Immunoreactive Cx43 is increased along lateral cell borders, and annular gap junctions that label with anti-Cx43 immunogold antibodies (*insets*) can be observed. (**A,** From Saffitz JE. Cell-to-cell communication in the heart. Cardiol Rev 1995;3:86; **C, E,** modified from Hesketh et al. Ultrastructure and regulation of lateralized connexin43 in the failing heart. Circ Res 2010;106:1153-63.)

Gap junctions permit a multicellular structure such as the heart to function electrically as an orderly, synchronized, interconnected unit and are responsible in part for conduction in the myocardium being anisotropic; that is, its anatomic and biophysical properties vary according to the direction in which they are measured. Usually, conduction velocity is two to three times faster longitudinally, in the direction of the long axis of the fiber, than it is transversely, in the direction perpendicular to this long axis. Resistivity is lower longitudinally than transversely. Interestingly, the *safety factor for propagation* is greater transversely than horizontally. The *safety factor for conduction* determines the success of action potential propagation and has been defined as the ratio of electrical charge that is generated to charge that is consumed during the excitation cycle of a single myocyte in tissue. Conduction delay or block occurs more frequently in the longitudinal direction than it does transversely. Cardiac conduction is discontinuous because of resistive discontinuities created by the gap junctions, which have an anisotropic distribution on the cell surface. Because of anisotropy, propagation is discontinuous and can be a cause of

reentry.[1]

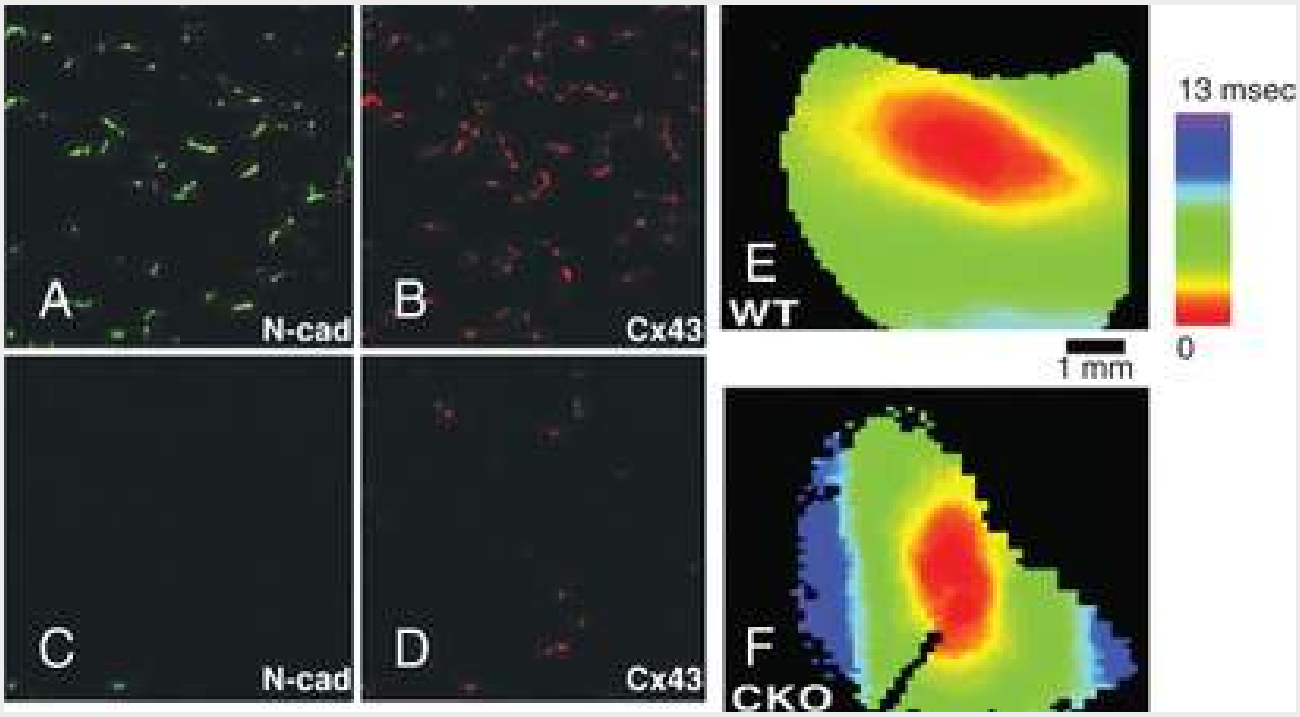
Gap junctions also provide “biochemical coupling,” which permits cell-to-cell movement of ATP (or other high-energy phosphates), cyclic nucleotides, and IP_3, the activator of the IP_3-sensitive SR Ca^{2+}-release channel. This demonstrates that diffusion of second-messenger substances through gap junctional channels constitutes a mechanism enabling coordinated responses of the myocardial syncytium to physiologic stimuli.[1]

Gap junctions can also change their electrical resistance. When the intracellular calcium level rises, as in myocardial infarction (MI), the gap junction may close to help seal off injured from noninjured cells. Acidosis increases and alkalosis decreases gap junctional resistance. Increased gap junctional resistance tends to slow the rate of action potential propagation, a condition that could lead to conduction delay or block. Cardiac-restricted inactivation of gap junctions decreases transverse conduction velocity to a greater degree than longitudinal conduction, thereby resulting in an increased anisotropic ratio, which may play a role in premature sudden death from ventricular arrhythmias.

Connexins are the proteins that form the intercellular channels of gap junctions. An individual channel is created by two hemichannels (*connexons*), each located in the plasma membrane of adjacent cells and composed of six integral membrane protein subunits (connexins). The hemichannels surround an aqueous pore and thereby create a transmembrane channel (**Fig. 34.7A**). *Connexin 43*, a 43-kDa polypeptide, is the most abundant cardiac connexin, with connexins 40 and 45 being found in smaller amounts. Ventricular muscle expresses connexins 43 and 45, whereas atrial muscle and components of the specialized conduction system express connexins 43, 45, and 40. Individual cardiac connexins form gap junctional channels with characteristic unitary conductances, voltage sensitivities, and permeabilities. Tissue-specific connexin expression and the spatial distribution of gap junctions determine the disparate conduction properties of cardiac tissue. The functional diversity of cardiac gap junctions is further enhanced by the ability of different connexin isoforms to form hybrid gap junctional channels with unique electrophysiologic properties (**Fig. 34.7B**). These channel chimeras appear to have a major function in controlling impulse transmission at the SA node–atrium border, the atrium–AV node transitional zone, and the Purkinje-myocyte border.[1]

Alterations in the distribution and function of cardiac gap junctions are associated with increased susceptibility to arrhythmias. Conduction slowing and arrhythmogenesis have been associated with redistribution of connexin 43 (Cx43) gap junctions from the end of cardiomyocytes to the lateral borders and with decreased phosphorylation of Cx43 in a dog model of nonischemic dilated cardiomyopathy (**Fig. 34.7C-E**). Adult mice genetically engineered to express progressively decreasing levels of cardiac Cx43 exhibited increased susceptibility to the induction of fatal tachyarrhythmias. Side-to-side electrical coupling between cardiomyocytes from the epicardial border zone of healing infarcts has been shown to be reduced, thereby exaggerating anisotropy and facilitating reentrant activity.[1] Lastly, mutations in the atrial-specific connexin 40 gene that exhibit altered function have been associated with AF.[27] Studies have suggested that normal electrical coupling of cardiomyocytes through gap junctions depends on normal mechanical coupling through cell-cell adhesion junctions. A defect in cell-cell adhesion or a discontinuity in the linkage between intercellular junctions and the cytoskeleton prevents normal localization of connexins in gap junctions, which in turn could contribute tachyarrhythmias causing sudden death. Mutations in *desmoplakin*, a protein that links desmosomal adhesion molecules to *desmin*, a filament protein of the cardiomyocyte cytoskeleton, and *plakoglobin*, a protein that connects N-

cadherins to actin and desmosomal cadherins to desmin, produce recessive variants of arrhythmogenic right ventricular cardiomyopathy (ARVC), Cavajal disease, and Naxos disease, respectively[28] (**see Chapter 77**). Notably, restoring plakoglobin (*JUP* gene) levels in a mouse model of Naxos disease caused by a truncation of plakoglobin prevented cardiac dysfunction, consistent with a loss of function defect of the truncated protein.[29] Approximately 40% of the pathogenic variants linked to familial ARVC are in the gene encoding the desmosomal protein plakophilin-2.[30] Demonstration of the important role of other adhesion proteins in stabilizing gap junctions comes from a study in which conditional loss of N-cadherin expression in mouse hearts resulted in a decrease in Cx43 gap junctions and changes in conduction velocity, with a concomitant increase in arrhythmogenicity (**eFig. 34.6**).



EFIGURE 34.6 Cardiac-restricted loss of N-cadherin leads to alteration in connexin 43 (Cx43) with conduction slowing. **A to D,** Anti–N-cadherin (**A, C**) and anti-Cx43 (**B, D**) immunoreactivity in a control mouse heart **(A, B)** and in a genetically manipulated mouse heart with knocked-out N-cadherin expression **(C, D).** N-cadherin was lost from intercalated disc in the knock-out heart, whereas Cx43 was significantly decreased. **E, F,** Optical mapping of electrical activation in the left ventricular epicardium of a control **(E)** and N-cadherin knocked-out heart **(F)** with a voltage-sensitive fluorescent dye. The heart was paced at the lateral wall, and activation maps were generated. Color-coded isochrone maps show that conduction was more impaired in the longitudinal than in the lateral direction, thereby increasing conduction anisotropy.
(From Li J et al. Cardiac-specific loss of N-cadherin leads to alteration in connexins with conduction slowing and arrhythmogenesis. Circ Res 2005;97:474.)

Structure and Function of the Cardiac Electrical Network

Sinoatrial Node

In humans, the sinoatrial node (SAN) is a spindle-shaped structure composed of a fibrous tissue matrix with closely packed cells. It is 10 to 20 mm long and 2 to 3 mm wide and tends to narrow caudally toward the inferior vena cava (IVC). It lies less than 1 mm from the epicardial surface, laterally in the right atrial sulcus terminalis at the junction of the superior vena cava (SVC) and right atrium. The proximity to the right phrenic nerve (RPN) is an important consideration when catheter ablation or modification of the SAN is contemplated (**Fig. 34.8**). The artery supplying the SAN branches from the right (55% to 60% of the time) or the left (40% to 45%) circumflex coronary artery and approaches the node from a clockwise or counterclockwise direction around the junction of the SVC and right atrium (**eFigs. 34.7 and 34.8**).

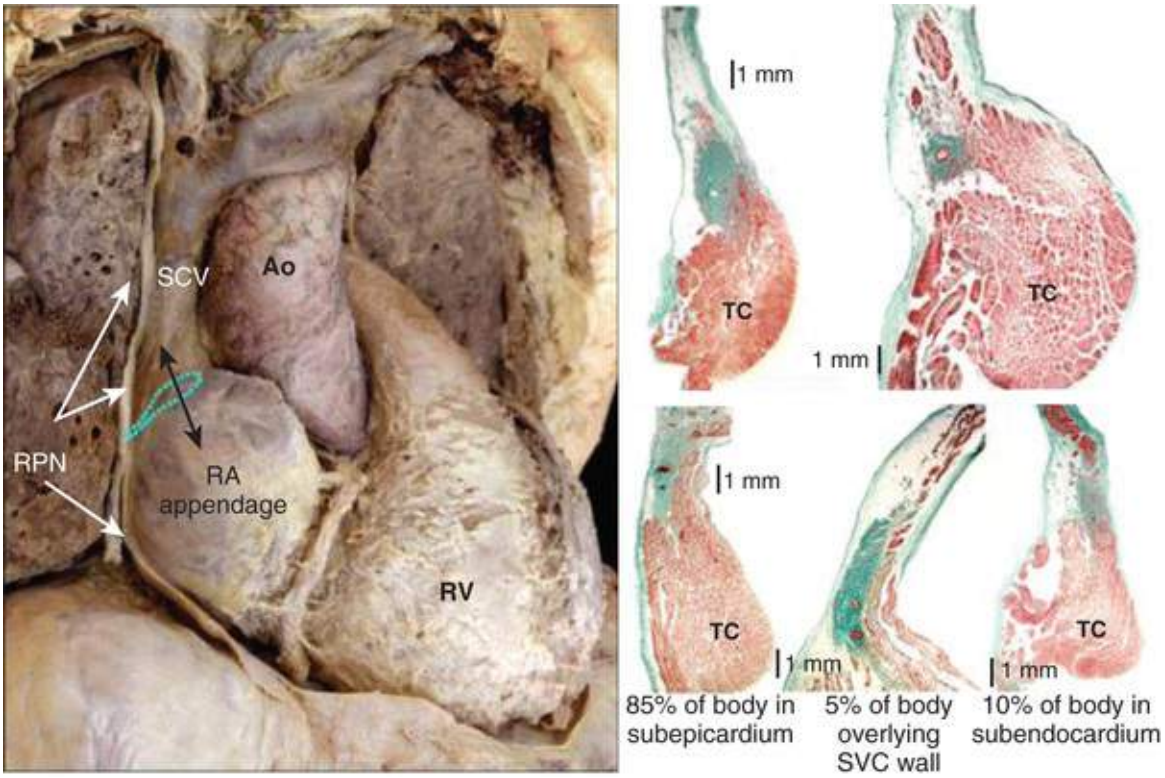


FIGURE 34.8 **Left,** Anterior view of the heart in a cadaver that has been dissected to show the course of the right phrenic nerve (*RPN*) relative to the right atrium (*RA*). The anticipated location of the sinus node outlined with the *dots*. The *double-headed arrow* represents the sectioning plane used for making the cross sections through the sinus node and the terminal crest (*TC*) shown in the histologic sections. *Ao,* Aorta; *RV,* right ventricle; *SCV,* superior caval vein. The histologic sections in the two **upper right panels** show variations in sizes of the sinus node cross section and the TC. With this stain (Masson trichrome), the node is recognizable by its fibrous matrix (*green*) and its artery. Two **lower right panels** show variations in nodal location relative to the epicardial and endocardial surfaces and to the SCV.; SVC, Superior vena cava. (From Ho SY, Sanchez-Quintana D. Anatomy and pathology of the sinus node. J Interv Card Electr 2016;46:3-8.)

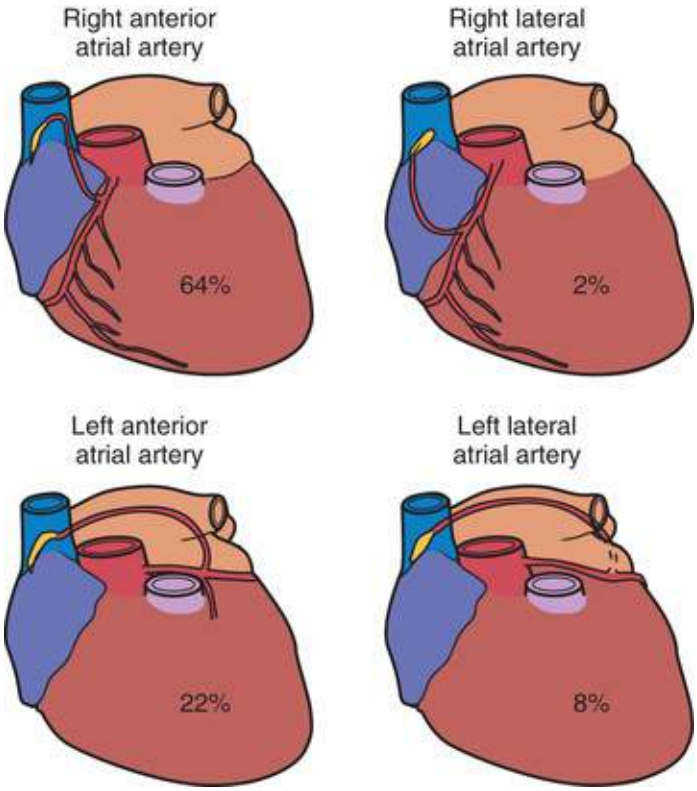
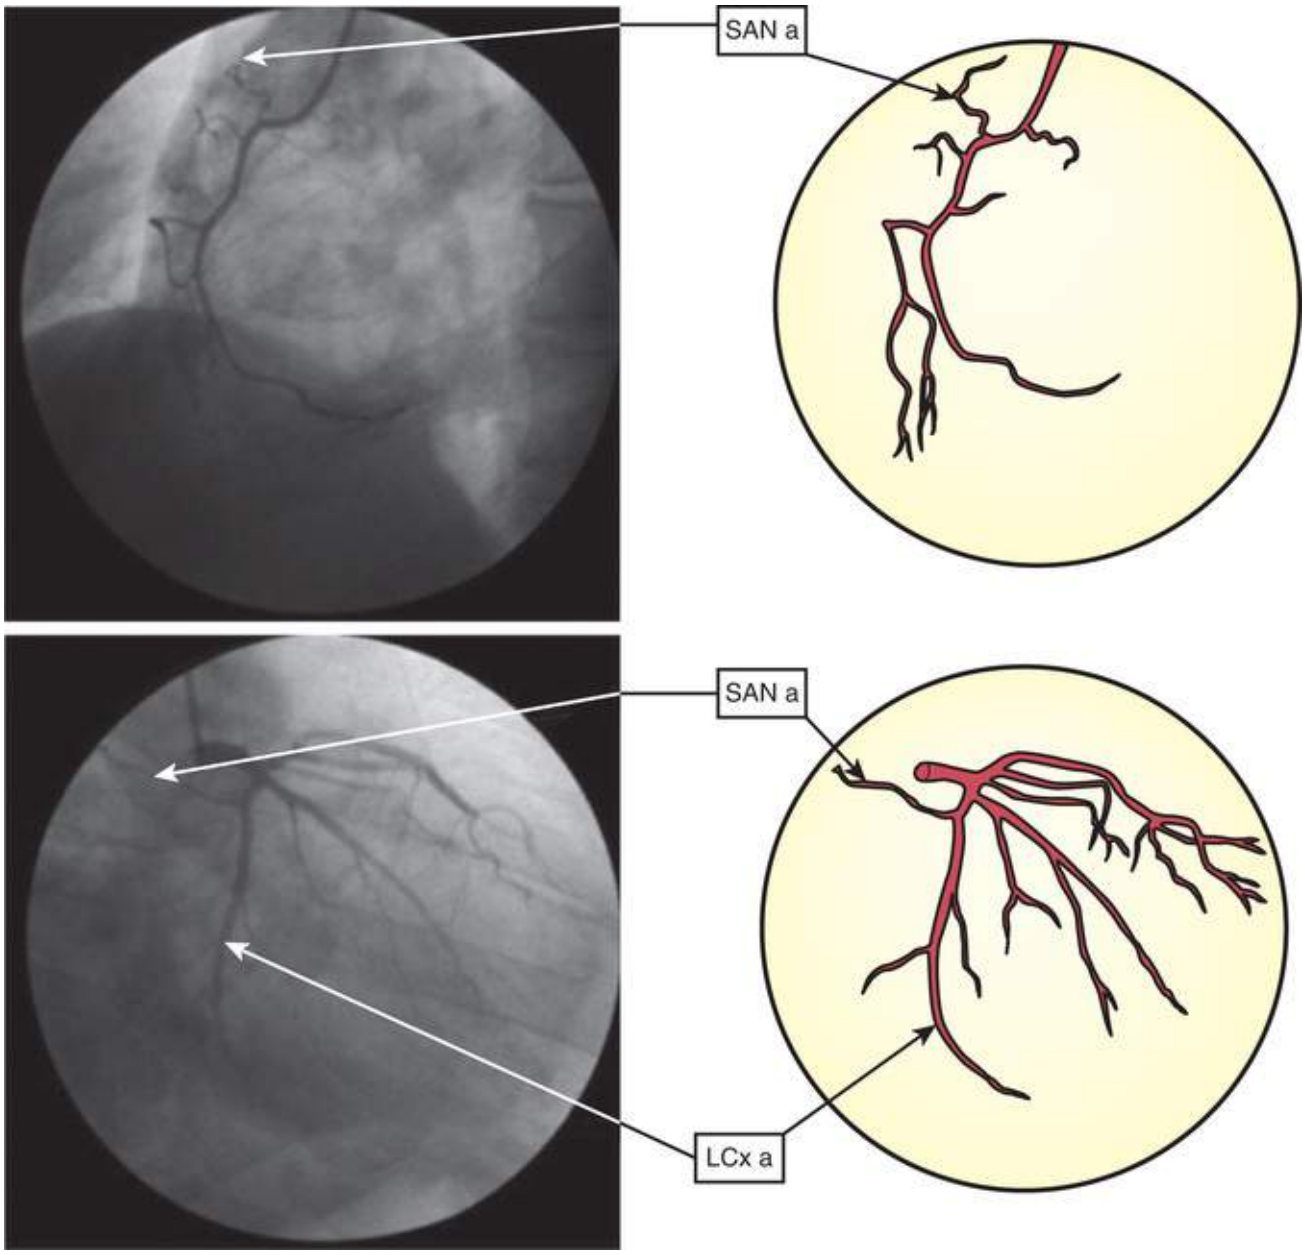


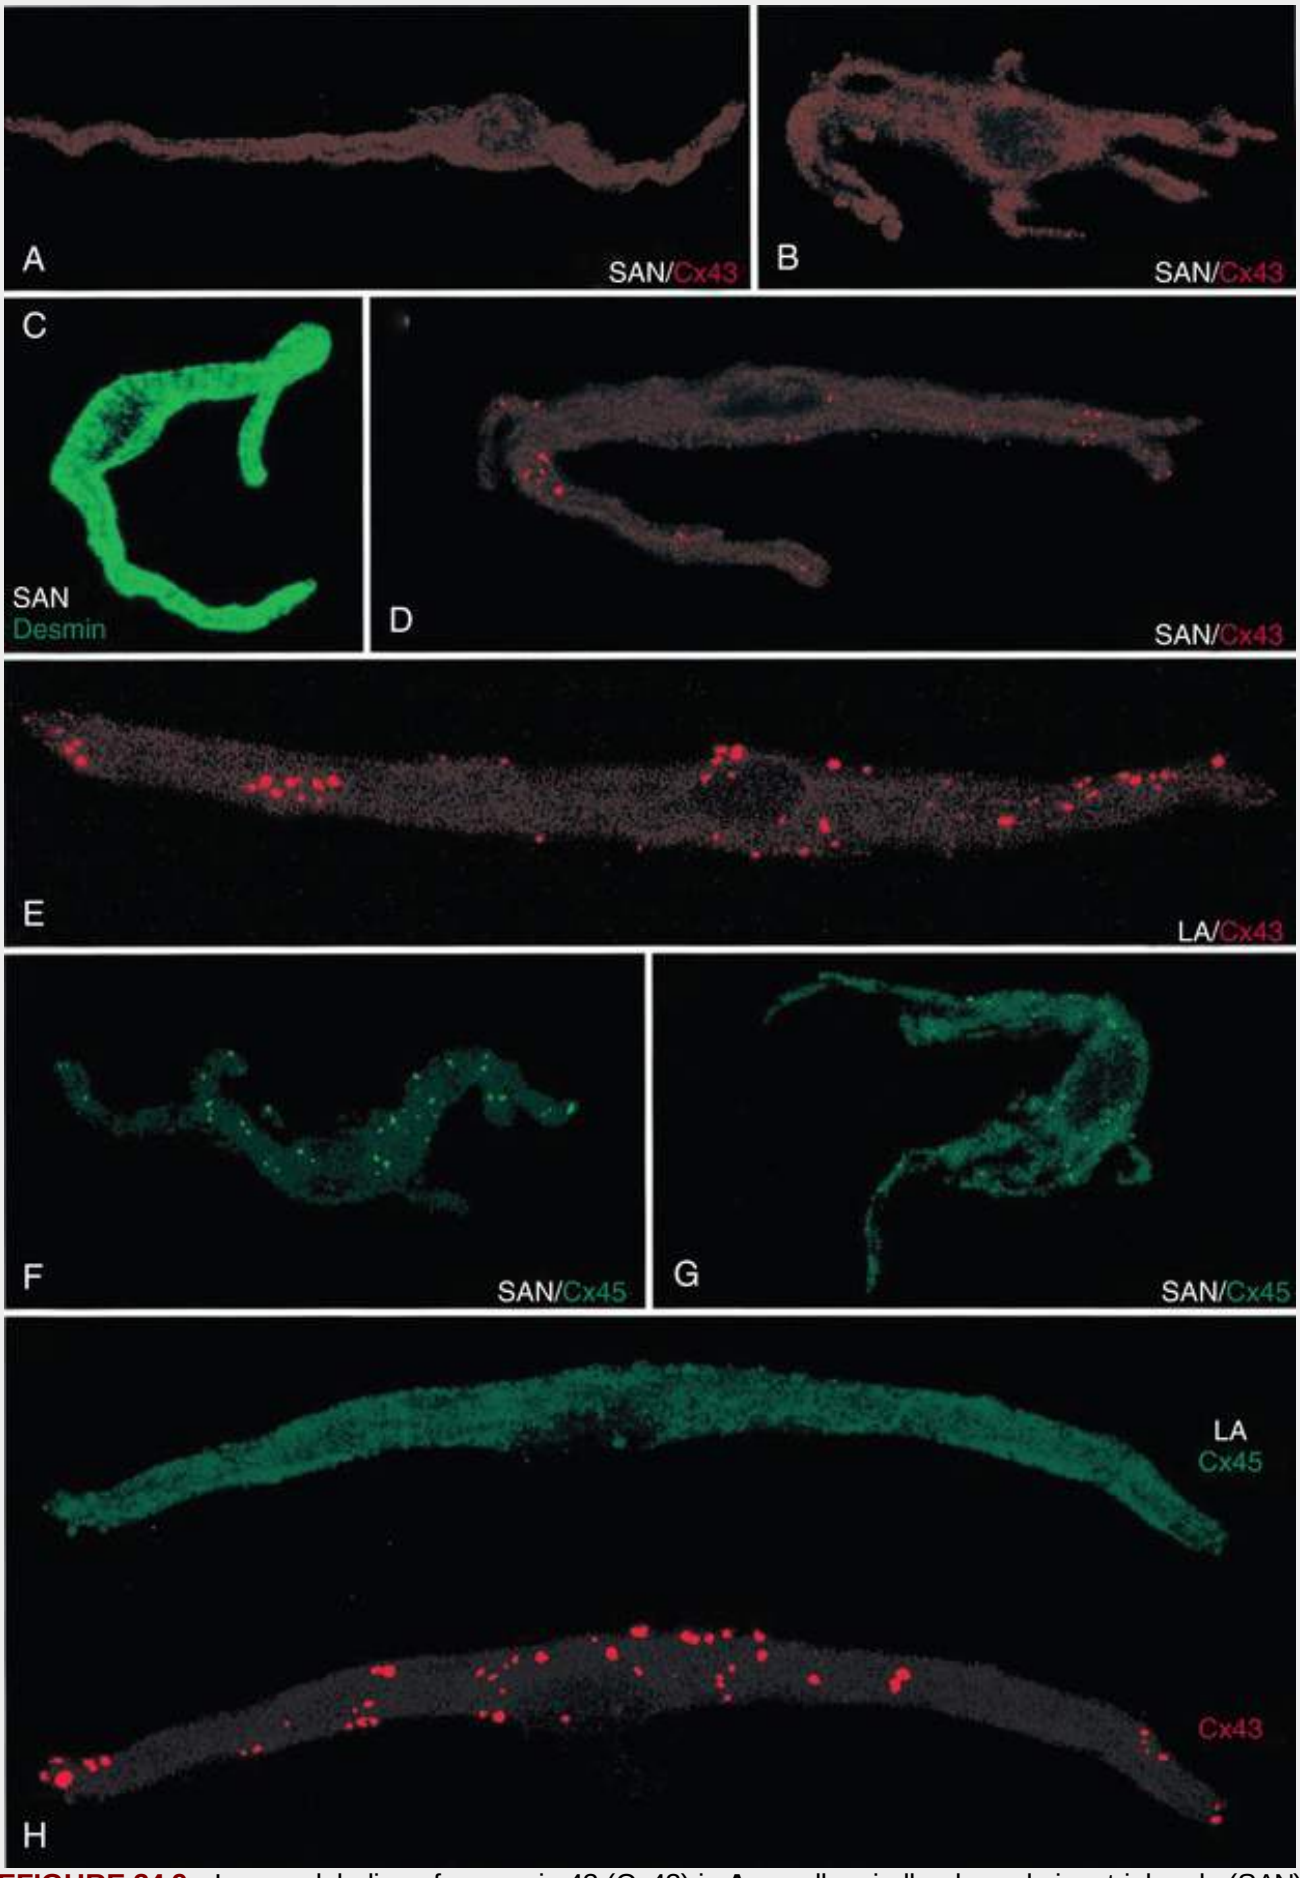
EFIGURE 34.7 Sinoatrial node (SAN) artery variations in the arterial supply of the sinus node (*yellow*). The SAN blood supply originates from a single coronary artery in 96% of cases and from both coronary arteries in 4 %. If the origin is from the left coronary artery, the nodal artery crosses the roof or the anterior wall of the left atrium. (From Ho SY, Sanchez-Quintana D. Anatomy and pathology of the sinus node. J Interv Card Electr 2016;46:3-8.)



EFIGURE 34.8 Angiographic view of the sinoatrial node blood supply. The sinoatrial node artery (SAN a) arises from the right coronary artery in a small majority of cases, but frequently is a branch of the left circumflex coronary artery (LCx a). (From Ramanathan L et al. Origin of the sinoatrial and atrioventricular nodal arteries in South Indians: an angiographic study. Arq Bras Cardiol 2009;92:342-8.)

Cellular Structure.

Cells from the SAN region exhibit a wide variety of morphologic features, including spindle- and spider-shaped cells, rod-shaped atrial cells with clear striations, and small, round cells corresponding to endothelial cells. The SAN cells stain for connexin 45 and in larger spindle-shaped cells, connexin 43 (**eFig. 34.9**). Only the spindle- and spider-shaped cells exhibit the typical electrophysiologic characteristics of pacemaker cells, including the hyperpolarization-activated current I_f and spontaneous beating under physiologic conditions.

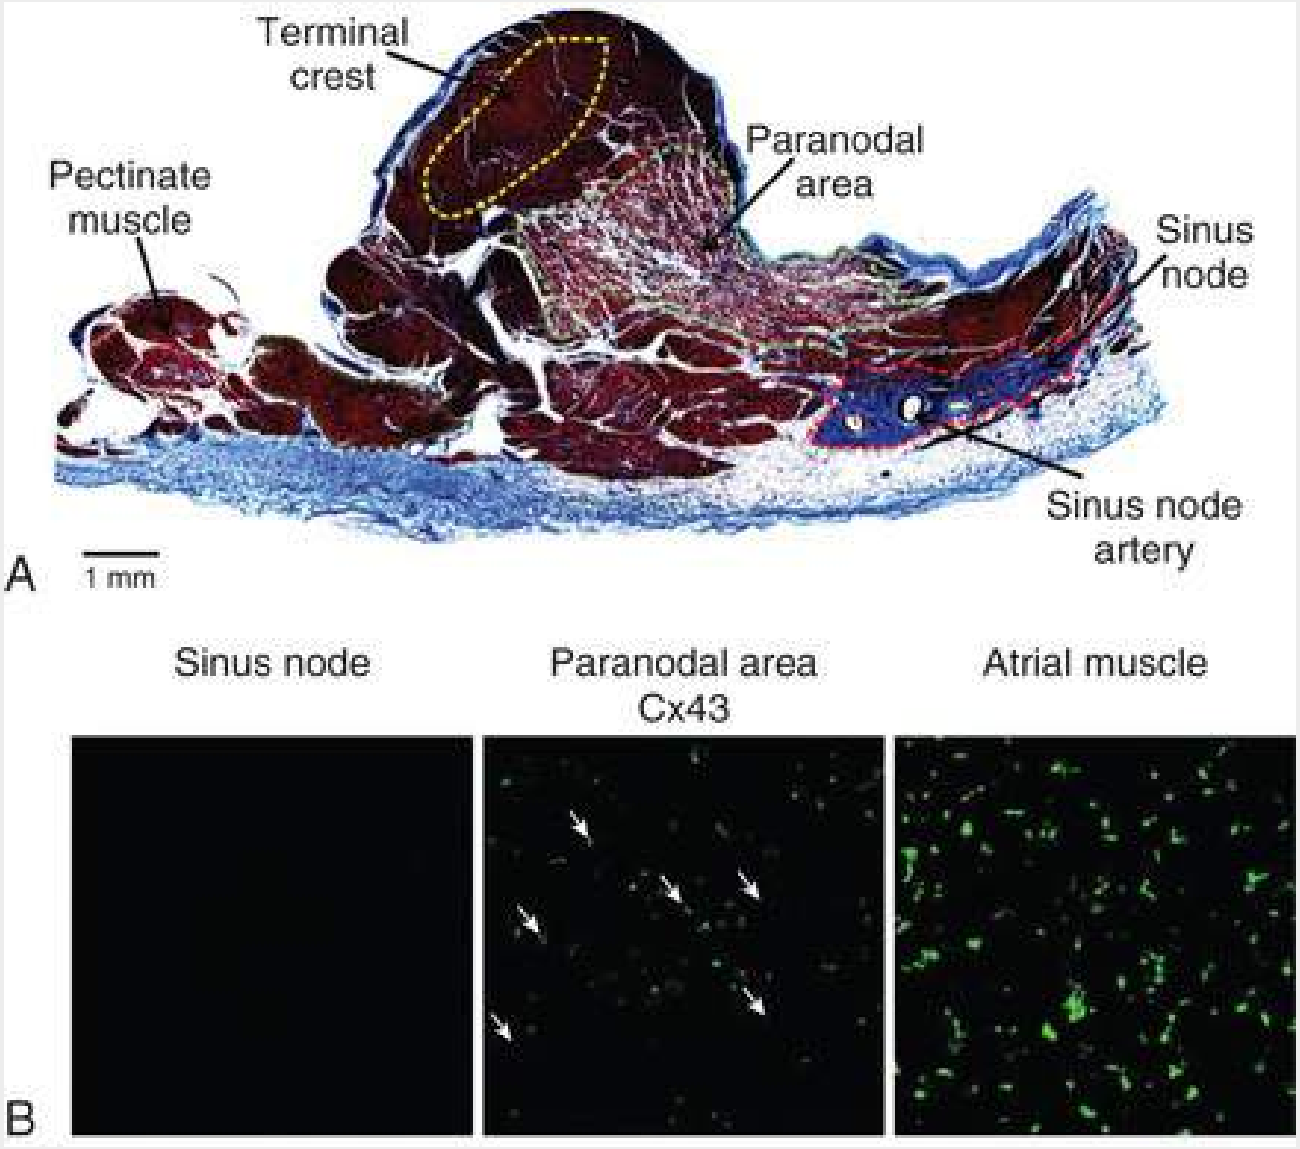


EFIGURE 34.9 Immunolabeling of connexin 43 (Cx43) in **A,** small, spindle-shaped sinoatrial node (SAN) cell, and **B,** spider-shaped SAN cell. **C,** Immunolabeling of desmin in small, spindle-shaped SAN cell. **D,** Immunolabeling of Cx43 in medium-sized, spindle-shaped SAN cell. **E,** Immunolabeling of Cx43 in left atrial (LA) cell. **F, G,** Immunolabeling of Cx45 in spider-shaped SAN cells. **H,** Immunolabeling of Cx45 (*top*) and Cx43 (*bottom*) in LA cell (cell *double-labeled*). Projection images shown in all panels. Scale bar = 20 μm. (From Honjo SY et al. Heterogeneous expression of connexins in rabbit sinoatrial node cells: correlation between

connexin isotype and cell size. Cardiovasc Res 2002;53:89.)

Function.

The ionic mechanism(s) underlying SAN cell automaticity has been controversial (see earlier, Normal Automaticity). Alternative models propose HCN channels in the surface membrane or intracellular Ca^{2+} oscillations affecting Ca^{2+}-sensitive ion channels and ion transporters in the cell surface membrane as the main regulators of the heart rate.[1] Similarly, the mechanism of *entrainment*, which enables synchronization of the electrical activity of multiple individual SAN cells to give rise to discharge of the SAN, has been uncertain. Most likely, no single cell in the SAN serves as the pacemaker. Rather, SAN cells function as electrically coupled oscillators that discharge synchronously. The interaction depends on the degree of coupling and the electrophysiologic characteristics of the individual SAN cell. The resulting rate is not just a simple average of each of the cells. With an individual pacemaker cell coupled to an average of five other cells, each likely with different electrophysiologic properties, the resulting discharge rate is not obvious. Functioning of the SAN as a pacemaker requires a delicate balance of intercellular electrical coupling. Excess electrical coupling depresses SAN automaticity because the SAN membrane potential is damped by the surrounding atrial myocardium to a more negative potential than the normal maximal diastolic potential, thereby inhibiting spontaneous diastolic depolarization. Insufficient coupling can prevent transmission of impulses to the adjacent atrial muscle. Restriction of the hyperpolarizing influence of the atrial muscle on the SAN while maintaining exit of impulses into the adjacent atrial myocardium is achieved by the composition and spatial organization of connexins, which form gap junction channels responsible for intercellular ion fluxes (see earlier). Connexins 40 and 45, but not connexin 43, are expressed in the central SAN (**eFig. 34.10B**). The major part of the crista terminalis–SAN border exhibits a sharply demarcated boundary of connexin 43–expressing atrial myocytes and connexin 40/45–expressing myocytes. On the endocardial side, a transitional zone (paranodal region; **eFig. 34.10A**) exists between the crista terminalis and the peripheral node where connexins 45 and 43 are colocalized. The colocalization of different connexin isoforms suggests that individual gap junctional channels in the transitional zone are formed by more than one connexin isoform.



EFIGURE 34.10 **A,** Masson trichrome–stained section through the human sinus node region. The node (*red dashed line*) is identified on the basis of the presence of the sinus node artery and the large amount of connective tissue (stained *blue*; myocytes stained *purple-pink*). The section also reveals the presence of a paranodal area (*green dashed line*) composed of loosely packed myocytes and sandwiched between the crista terminalis (*yellow dashed line*) and the sinus node. **B,** Cx43 is expressed prominently at cell ends in atrial muscle in the paranodal region and in the terminal crest. (From Chandler NJ et al. Molecular architecture of the human sinus node. Circulation 2009;119:1562.)

These disparate connexin phenotypes may create specific types of hybrid channels with rectifying electrical properties that ensure the maintenance of SAN pacemaker activity but diminish electrotonic interference from the atrial muscle. At the level of the intact SAN in situ, studies combining immunohistochemistry and high-resolution optical mapping of action potentials have provided structural and functional evidence of the existence of discrete exit pathways that electrically connect the SAN and atria. Electrical excitation during sinus rhythm originates in the central portion of the SAN and spreads slowly, bidirectionally (1 to 14 cm/sec) within the SAN, with failure to conduct laterally to the crista terminalis and interatrial septum. After a conduction delay of approximately 50 milliseconds within the SAN, the impulse reaches the atrial myocardium by two main superior or inferior exit pathways located a few millimeters from the leading pacemaker site. The ellipsoidal SAN is thus functionally insulated from the adjacent working myocardium. This insulation coincides with the lack of Cx43 expression and the presence of connective tissue and coronary arteries at the sinoatrial border (**eFig. 34.10**). The intranodal location of the primary pacemaking site is not fixed but rather appears to shift under varying conditions (e.g., sympathetic stimulation).

Several experimental studies have investigated the usefulness of gene delivery–based or cell-based approaches to generate biologic pacemakers in the mammalian heart. Gene-based techniques included transduction of in situ left ventricular cardiomyocytes with genes encoding a dominant-negative, inwardly rectifying potassium channel or isoforms of the HCN channel or somatic reprogramming of myocardial cells by expression of the appropriate transcription factors.[31] Cell-based approaches have used human induced pluripotent stem cell (iPSC)–derived pacemaker-like cardiomyocytes and mesenchymal stem cells ectopically expressing HCN isoforms.[32] Clinical translatability of these approaches will require additional experimental testing.[33]

Innervation.

The sinoatrial node is densely innervated by postganglionic adrenergic and cholinergic nerve terminals. Discrete vagal efferent pathways innervate both the sinoatrial (SA) and the atrioventricular (AV) region of the dog and nonhuman primate, as well as other species. Most efferent vagal fibers to the atria appear to converge first at a single fat pad between the medial portion of the SVC and the aortic root, superior to the right pulmonary artery; the fibers then project onto two other fat pads found at the junction of the IVC and left atrium and the junction of the right pulmonary vein and atrium and subsequently project to both atria. Vagal fibers to the SA and AV nodes also converge at the SVC–aortic root fat pad before projection to the right pulmonary vein and IVC fat pads. Although the SAN region contains amounts of norepinephrine equivalent to those in other parts of the right atrium, acetylcholine, acetylcholinesterase, and choline acetyltransferase (enzyme necessary for ACh synthesis) have been found in greatest concentration in the SAN, with the next highest concentration located in the right and then the left atrium. The ACh concentration in the ventricles is only 20% to 50% of that in the atria.[1]

Neurotransmitters modulate the discharge rate of the SAN by stimulation of beta-adrenergic and muscarinic receptors. Both $beta_1$- and $beta_2$-adrenoceptor subtypes are present in the SAN. Human sinoatrial nodes contain more than a threefold greater density of beta-adrenergic and muscarinic cholinergic receptors than adjacent atrial tissue. The functional significance of beta-adrenoceptor subtype diversity in the SAN is unclear. Binding of receptor agonists released from sympathetic nerve terminals causes a positive chronotropic response through a $beta_1$-receptor–activated pathway involving the stimulatory guanosine triphosphate (GTP) regulatory protein (G_s), activation of adenylyl cyclase, intracellular accumulation of cAMP, stimulation of cAMP-dependent PKA, and phosphorylation of ion-handling proteins, which ultimately results in an increased SAN discharge rate (see earlier, Phases of the Cardiac Action Potential). The negative chronotropic response of vagal stimulation is mediated by ACh binding to and ensuing activation of M_2 muscarinic receptors.[34,35]

In addition to its negative chronotropic effect, acetylcholine also prolongs intranodal conduction time, at times to the point of SAN exit block. ACh increases, whereas norepinephrine decreases refractoriness in the center of the SAN. The phase (timing) in the cardiac cycle at which vagal discharge occurs and the background sympathetic tone importantly influence vagal effects on the sinus rate and conduction (see earlier, Normal Automaticity). After cessation of vagal stimulation, SAN automaticity may accelerate transiently (postvagal tachycardia). The neurotransmitters neuropeptide Y (NPY) and vasoactive intestinal peptide (VIP) are localized in sympathetic and parasympathetic nerve terminals, respectively. VIP reversibly increases I_f, whereas NPY reversibly decreases I_f. The role of other peripheral neurotransmitters (e.g., calcitonin gene–related peptide, substance P) in controlling sinoatrial node electrophysiology is unclear.[1]

Atrioventricular Junctional Area and Intraventricular Conduction System

Atrioventricular Node

Based on histology and immunolabeling, the normal AV junctional area is composed of multiple distinct structures, including transitional tissue, inferior nodal extension, compact portion, penetrating bundle, His bundle, atrial and ventricular muscle, central fibrous body, tendon of Todaro, and valves[36] (**Fig. 34.9A and eFig. 34.11**).

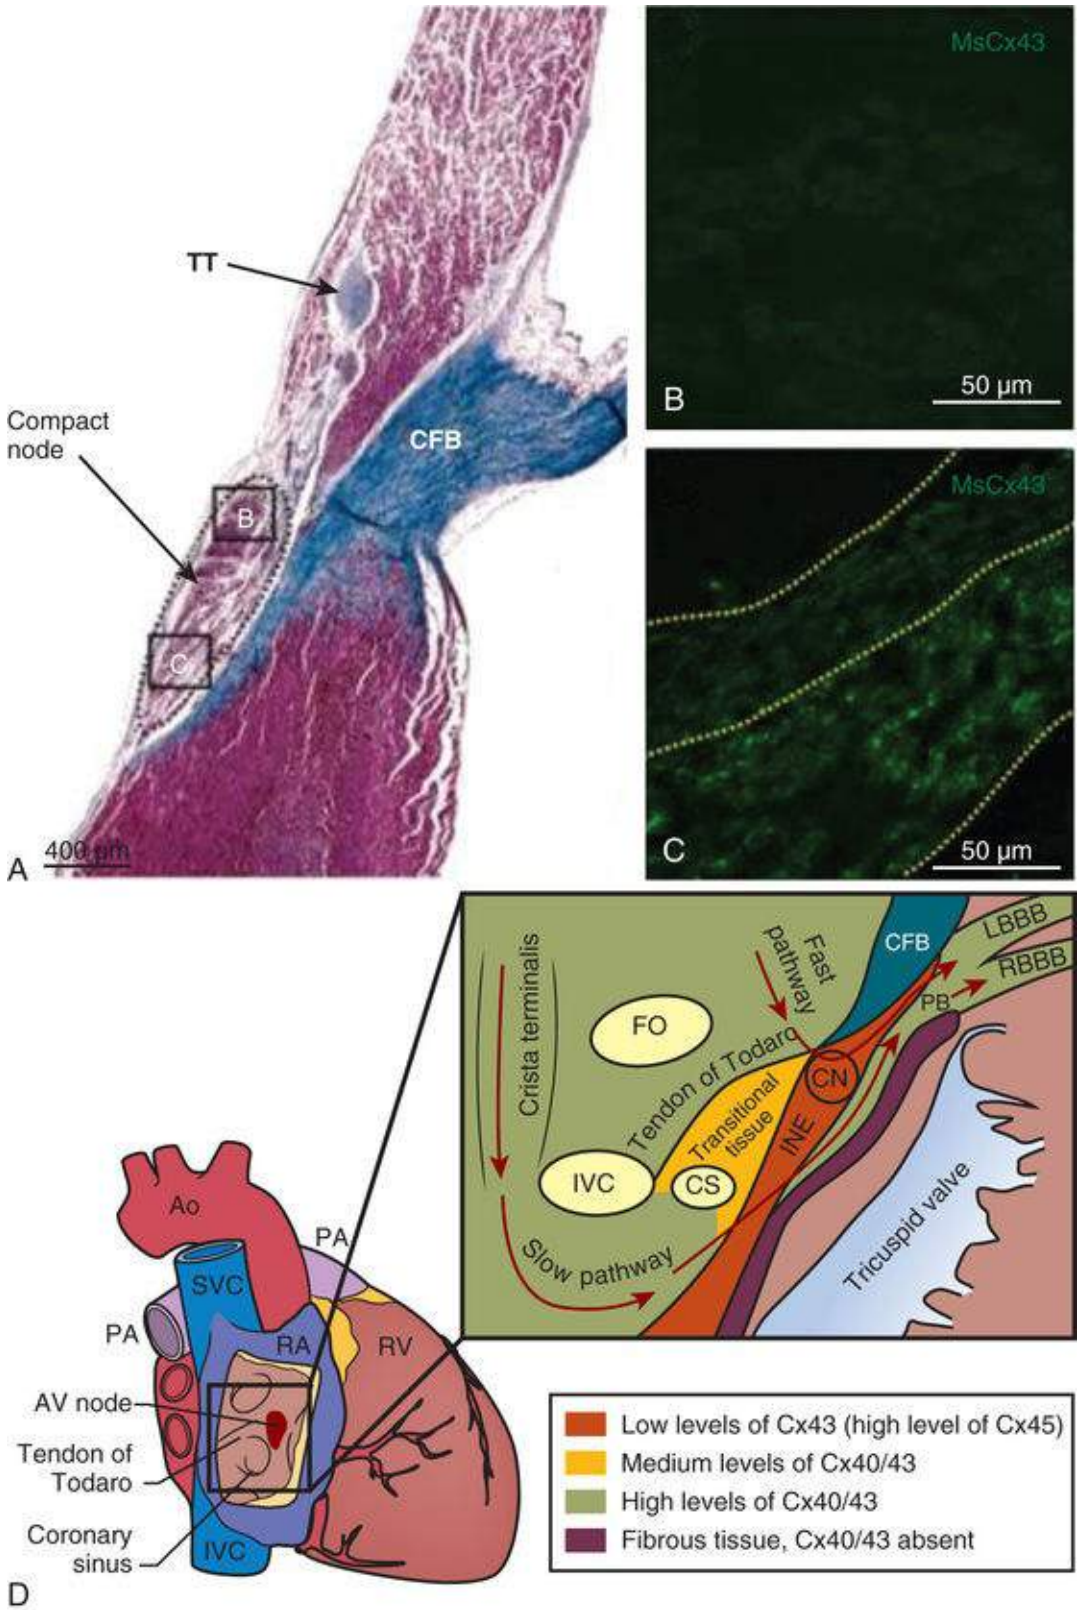


FIGURE 34.9 **A,** Masson's trichrome–stained section through the compact node of the rabbit heart (*red,* myocytes; *blue,* connective tissue). The compact node is enclosed with a *dashed line*. **B, C,** High-magnification images of boxed regions in **A** (**B** is the compact node; **C** is the lower nodal bundle) showing Cx43 expression (immunofluorescence, *bright-green* punctate spots). In **C,** *dotted yellow lines* divide tissue into Cx43-negative (*top*) and Cx43-positive (*bottom*) regions. (Modified from Dobrzynski et al. Site of origin and molecular substrate of atrioventricular junctional rhythm in the rabbit heart. Circ Res 2003;93:1102-10.) *CFB,* Central fibrous body; *TT,* tendon of Todaro. **D,** Color-coded map of the distribution of connexins (Cx) in the atrioventricular (AV) junction. *Ao,* Aorta; *CN,* compact AV node; *CS,* coronary sinus; *FO,* foramen ovale; *INE,* inferior nodal extension; *IVC,* inferior vena cava; *LBBB,* left bundle branch block; *PA,* pulmonary artery; *PB,* penetrating bundle; *RA,* right atrium; *RBBB,* right bundle branch block; *RV,* right ventricle. (From Temple IP et al. Connexins and the atrioventricular node. Heart Rhythm 2010;10:297.)

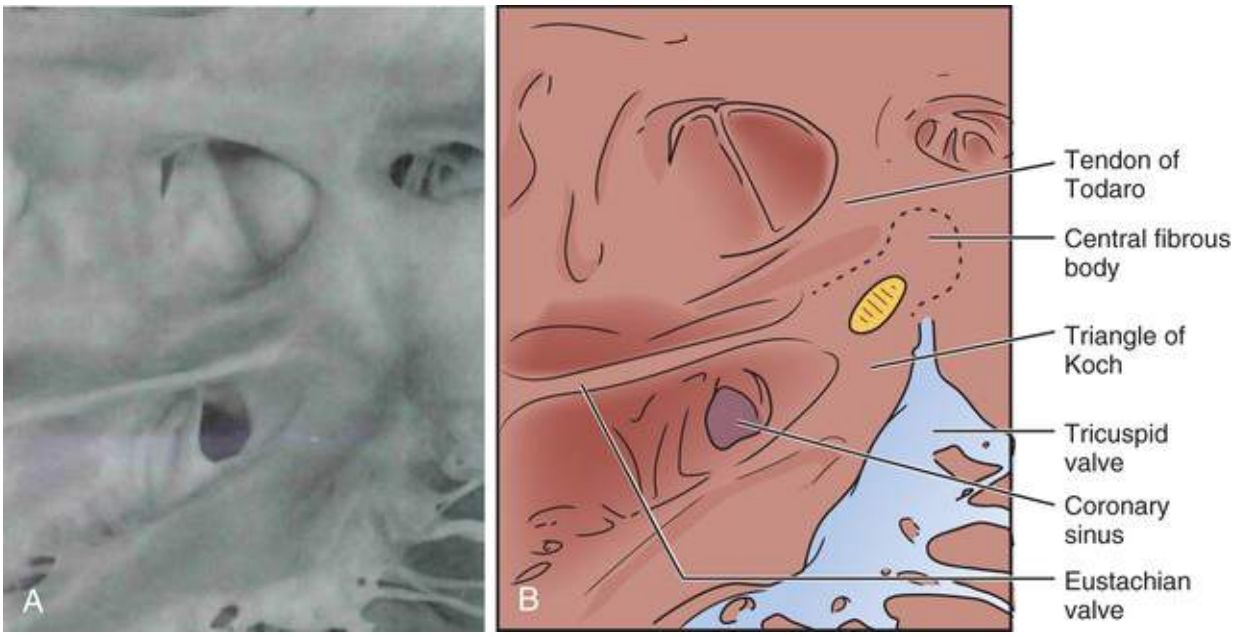
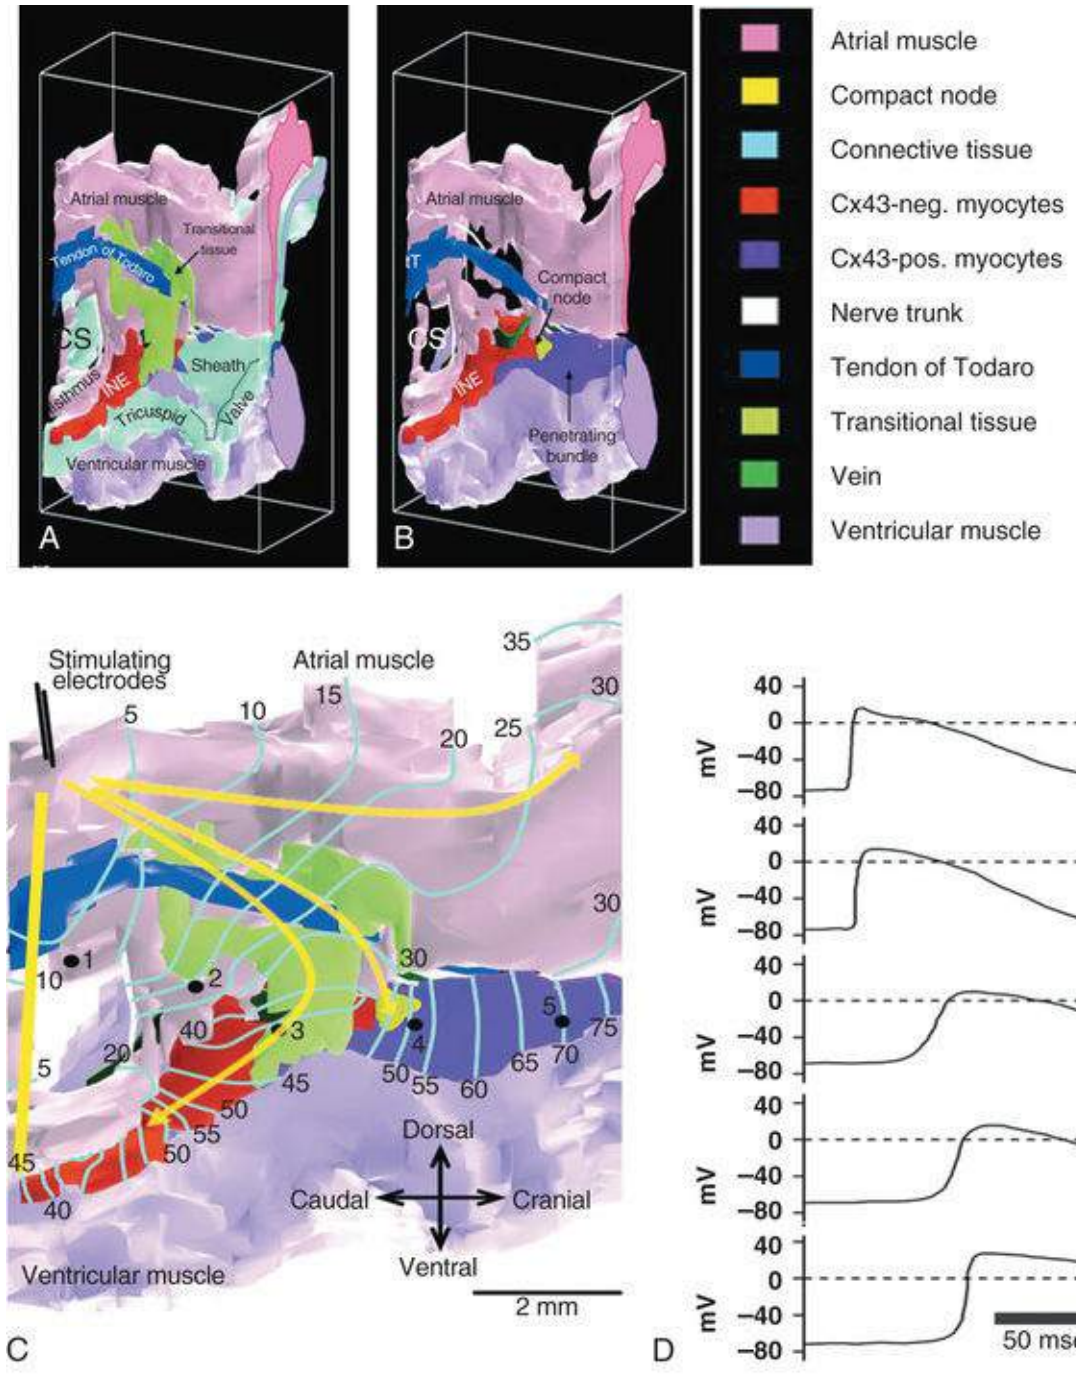


EFIGURE 34.11 **A,** Photograph of a normal human heart showing the anatomic landmarks of the triangle of Koch. This triangle is delimited by the tendon of Todaro superiorly, by the fibrous commissure of the flap guarding the openings of the inferior vena cava and coronary sinus, by the attachment of the septal leaflet of the tricuspid valve inferiorly, and by the mouth of the coronary sinus at the base. **B,** The *stippled area (orange)* adjacent to the central fibrous body is the approximate site of the compact atrioventricular node. (From Janse MJ et al. "AV nodal" reentry: I. "AV nodal" reentry revisited. J Cardiovasc Electrophysiol 1993;4:561.)

At the level of the AV junction, the tract of nodal tissue is divided into two major components, the inferior nodal extension and the penetrating bundle. The *inferior nodal extension* (INE) is located between the coronary sinus and the tricuspid valve, and the end of the INE is covered by transitional tissue (**Fig. 34.9D**). The small myocytes in the INE are dispersed among connective tissue and do not express connexin 43, whereas myocytes in the transitional zone do express Cx43; however, unlike the Cx43-positive atrial myocytes in the working myocardium, they are loosely packed between collagen septa (**Fig. 34.9B-C and eFig. 34.12**). The INE is continuous with the penetrating bundle, which penetrates the fibrous tissue separating the atria and ventricles and emerges in the ventricles as the bundle of His. Both structures are covered by connective tissue and are therefore enclosed. Myocytes in the *penetrating bundle* express Cx43 and are dispersed among connective tissue. A tract of Cx43-positive nodal tissue projects into the Cx43-negative INE.

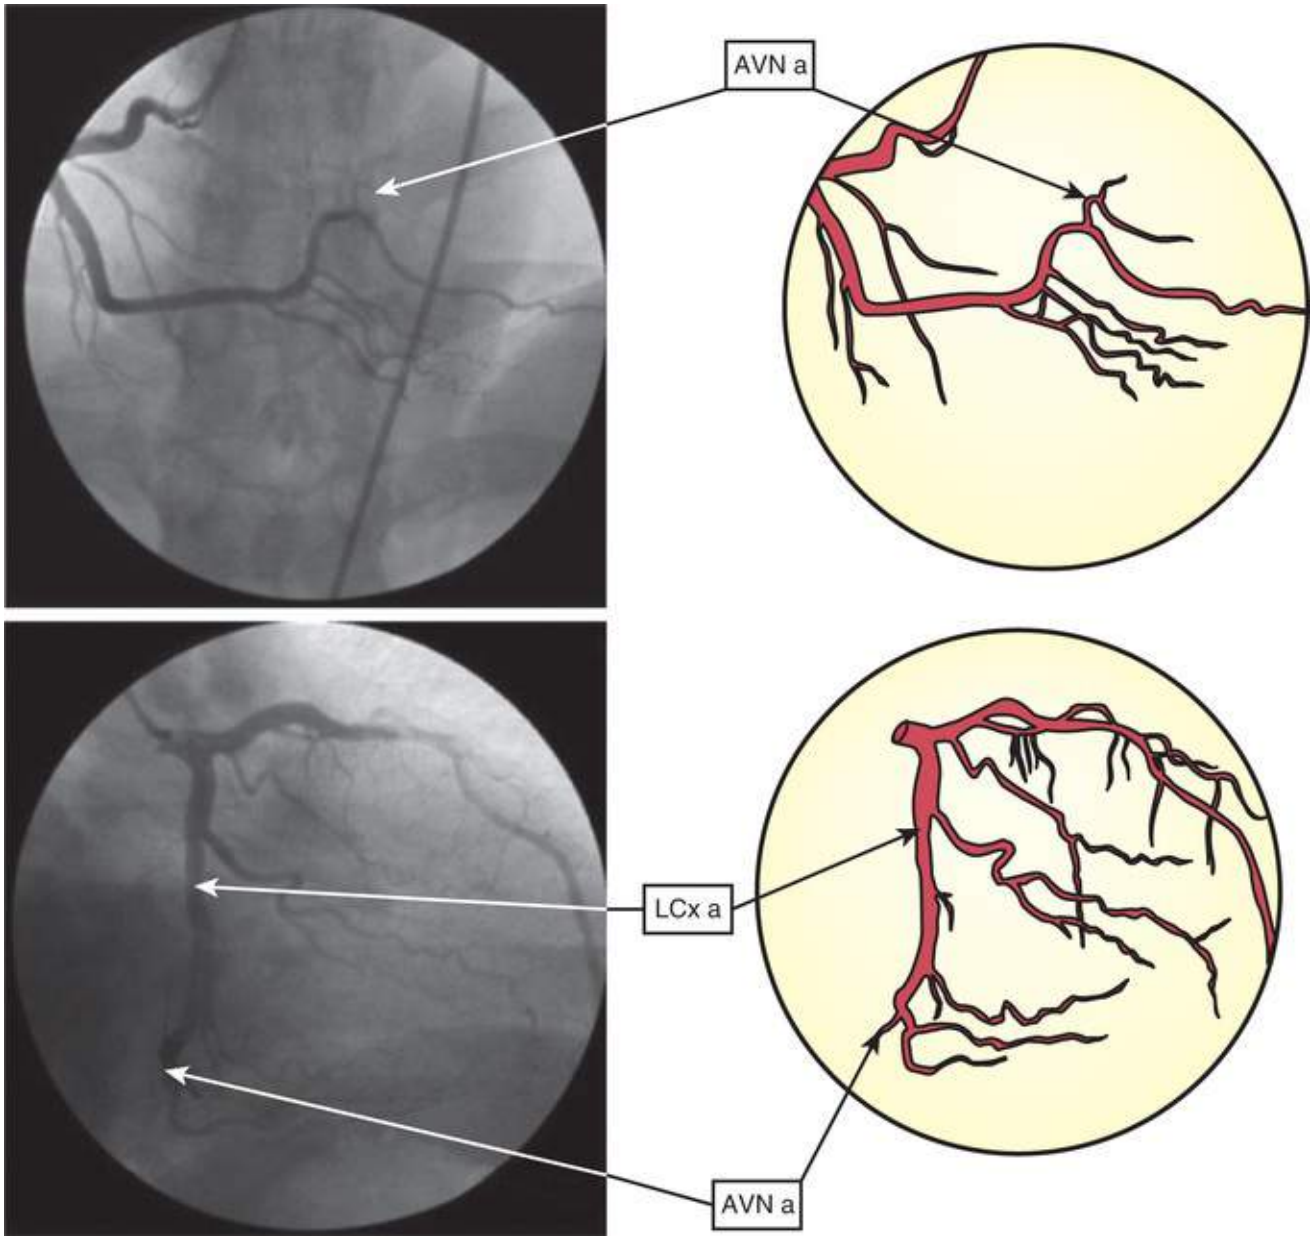


EFIGURE 34.12 **A, B,** Computer-generated three-dimensional anatomic model of the atrioventricular (AV) node as viewed from the right atrium-ventricle. **A** shows all cell types. **B** shows the model after removal of transitional and connective tissue. The inferior nodal extension (*INE*) is located between the coronary sinus (*CS*) and the tricuspid valve; the end of the INE is covered by transitional tissue; the penetrating bundle begins at the apex of the triangle of Koch (formed by CS, tendon of Todaro [*tT*], and tricuspid valve); and the penetrating bundle and His bundle are covered by connective tissue ("sheath"). After removal of the transitional and connective tissue, one sees protraction of a connexin 43 (Cx43)–positive portion of nodal tissue into the Cx43-negative INE. The compact node is located at the junction of Cx43-negative and Cx43-positive nodal tissue. **C, D,** Structure-function relationships of the AV node. **C,** Schematic representation of the sequence of anterograde AV conduction by using a combination of mathematical modeling and experimental mapping of action potential propagation. The preparation is electrically stimulated at the crista terminalis. The activation sequence is shown as isochrones at 5-millisecond intervals. *Yellow arrows* delineate the conduction pathways. (See also Video 34.1.) **D,** Transmembrane action potentials recorded at locations indicated by *black dots* in C (numbered *1* through *5*). (Modified from Li J et al. Computer three dimensional reconstruction of the atrioventricular node. Circ Res 2008;102:975.)

The compact portion of the AV node (**Fig. 34.9A**) is a superficial structure lying just beneath the right atrial endocardium, anterior to the ostium of the coronary sinus, and directly above the insertion of the septal leaflet of the tricuspid valve. It is at the apex of a triangle formed by the tricuspid annulus and the

tendon of Todaro (**Fig. 34.9D**), which originates in the central fibrous body and passes posteriorly through the atrial septum to continue with the eustachian valve. The term *triangle of Koch*, however, has to be used with caution because histologic studies of anatomically normal adult hearts have demonstrated that the tendon of Todaro, which forms one side of the triangle of Koch, is absent in about two thirds of hearts. The compact node is located at the junction where the Cx43-negative nodal tissue meets the Cx43-positive nodal tissue (**Fig. 34.9B-D**).

In 85% to 90% of human hearts, the arterial supply to the AV node is derived from a branch of the right coronary artery that originates at the posterior intersection of the AV and interventricular grooves (crux). A branch of the circumflex coronary artery provides the arterial supply to the AV node in the remaining hearts (**eFig. 34.13**).



EFIGURE 34.13 The atrioventricular node artery (AVN a) arises from the posterior descending branch of the right coronary artery in the large majority of cases. AVN artery arises from the left circumflex coronary artery (LCx a) in most of the remaining cases, although in some circumstances, there is dual blood supply. (From Ramanathan L et al. Origin of the sinoatrial and atrioventricular nodal arteries in South Indians: an angiographic study. Arq Bras Cardiol 2009;92:342-8.)

During normal anterograde AV conduction, the action potential propagates from the SAN through atrial working myocardium (the existence of specialized internodal conduction pathways has been controversial) and enters the tract of nodal tissue at two points (**Fig. 34.9D and eFig. 34.12**; see also Video 34.1). The first point is at the end of the INE (next to the penetrating bundle) via the transitional tissue. This conduction pathway most likely corresponds to the fast-pathway route previously observed in electrical mapping experiments.[36] Second, the action potential enters toward the beginning of the INE. This conduction pathway probably constitutes the slow-pathway route. The action potential cannot enter the nodal tissue at other tissue points because the nodal and atrial tissues are isolated from each other by a vein along this length of tissue. From the two entry points, the action potentials propagate both anterogradely and retrogradely along the INE and eventually annihilate each other. The action potential entering the nodal tract via the transitional zone also propagates into the compact node and then reaches the His bundle and propagates down the left and right bundle branches.

Transmembrane action potentials recorded from cardiomyocytes in situ at various locations within the nodal tract exhibit distinct shapes and time courses. Action potentials from extranodal atrial tissue and the His bundle have more hyperpolarized diastolic potentials and faster upstrokes (**Fig. 34.4B, E**) than do myocytes in the transitional zone and penetrating bundle (**Fig. 34.4C and eFig. 34.12D**). This smaller rate of depolarization results in slowing of conduction across the compact portion and penetrating bundle (conduction velocity <10 cm/sec versus 35 cm/sec in atrial working myocardium), thereby giving rise to the AV conduction delay.

Bundle of His (Penetrating Portion of Atrioventricular Bundle)

This structure is the continuation of the penetrating bundle on the ventricular side of the AV junction before it divides to form the left and right bundles. Myocytes in the His bundle are small and Cx43 positive (**see Fig. 34.9D**). However, large, well-formed fasciculoventricular connections between the penetrating portion of the AV bundle and the ventricular septal crest are rarely found in adult hearts. Branches from the anterior and posterior descending coronary arteries supply the upper muscular interventricular septum with blood, which makes the conduction system at this site more impervious to ischemic damage unless the ischemia is extensive.

Bundle Branches (Branching Portion of Atrioventricular Bundle)

The bundle branches begin at the superior margin of the muscular interventricular septum, immediately beneath the membranous septum, with cells of the left bundle branch (LBB) cascading downward as a continuous sheet onto the septum beneath the noncoronary aortic cusp (**Fig. 34.10A**). The AV bundle may then give off other LBBs, sometimes constituting a true bifascicular system with an anterosuperior branch, in other hearts giving rise to a group of central fibers, and in still others appearing more as a network without clear division into a fascicular system (**Fig. 34.10B, C**). The right bundle branch continues intramyocardially as an unbranched extension of the AV bundle down the right side of the interventricular septum to the apex of the right ventricle and base of the anterior papillary muscle. In some human hearts, the His bundle traverses the right interventricular crest and gives rise to a right-sided narrow stem origin of the LBB. The anatomy of the LBB system can be variable and may not conform to a constant bifascicular division. However, the concept of a trifascicular system remains useful to both electrocardiographers and clinicians (**see Chapter 12**).

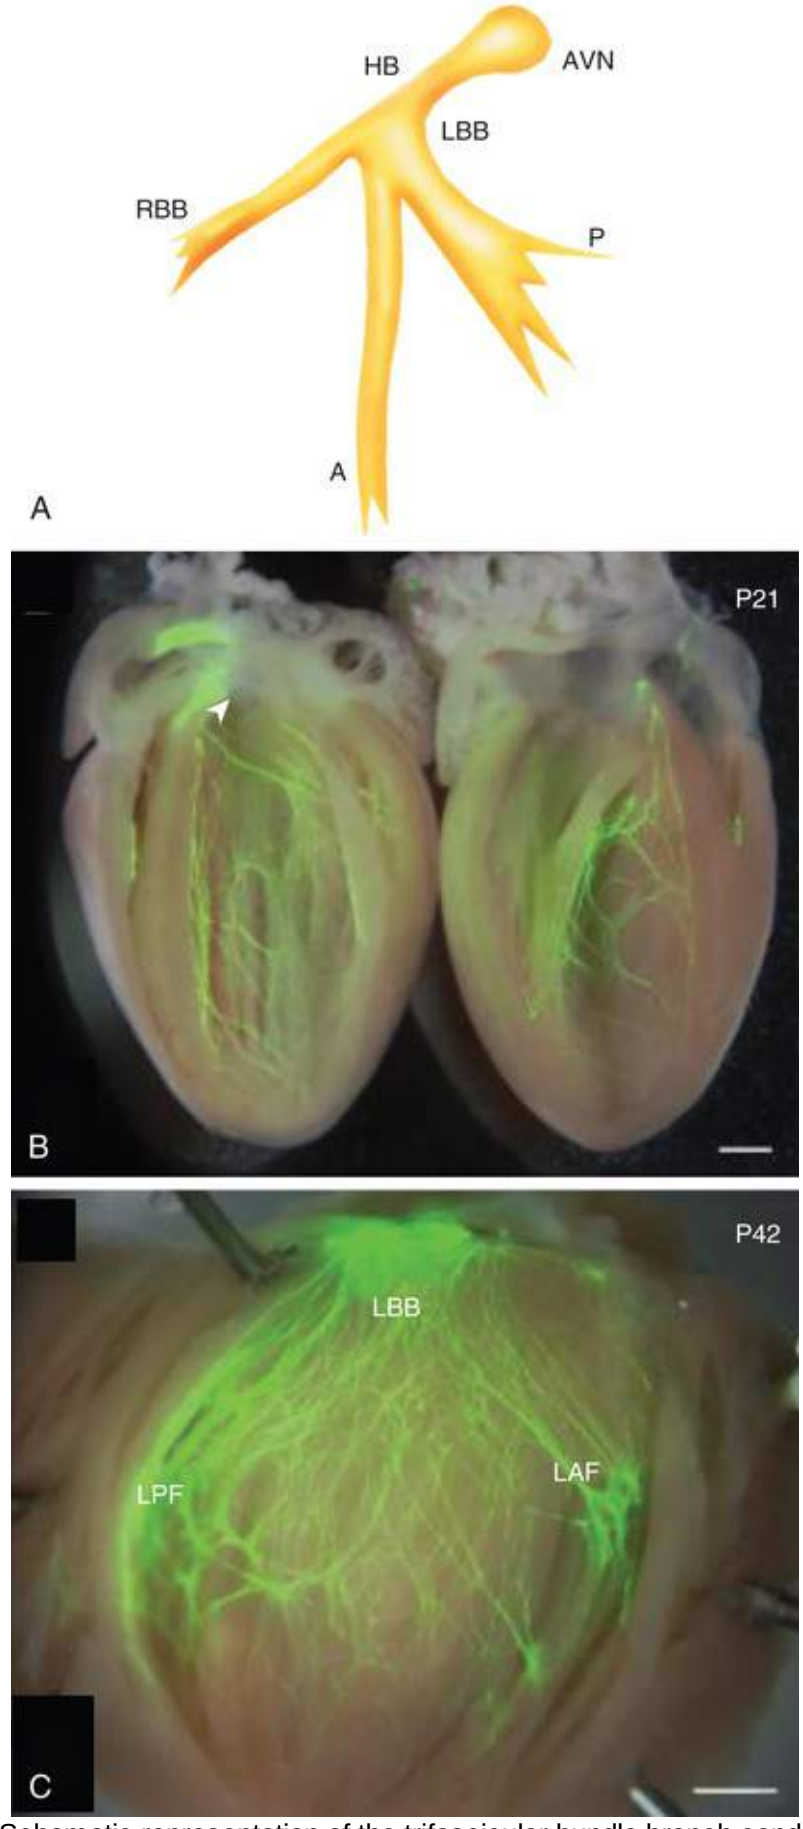


FIGURE 34.10 **A,** Schematic representation of the trifascicular bundle branch conduction system. **B, C,** Whole mount of murine hearts expressing contactin-2 eGFP reporter gene (Cntn2^{EGFP}) demonstrate the presence of Cntn2 throughout the cardiac conduction system. The hearts are from mice **(B)** 21 days (P21) and **(C)** and 42 days (P42) postpartum. There is robust expression of Cntn2 within the atrioventricular node (*AVN*) (*arrowhead*) His bundle (*HB*), bundle branches, and Purkinje network. Scale bars = 500 µm. *LAF,* Left anterior fascicle; *LBB,* left bundle branch; *LPF,* left posterior fascicle; *RBB,* right bundle branch. (**A,** Modified from Rosenbaum MB et al. The Hemiblocks. illustration; **B, C,** from Maass K et al. Isolation and characterization of embryonic stem cell–derived cardiac Purkinje cells. Stem Cells 2015;33:1102-12.)

Terminal Purkinje Fibers

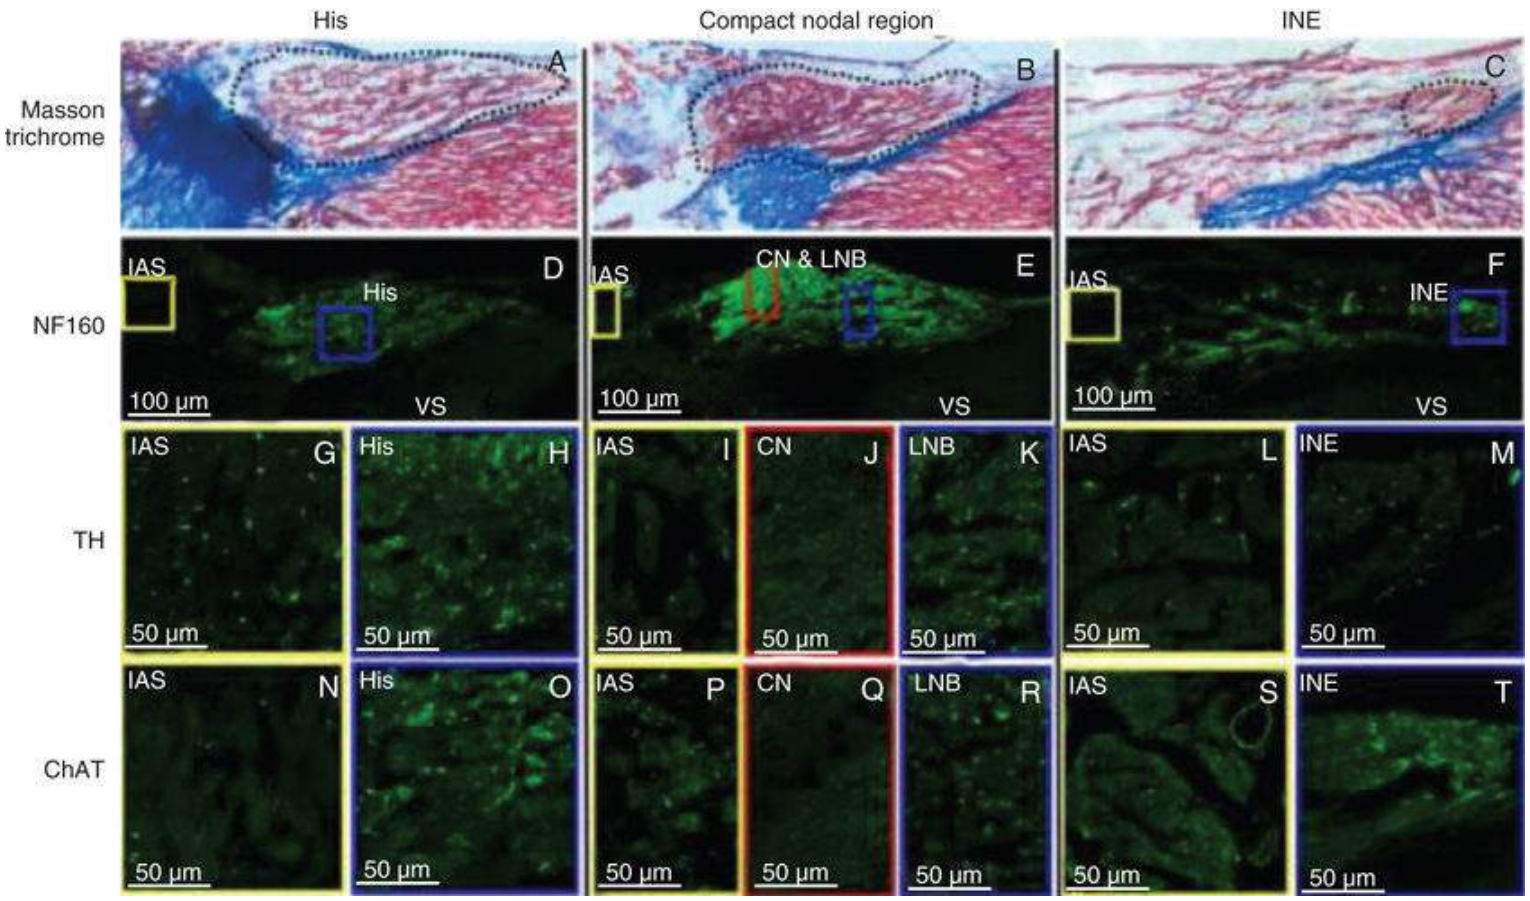
The Purkinje fibers connect with the ends of the bundle branches to form interweaving networks on the endocardial surface of both ventricles and transmit the cardiac impulse almost simultaneously to the entire right and left ventricular endocardium. Purkinje fibers tend to be less concentrated at the base of the ventricle and at the papillary muscle tips. They penetrate the myocardium for varying distances, depending on the species. In humans, Purkinje fibers apparently penetrate only the inner third of the endocardium, whereas in pigs, they almost reach the epicardium. Such variations could influence changes produced by myocardial ischemia, for example, because Purkinje fibers appear to be more resistant to ischemia than are ordinary myocardial fibers. Purkinje myocytes are found in the His bundle and bundle branches, cover much of the endocardium of both ventricles (**see Fig. 34.10B**), and align to form multicellular bundles in longitudinal strands separated by collagen. Although conduction of cardiac impulses appears to be their major function, free-running Purkinje fibers composed of many Purkinje cells in a series, sometimes called *false tendons*, are capable of contraction. Action potentials propagate within the thin Purkinje fiber bundles from the base to the apex before activation of the surrounding myocytes occurs. Purkinje myocytes have less well-developed transverse tubules (**see eFig. 34.5B**), which reduces membrane capacitance and thus accelerates action potential propagation. Propagation of action potentials within the His-Purkinje system and working myocardium is mediated by connexins. Ventricular myocytes express mainly Cx43, and Purkinje fibers express connexins 40 and 45. The molecular identity of the connexin type that enables transmission of impulses at the Purkinje fiber–myocyte junction (PMJ) is unclear. It is also still not clear how the small amount of depolarizing current provided by the thin bundle of Purkinje fibers can activate a much larger mass of ventricular muscle (current-to-load mismatch). It is possible that individual gap junctional channels at the PMJ are formed by more than one connexin isoform. These disparate connexin phenotypes may create specific types of hybrid channels with unique properties that ensure safe conduction at the PMJ. Because Purkinje cells have markedly longer repolarization times than surrounding myocytes (**see Fig. 34.3E**), these connexin hybrids could also decrease entrainment of repolarization at the PMJ and thereby increase repolarization gradients.

Innervation of Atrioventricular Node, His Bundle, and Ventricular Myocardium

Pathways of Innervation

The AV node and His bundle region are innervated by a rich supply of cholinergic and adrenergic fibers with densities exceeding those found in the ventricular myocardium.[1,34,35] Immunolabeling with markers for sympathetic and parasympathetic nerves revealed nonuniform innervation density in the AV junctional area. For example, the INE has been shown to exhibit a higher density of both nerve types than the working atrial myocardium, whereas the opposite is true for the compact node (**eFig. 34.14**). Ganglia, nerve fibers, and nerve nets lie close to the AV node. Parasympathetic nerves to the AV node region enter the canine heart at the junction of the IVC and the inferior aspect of the left atrium, adjacent to the entrance to the coronary sinus. Nerves in direct contact with AV nodal fibers have been observed, along with agranular and granular vesicular processes, which presumably represent cholinergic and adrenergic

processes.



EFIGURE 34.14 Innervation of atrioventricular node (AVN). **A to C,** Masson trichrome staining of the His bundle, compact AVN region, and inferior nodal extension (INE). **D to F,** Neurofilament 160 (NF160) staining of sections adjacent to those shown in **A, B,** and **C** showing that NF160 specifically marks the rabbit conduction system. **G to M,** Tyrosine hydroxylase (TH) staining of areas marked with boxes in **D to F. N to T,** Choline acetyltransferase (ChAT) staining of areas marked with boxes in **D to F.** Interatrial septum (IAS) staining was actually taken from areas 200 to 300 µm to the left of the areas marked with *yellow boxes* in **D, E,** and **F.** *LNB,* Lower nodal bundle. Other abbreviations as in previous figures. (From Hucker WJ et al. Autonomic control and innervation of the atrioventricular junctional pacemaker. Heart Rhythm 2007;4:1326-35.)

In general, autonomic neural input to the heart exhibits some degree of "sidedness," with the right sympathetic and vagal nerves affecting the sinoatrial node more than the AV node and the left sympathetic and vagal nerves affecting the AV node more than the SA node. The distribution of neural input to the SA and AV nodes is complex because of substantial overlapping innervation. Despite the overlap, specific branches of the vagal and sympathetic nerves can be shown to innervate certain regions preferentially. Supersensitivity to acetylcholine follows vagal denervation. Stimulation of the right stellate ganglion produces sinus tachycardia with less effect on AV nodal conduction, whereas stimulation of the left stellate ganglion generally produces a shift in the sinus pacemaker to an ectopic site and consistently shortens AV nodal conduction time and refractoriness but inconsistently speeds the SA nodal discharge rate. Stimulation of the right cervical vagus nerve primarily slows the SA nodal discharge rate, and stimulation of the left vagus primarily prolongs AV nodal conduction time and refractoriness when sidedness is present. Neither sympathetic nor vagal stimulation affects normal conduction in the His bundle. The negative dromotropic response of the heart to vagal stimulation is mediated by the activation of $I_{K.ACh}$, which results in hyperpolarization of the AV nodal cells and thereby influences the conductive

properties of the node. The positive dromotropic effect of sympathetic stimulation arises because of an increase in cytosolic cAMP levels and ensuing activation of the L-type Ca^{2+} current $I_{Ca.L}$.

Most efferent sympathetic impulses reach the canine ventricles over the ansae subclavia, branches from the stellate ganglia. Sympathetic nerves then synapse primarily in the caudal cervical ganglia and form individual cardiac nerves that innervate relatively localized parts of the ventricles. The major route to the heart is the recurrent cardiac nerve on the right side and the ventrolateral cardiac nerve on the left. In general, the right sympathetic chain shortens refractoriness primarily of the anterior portion of the ventricles, and the left affects primarily the posterior surface of the ventricles, although overlapping areas of distribution occur.

The intraventricular route of sympathetic nerves generally follows the coronary arteries. Functional data suggest that afferent and efferent sympathetic nerves travel in the superficial layers of the epicardium and dive to innervate the endocardium, and anatomic observations support this conclusion. Vagal fibers travel intramurally or subendocardially and rise to the epicardium at the AV groove (**Fig. 34.11A**). Sympathetic nerve density in the left ventricle appears to be higher in the epicardial than in the endocardial portion of the ventricle, which at least in part results from transmural gradients in the expression of cytokines during cardiac development that attract and repel, respectively, sympathetic nerve growth[1,34,35] (**Fig. 34.11B**).

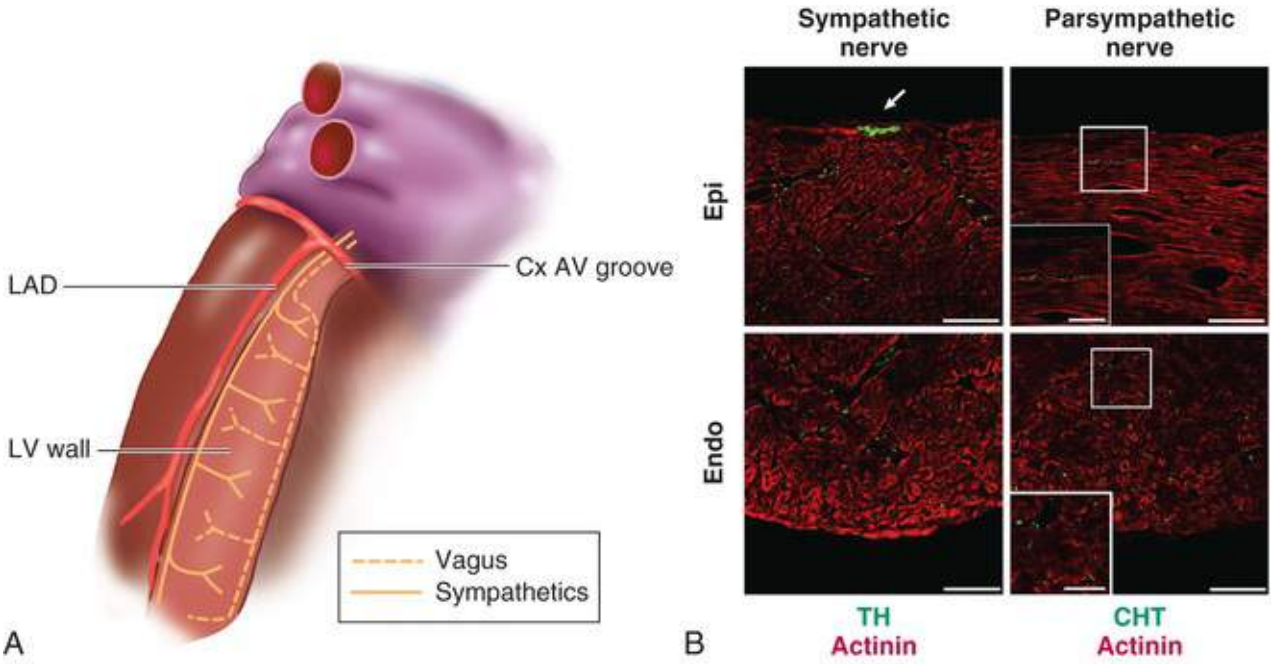


FIGURE 34.11 **A,** Intraventricular route of the sympathetic and vagal nerves to the left ventricle (*LV*); *LAD,* left anterior descending artery. **B,** Distribution of sympathetic and parasympathetic nerves in the mammalian heart. Immunofluorescence staining for the sympathetic and parasympathetic nerve markers tyrosine hydroxylase (*TH*) and choline transporter (*CHT*) is shown in the LV of a rat heart (*green,* nerves; *red,* alpha-actinin, a cardiomyocyte marker). TH-positive nerves are more abundant in the subepicardial (Epi) layer than in the subendocardial (Endo) layer. The *arrow* indicates sympathetic nerves at the epicardial surface. No CHT-positive nerves are present at the epicardial surface, and CHT-positive nerves are more abundant in the subendocardial layer. Higher magnification views of the boxed regions are shown in the *insets*. Scale bars = 100 µm. (**A,** From Ito M, Zipes DP. Efferent sympathetic and vagal innervation of the canine right ventricle. Circulation 1994;90:1459. By permission of the American Heart Association; **B,** from Kanazawa H et al. Heart failure causes cholinergic transdifferentiation of cardiac sympathetic nerves via gp130-signaling cytokines in rodents. J Clin Invest 2010;120:408.)

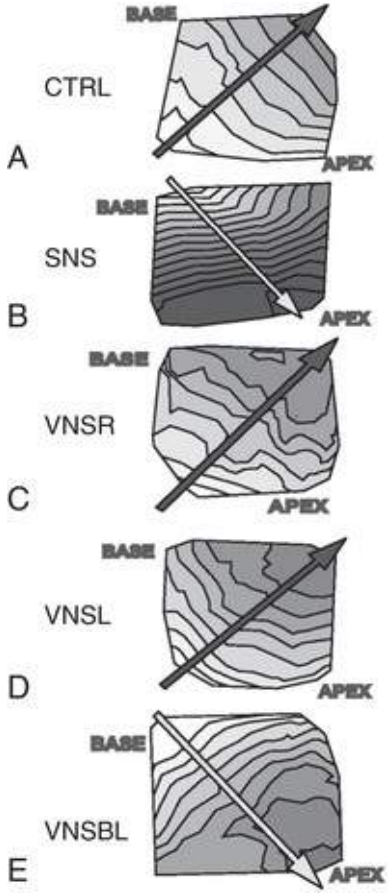
Effects of Vagal Stimulation

The vagus nerve modulates cardiac sympathetic activity at prejunctional and postjunctional sites by regulating the amount of norepinephrine released and by inhibiting cAMP-induced phosphorylation of cardiac proteins, including ion channels and calcium pumps. The latter inhibition occurs at more than one level in the series of reactions constituting the adenylate cyclase–cAMP-dependent protein kinase system. Neuropeptides released from the nerve fibers of both autonomic limbs also modulate autonomic responses. For example, NPY released from sympathetic nerve terminals inhibits cardiac vagal effects.

Tonic vagal stimulation produces a greater absolute reduction in the sinoatrial rate in the presence of tonic background sympathetic stimulation, a sympathetic-parasympathetic interaction termed *accentuated antagonism*. In contrast, changes in AV conduction during concomitant sympathetic and vagal stimulation are essentially the algebraic sum of the individual AV conduction responses to tonic vagal and sympathetic stimulation alone. Cardiac responses to brief vagal bursts begin after a short latency and dissipate quickly; in contrast, cardiac responses to sympathetic stimulation commence and dissipate slowly. The rapid onset and offset of responses to vagal stimulation allow dynamic beat-to-beat vagal modulation of the heart rate and AV conduction, whereas the slow temporal response to sympathetic stimulation precludes any beat-to-beat regulation by sympathetic activity. Periodic *vagal bursting*, as may occur each time that a systolic pressure wave arrives at the baroreceptor regions in the aortic and carotid sinuses, induces phasic changes in sinus cycle length and can entrain the sinus node to discharge faster or slower at periods identical to those of the vagal burst. In a similar phasic manner, vagal bursts prolong AV nodal conduction time and are influenced by background levels of sympathetic tone. Because the peak vagal effects on sinus rate and AV nodal conduction occur at different times in the cardiac cycle, a brief vagal burst can slow the sinus rate without affecting AV nodal conduction or can prolong AV nodal conduction time and not slow the sinus rate. Bilateral but not unilateral vagal nerve stimulation increases and reverses the spatial dispersion of ventricular repolarization as the direction of repolarization from the apex to the base in sinus rhythm shifts from the base to the apex. This effect is attributable to more pronounced prolongation of the action potential at the apex than at the base of the heart (**eFig. 34.15**).



EFIGURE 34.15 Reversal of the ventricular repolarization sequence during autonomic nerve stimulation in a rabbit heart. Each map represents the dispersion of repolarization for a single cardiac beat and is displayed as an isochronal map with lines 2 milliseconds apart. *Light to dark shades* represent early to late repolarization time points. *Arrows* point to the direction of the repolarization sequence. CTRL, Control; SNS, sympathetic nerve stimulation; VNSBL, bilateral vagal nerve stimulation; VNSL, left vagal nerve stimulation; VNSR, right vagal nerve stimulation.

Effects of Sympathetic Stimulation

Similar to bilateral vagal nerve stimulation, sympathetic nerve stimulation also increases and reverses the spatial gradients of ventricular repolarization as the direction of polarization from the apex to the base in sinus rhythm shifts from base to apex. This reversal results from a marked shortening of action potential duration at the base, with no or negligible effect on the repolarization time course at the apex of the heart (**eFig. 34.15**). Nonuniform distribution of sympathetic nerves—and thus norepinephrine levels—may in part contribute to some of the nonuniform electrophysiologic effects, because the ventricular content of norepinephrine is greater at the base than at the apex of the heart. In humans, both direct and reflex sympathetic stimulation increases regional differences in cardiac repolarization. The dispersion of repolarization is significantly enhanced in patients with ischemic cardiomyopathy.[37] Afferent vagal activity appears to be higher in the posterior ventricular myocardium, which may account for the vagomimetic effects of inferior MI.

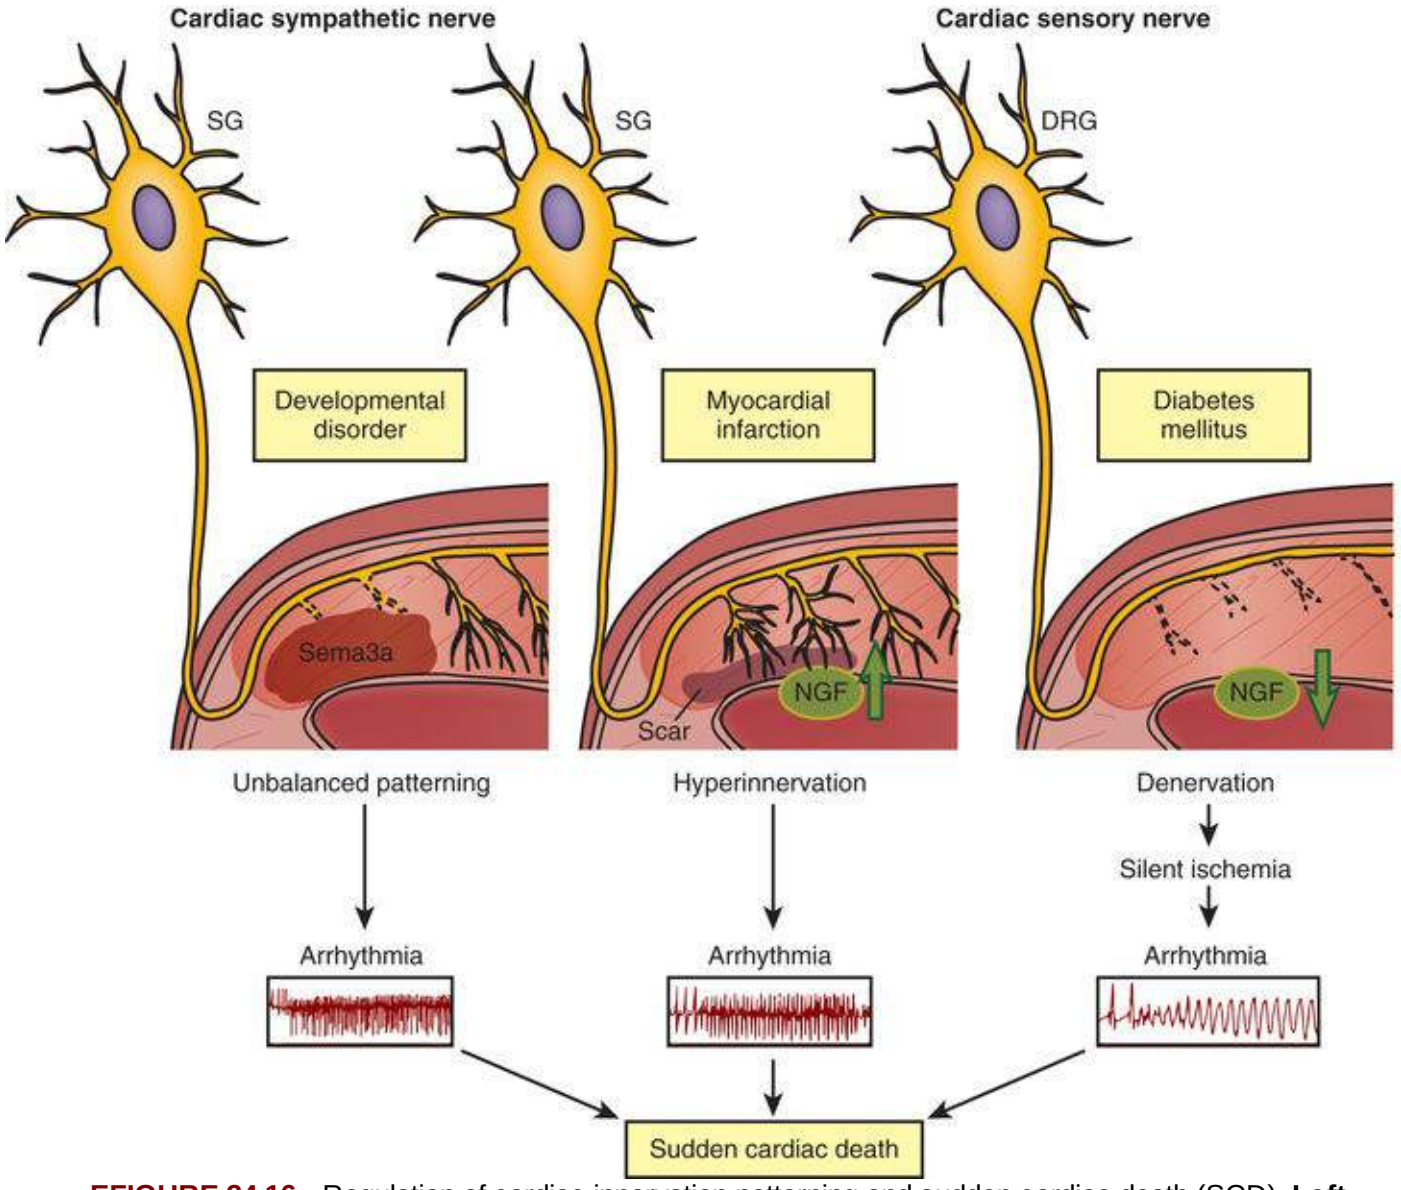
The vagi exert minimal but measurable effects on ventricular tissue; they decrease the strength of myocardial contraction and prolong refractoriness. Under some circumstances, acetylcholine can cause a positive inotropic effect. It is now clear that the vagus (ACh) can exert direct effects on some types of ventricular fibers, as well as indirect effects by modulating sympathetic influences.

Beyond the beat-to-beat regulation of rate and contractile force, sympathetic input to the heart, through both translational and post-translational modifications, also exerts long-term regulation of adrenergic receptor sensitivity and ionic channels. These long-term changes in autonomic responsiveness and cardiac

electrical properties appear to be mediated, at least in part, by highly localized signaling cascades involving neurally released molecules such as NPY.[1]

Arrhythmias and the Autonomic Nervous System

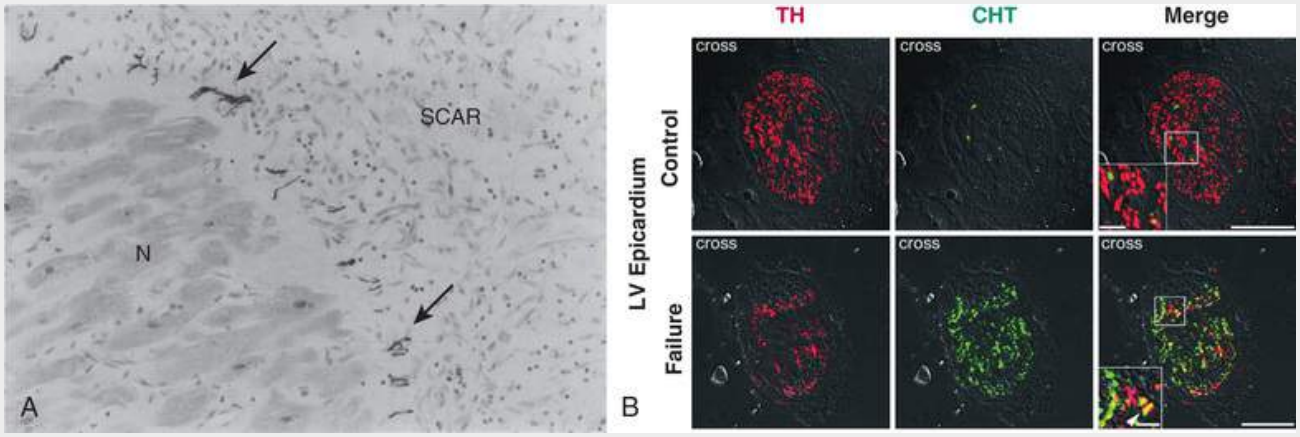
Alterations in vagal and sympathetic innervation (autonomic remodeling) can influence the development of arrhythmias and result in sudden cardiac death (SCD) from ventricular tachyarrhythmias.[34,35] Damage to nerves extrinsic to the heart, such as the stellate ganglia, and to intrinsic cardiac nerves from diseases that may affect primarily nerves, such as viral infections, or from diseases that secondarily cause cardiac damage may produce cardioneuropathy. Although the mechanisms by which altered sympathetic innervation modulates cardiac electrical properties are largely unknown, spatially heterogeneous sympathetic hyperinnervation could result in enhanced dispersion of myocardial excitability and refractoriness through patchy adrenergic stimulation of ionic currents, including $I_{Ca.L}$, I_{Ks}, and I_{Cl} (**see Table 34.1**). Sympathetic hypoinnervation has been shown to increase the sensitivity of adrenergic receptors to activation by circulating catecholamines (*denervation supersensitivity*) (**eFig. 34.16**).



EFIGURE 34.16 Regulation of cardiac innervation patterning and sudden cardiac death (SCD). **Left,** Overexpression or lack of semaphorin 3A (sema3A) in endocardium causes unbalanced patterning of sympathetic nerves, which alters the susceptibility to lethal arrhythmias. **Middle,** Upregulation of secreted nerve growth factor (*NGF*) from cardiomyocytes with hyperinnervation in diseased hearts may cause lethal arrhythmias and SCD. **Right,** Downregulation of NGF in diabetic hearts induces denervation of cardiac sensory nerves, which may lead to silent ischemia and lethal arrhythmias. *DRG,* Dorsal root ganglia; *SG,* stellate ganglia. (From Fukuda K et al. Cardiac innervation and sudden cardiac death. Circ Res 2015;116:2005.)

Numerous studies have suggested a primary role of altered cardiac sympathetic innervation in arrhythmogenesis. Chronic infusion of nerve growth factor (NGF) into the left stellate ganglion in dogs with chronic MI and complete AV block caused spatially heterogeneous sympathetic cardiac hyperinnervation (nerve sprouting) and dramatically increased the incidence of SCD from ventricular tachyarrhythmias. Ambulatory long-term recordings of left stellate ganglion nerve activity in these dogs revealed that most malignant ventricular arrhythmias were preceded by increased neuronal discharge, thus suggesting a causal role of sympathetic input in triggering arrhythmogenic SCD. A high-cholesterol diet was reported to result in cardiac sympathetic hyperinnervation in rabbits and a marked increase in the incidence of ventricular fibrillation (VF).[1] Explanted human hearts from transplant recipients with a history of arrhythmias exhibited a significantly higher and also more heterogeneous density of

sympathetic nerve fibers than did those from patients without arrhythmias (**eFig. 34.17A**). Whether neural remodeling also involved parasympathetic nerve fibers in the heart was not examined in these studies. In a canine model of heart failure with dyssynchronous ventricular contraction, cardiac resynchronization therapy (CRT) restored sympathovagal balance by upregulation of cholinergic signaling with a reduction in arrhythmogenic afterdepolarizations.[38] In patients with congestive heart failure, sympathetic neural tone is upregulated, and excess activation of the sympathetic nervous system leads to adverse myocardial effects, including lethal arrhythmias, and also causes depletion of cardiac norepinephrine content. This depletion of norepinephrine has recently been shown to result, at least partially, from neurotransmitter switching and transdifferentiation from catecholaminergic into cholinergic neurons in the chronically failing heart (**eFig. 34.17B**). This process is induced by release of cholinergic differentiation factors from failing cardiomyocytes. It remains to be determined, however, whether neurotransmitter switching is an adaptive response to protect the heart from excess sympathetic stimulation and thus lethal arrhythmias.



EFIGURE 34.17 Sympathetic neural remodeling in the diseased heart. **A,** Regional hyperinnervation (*arrows*) at the junction between scar and surviving myocardium (*N*) in a patient with cardiomyopathy and ventricular tachyarrhythmias. **B,** Cholinergic transdifferentiation of cardiac sympathetic nerves in failing human hearts. Shown are representative cross sections of epicardial nerve bundles in the left ventricle (LV) of a nonfailing **(upper row)** and a failing human heart **(lower row).** Hearts were stained for tyrosine hydroxylase (TH; *red*) and choline transporter (CHT; *green*) as catecholaminergic and cholinergic nerve markers, respectively. The failing heart exhibits fewer TH-positive nerves and many more CHT-positive nerves than does the nonfailing heart, whereas overall nerve density appears to be similar. The **right panels** display merged images of the TH and CHT signal, which reveals that in the failing heart, some nerves coexpress TH and CHT (*yellow* because of overlap of *red* TH and *green* CHT fluorescence). Higher-magnification views of the boxed regions are shown in the *insets*. The *arrowhead* in the lower left corner of the lower right image denotes a nerve coexpressing TH and CHT. Scale bar = 10 µm; insets = 50 µm. (**A,** From Chen PS et al. Sympathetic nerve sprouting, electrical remodeling and the mechanisms of sudden cardiac death. Cardiovasc Res 2001;50:409; **B,** from Kanazawa H et al. Heart failure causes cholinergic transdifferentiation of cardiac sympathetic nerves via gp130-signaling cytokines in rodents. J Clin Invest 2010;120:408.)

The junctions between pulmonary veins and the left atrium are highly innervated structures. Both sympathetic and parasympathetic nerves are colocated and concentrated in “ganglionated plexuses” around the pulmonary veins. Selective ablation of ganglionated plexuses, as well as extensive regional ablation targeting anatomic areas containing ganglionated plexuses, has been shown to reduce the incidence of paroxysmal AF in some but not all clinical and experimental studies, thus further supporting a causal involvement of autonomic nerve activity in atrial arrhythmogenesis[35,39] (**eFig. 34.18**). On the other hand, spatially heterogeneous sympathetic denervation was similarly associated with an increased risk for atrial and ventricular arrhythmias. Mutations in genes encoding cardiac ion channel subunits also affect channel function in the central and peripheral autonomic nervous system and thereby result in

abnormal firing properties of affected neurons.[1,10] This observation may partially explain the clinical finding that SCD in some variants of LQTS (**see Chapters 33 and 39**) is typically preceded by sympathetic arousal. Also, the antiarrhythmic efficacy of surgical left cardiac sympathetic denervation has previously been demonstrated in young patients with catecholaminergic polymorphic ventricular tachycardia (CPVT, see later). Thus the cardiac sympathetic nervous system provides a potentially useful target for treating patients at risk for clinical arrhythmias.[34,35,40]

Pulmonary veins, caval veins, ganglionated plexi, and ligament of Marshall. Int J Cardiol 2013;168:1769-78.)

Mechanisms of Arrhythmogenesis

The mechanisms responsible for cardiac arrhythmias are generally divided into disorders of impulse formation, disorders of impulse conduction, or combinations of both (**Table 34.3**). However, our currently available diagnostic tools do not permit unequivocal determination of the electrophysiologic mechanisms

responsible for many clinical arrhythmias or their ionic bases. This is especially true for ventricular arrhythmias. It is clinically difficult to separate microanatomic reentry from automaticity, and often one is left with the consideration that a particular arrhythmia is “most consistent with” or “best explained by” one or the other electrophysiologic mechanism. Some tachyarrhythmias can be started by one mechanism and perpetuated by another. An episode of tachycardia caused by one mechanism can precipitate another episode caused by a different mechanism. For example, a premature complex caused by abnormal automaticity can precipitate an episode of tachycardia sustained by reentry. However, entrainment can identify arrhythmias caused by macroreentry (see later and **Chapter 37**).

TABLE 34.3

Mechanisms of Arrhythmias

DISORDER	EXPERIMENTAL EXAMPLES	CLINICAL EXAMPLES
Disorders of Impulse Formation		
Automaticity		
Normal automaticity	Normal in vivo or in vitro in SA nodal, AV nodal, and Purkinje cells	Sinus tachycardia or bradycardia inappropriate for the clinical situation; possibly ventricular parasystole
Abnormal automaticity	Depolarization-induced automaticity in Purkinje myocytes	Possibly accelerated ventricular rhythms after myocardial infarction
Triggered activity		
EADs	Drugs (sotalol, *N*-acetylprocainamide, terfenadine, erythromycin), cesium, barium, low $[K^+]_o$	Acquired LQTS and associated ventricular arrhythmias
DADs	Gain-of-function mutations in the gene encoding RyR2	Catecholaminergic polymorphic ventricular tachycardia
Disorders of Impulse Conduction		
Block		
Bidirectional or unidirectional without reentry	SA, AV, bundle branch, Purkinje-muscle	Sinoatrial, AV, bundle branch block
Unidirectional block with reentry	AV node, Purkinje-muscle junction, infarcted myocardium	Reciprocating tachycardia in Wolff-Parkinson-White syndrome, AV nodal reentry tachycardia, ventricular tachycardia caused by bundle branch reentry
Reflection	Purkinje fiber with area of inexcitability	Unknown
Combined Disorders		
Interactions between automatic foci	Depolarizing or hyperpolarizing subthreshold stimuli speed or slow the automatic discharge rate	Modulated parasystole
Interactions between automaticity and conduction	Deceleration-dependent block, overdrive suppression of conduction, entrance and exit block	Similar to experimental

AV, Atrioventricular; *DADs,* delayed afterdepolarizations; *EADs,* early afterdepolarizations; *LQTS,* long-QT syndrome; *SA,* sinoatrial.

Disorders of Impulse Formation

Disorders of impulse formation are characterized by an inappropriate discharge rate of the normal pacemaker, the SA node (e.g., sinus rates too fast or too slow for physiologic needs of patient), or discharge of an ectopic pacemaker that controls the atrial or ventricular rhythm. Pacemaker discharges from ectopic sites, often called *latent* or *subsidiary* pacemakers, can occur in fibers located in several parts of the atria, coronary sinus and pulmonary veins, AV valves, portions of the AV junction, and His-Purkinje system. Usually kept from reaching the level of threshold potential because of overdrive suppression by the more rapidly firing sinus node or electrotonic depression from contiguous fibers, ectopic pacemaker activity at one of these latent sites can manifest when the sinus nodal discharge rate slows or block occurs at some level between the SA node and the ectopic pacemaker site, which permits *escape* of the latent pacemaker at the latter's normal discharge rate. A clinical example would be sinus bradycardia to a rate of 45 beats/min that permits an AV junctional escape complex to occur at a rate of 50 beats/min.

Alternatively, the discharge rate of the latent pacemaker can speed inappropriately and usurp control of

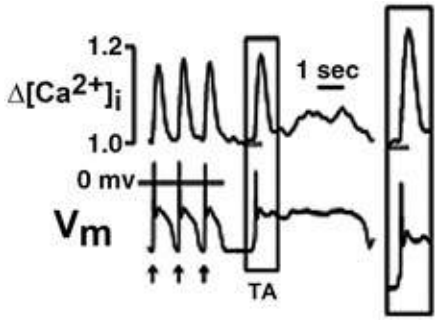
cardiac rhythm from the SA node, which has been discharging at a normal rate, such as may occur with a premature ventricular complex (PVC) or a burst of ventricular tachycardia (VT). Such disorders of impulse formation can be caused by speeding or slowing of a *normal* pacemaker mechanism (e.g., phase 4 diastolic depolarization that is physiologically normal for SA node or for ectopic site such as a Purkinje fiber, but occurs inappropriately fast or slow) or by a physiologically *abnormal* pacemaker mechanism.

A patient with persistent sinus tachycardia at rest or sinus bradycardia during exertion exhibits inappropriate sinus nodal discharge rates, but the ionic mechanisms responsible for sinus nodal discharge can still be normal, although the kinetics or magnitude of the currents can be altered. Conversely, when a patient experiences VT during acute MI, ionic mechanisms ordinarily not involved in the formation of spontaneous impulses for this fiber type can be operative and generate the tachycardia. For example, although pacemaker activity is not generally found in typical working myocardium, the effects of myocardial ischemia and infarction can depolarize these cells to membrane potentials at which inactivation of I_K and activation of $I_{Ca.L}$ cause automatic discharge. In vitro studies have demonstrated that myofibroblasts in infarct scars depolarize cardiomyocytes by heterocellular electrotonic interactions via gap junctions and also induce synchronized spontaneous activity in neighboring cardiomyocytes.[1]

Abnormal Automaticity

The mechanisms responsible for normal automaticity are described earlier (Phase 4: Diastolic Depolarization). Abnormal automaticity can arise from cells that have reduced maximum diastolic potentials, often at membrane potentials positive to −50 mV, when I_K and $I_{Ca.L}$ may be operative. Automaticity at membrane potentials more negative than −70 mV may be caused by I_f. When the membrane potential is between −50 and −70 mV, the cell may be quiescent. Electrotonic effects from surrounding normally polarized or more depolarized myocardium influence the development of automaticity.

Abnormal automaticity can be produced in normal muscle or Purkinje fibers by appropriate interventions, such as passage of current that reduces the diastolic membrane potential. An automatic discharge rate speeds up with progressive depolarization, and hyperpolarizing pulses slow the spontaneous firing. It is possible that partial depolarization and failure to reach normal maximal diastolic potential can induce automatic discharges in most if not all cardiac fibers. Although this type of spontaneous automatic activity has been found in human atrial and ventricular fibers, its relationship to the genesis of clinical arrhythmias has not been established. Abnormal automaticity in Purkinje cells can also originate secondary to spontaneous, submembrane Ca^{2+} elevations through activation of calcium-sensitive membrane conductances, a process identical to that previously identified in SA node myocytes. Indeed, Purkinje myocytes isolated from mice heterozygous for an arrhythmia-causing mutation in the gene encoding the cardiac ryanodine receptor Ca^{2+}-release channel (RyR2) display a greater propensity for the development of arrhythmogenic Ca^{2+}-handling abnormalities than do nonmutant ventricular cardiomyocytes. This proarrhythmic behavior is further exacerbated by catecholaminergic stimulation with the development of triggered beats (**eFig. 34.19**), thus supporting the concept that Purkinje cells are critical contributors to arrhythmic triggers in animal models and humans with RyR2 mutations that are linked to CPVT.[41]



EFIGURE 34.19 Arrhythmogenic spontaneous Ca^{2+} elevations in a Purkinje myocyte isolated from a mouse heterozygous for a gain-of-function mutation in the *RYR2* gene. Changes in intracellular free calcium ($\Delta[Ca^{2+}]_i$, *upper trace*) and transmembrane action potential (V_m) were simultaneously recorded in a mutant Purkinje myocyte during electrical field stimulation (*arrows*) and during a spontaneous elevation in Ca^{2+} (triggered action potential, TA). Note that the action potential upstroke is preceded by a low-amplitude elevation in Ca^{2+}, followed by a suprathreshold membrane depolarization that triggers a markedly prolonged action potential. (From Kang G et al. Purkinje cells from RyR2 mutant mice are highly arrhythmogenic but responsive to targeted therapy. Circ Res 2010;107:512.)

Rhythms resulting from abnormal automaticity may be slow atrial, junctional, or ventricular escape rhythms; certain types of atrial tachycardias (e.g., those produced by digitalis or perhaps those coming from pulmonary veins); accelerated junctional (nonparoxysmal junctional tachycardia) and idioventricular rhythms; and parasystole (**see Chapters 37 and 39**).

Triggered Activity

Automaticity is the property of a fiber to initiate an impulse spontaneously, without need for prior stimulation, so that electrical quiescence does not occur. Triggered activity is initiated by *afterdepolarizations,* which are depolarizing oscillations in membrane voltage induced by one or more preceding action potentials. Thus, triggered activity is pacemaker activity that results *as a consequence* of a preceding impulse or series of impulses, without which electrical quiescence occurs (**Fig. 34.12 and eFig. 34.20**). This triggering activity is not caused by an automatic self-generating mechanism, and the term "triggered automaticity" is therefore contradictory. These depolarizations can occur before or after full repolarization of the fiber and are best termed *early afterdepolarizations* (EADs) when they arise from a reduced level of membrane potential during phases 2 and 3 of the cardiac action potential (**Fig. 34.12C**) or *late afterdepolarizations* or DADs (**Fig. 34.12B**) when they occur after completion of repolarization (phase 4), generally at a more negative membrane potential than that from which EADs arise. Not all afterdepolarizations may reach the threshold potential, but if they do, they can trigger another afterdepolarization and thus self-perpetuate.

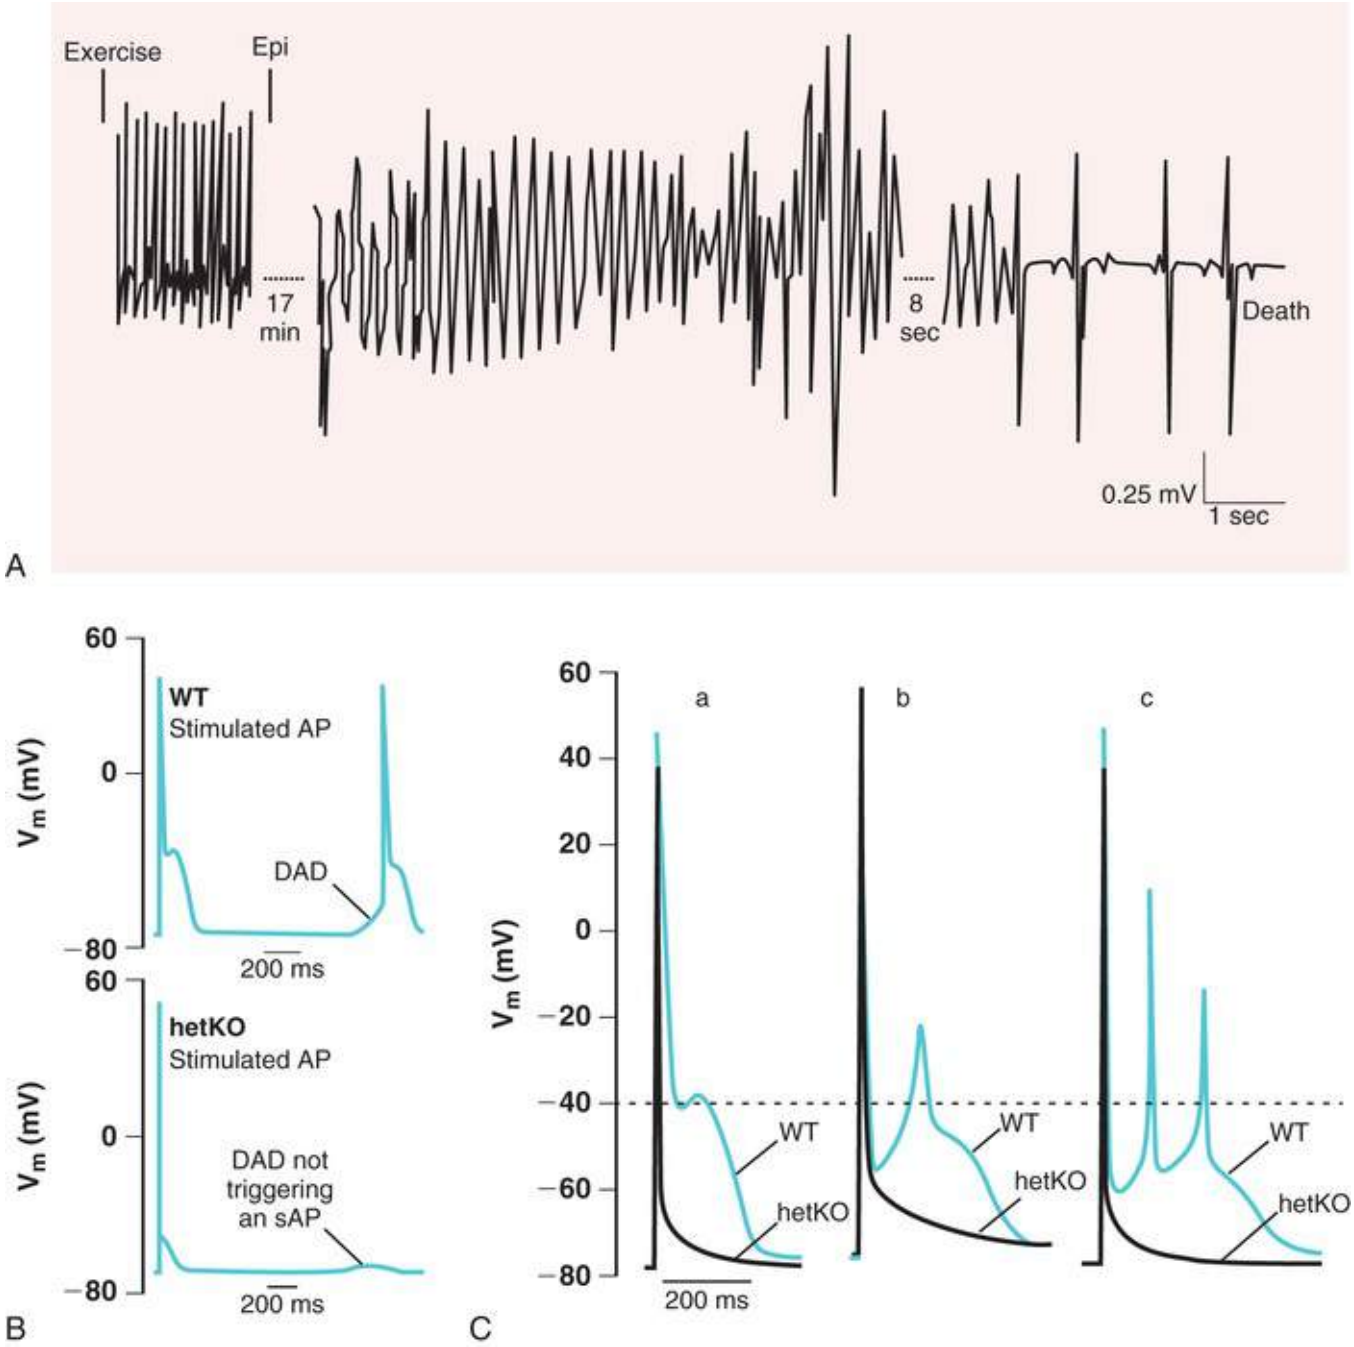


FIGURE 34.12 **A,** Electrocardiogram after exercise and administration of epinephrine in a mouse heterozygous for a loss-of-function mutation in the gene encoding ankyrin-B ($AnkB^{-/+}$). Polymorphic ventricular tachycardia (torsades de pointes) occurred within about 17 minutes of epinephrine administration, followed by marked bradycardia and death 2 minutes after the arrhythmia. **B,** Impaired translation of delayed afterdepolarizations (DADs) into spontaneous action potentials (APs) in heterozygous knockout of Na^+/Ca^{2+} exchanger (hetKO) versus wild-type (WT) exposed to isoproterenol and an arrhythmogenic pacing protocol. The first AP is initiated by current injection. The second AP in the **upper panel** is triggered by a DAD in the WT, it fails to generate an AP in the hetKO. **C,** Early afterdepolarizations (EADs) in WT and heterozygous knockout of Na^+/Ca^{2+} exchanger. The EAD shape varied between low-amplitude, slow-transient membrane fluctuations **(a),** spike-like depolarizations **(b),** and steep upstrokes **(c).** (**A,** From Mohler PJ et al. Ankyrin-B mutation causes type 4 long-QT cardiac arrhythmia and sudden cardiac death. Nature 2003;421:634; **B** and **C,** from American Heart Association; Bögeholz N et al. Suppression of early and late afterdepolarizations by heterozygous knockout of the Na^+/Ca^{2+} exchanger in a murine model. Circ Arrhythm Electrophysiol 2015;8:1210.)

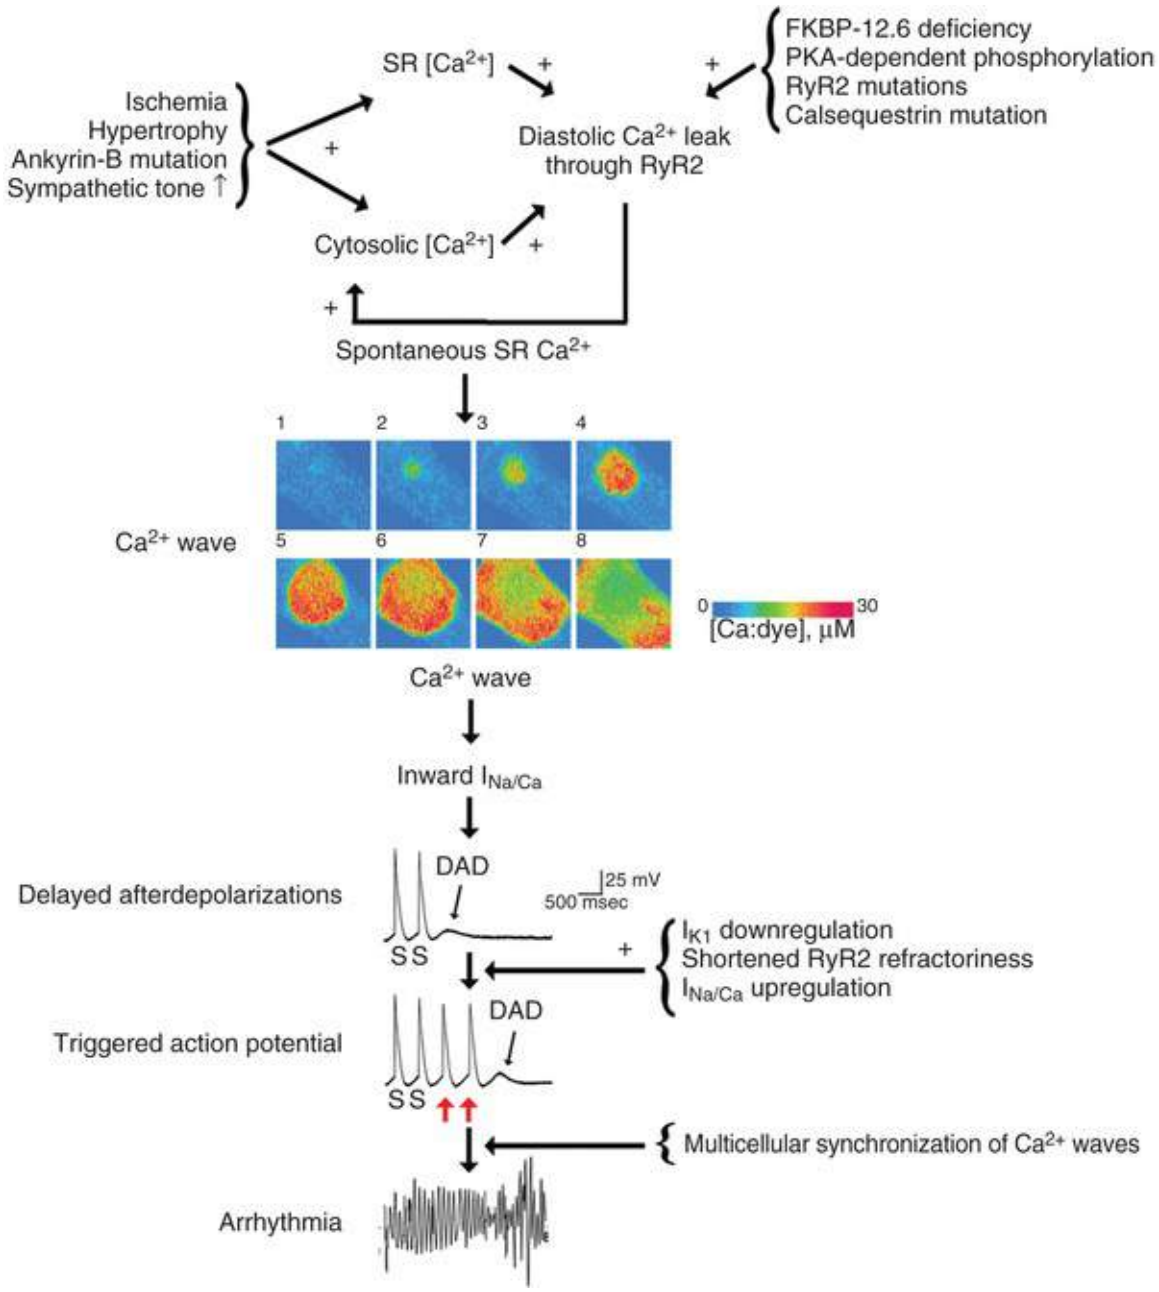


EFIGURE 34.20 Proposed scheme of events leading to delayed afterdepolarizations (DADs) and triggered tachyarrhythmia. **Top panel,** Congenital (e.g., gain-of-function mutations in the *RYR2* or *CASQ2* genes) or acquired factors (e.g., ischemia, hypertrophy, increased sympathetic tone, heart failure) will cause a diastolic Ca^{2+} leak through RyR2 that results in localized and transient increases in $[Ca^{2+}]_i$ in cardiomyocytes. **Middle panel,** Representative series of images showing changes in $[Ca^{2+}]_i$ during a Ca^{2+} wave in a single cardiomyocyte loaded with a Ca^{2+}-sensitive fluorescent dye. Images were obtained at 117-millisecond intervals. Focally elevated Ca^{2+} (*2*) diffuses to the adjacent junctional sarcoplasmic reticulum (SR), where it initiates more Ca^{2+} release events that result in a propagating Ca^{2+} wave (*frames 3-8*). **Bottom panel,** The Ca^{2+} wave, through activation of inward $I_{Na/Ca}$, will depolarize the cardiomyocyte (DAD). If of sufficient magnitude to overcome the source-sink mismatch, the DAD will depolarize the cardiomyocyte above threshold and result in a single or repetitive premature activations (*red arrows*), which can trigger an arrhythmia. Downregulation of the inwardly rectifying potassium current (I_{K1}), upregulation of $I_{Na/Ca}$, and shortened Ca^{2+} signaling refractoriness because of ryanodine receptor phosphorylation and/or oxidation can promote the generation of DAD-triggered action potentials. *S,* Stimulus. (Modified from Rubart M, Zipes DP. Mechanisms of sudden cardiac death. J Clin Invest 2005;115:2305. With permission from the Journal of Clinical Investigation.)

Delayed Afterdepolarizations

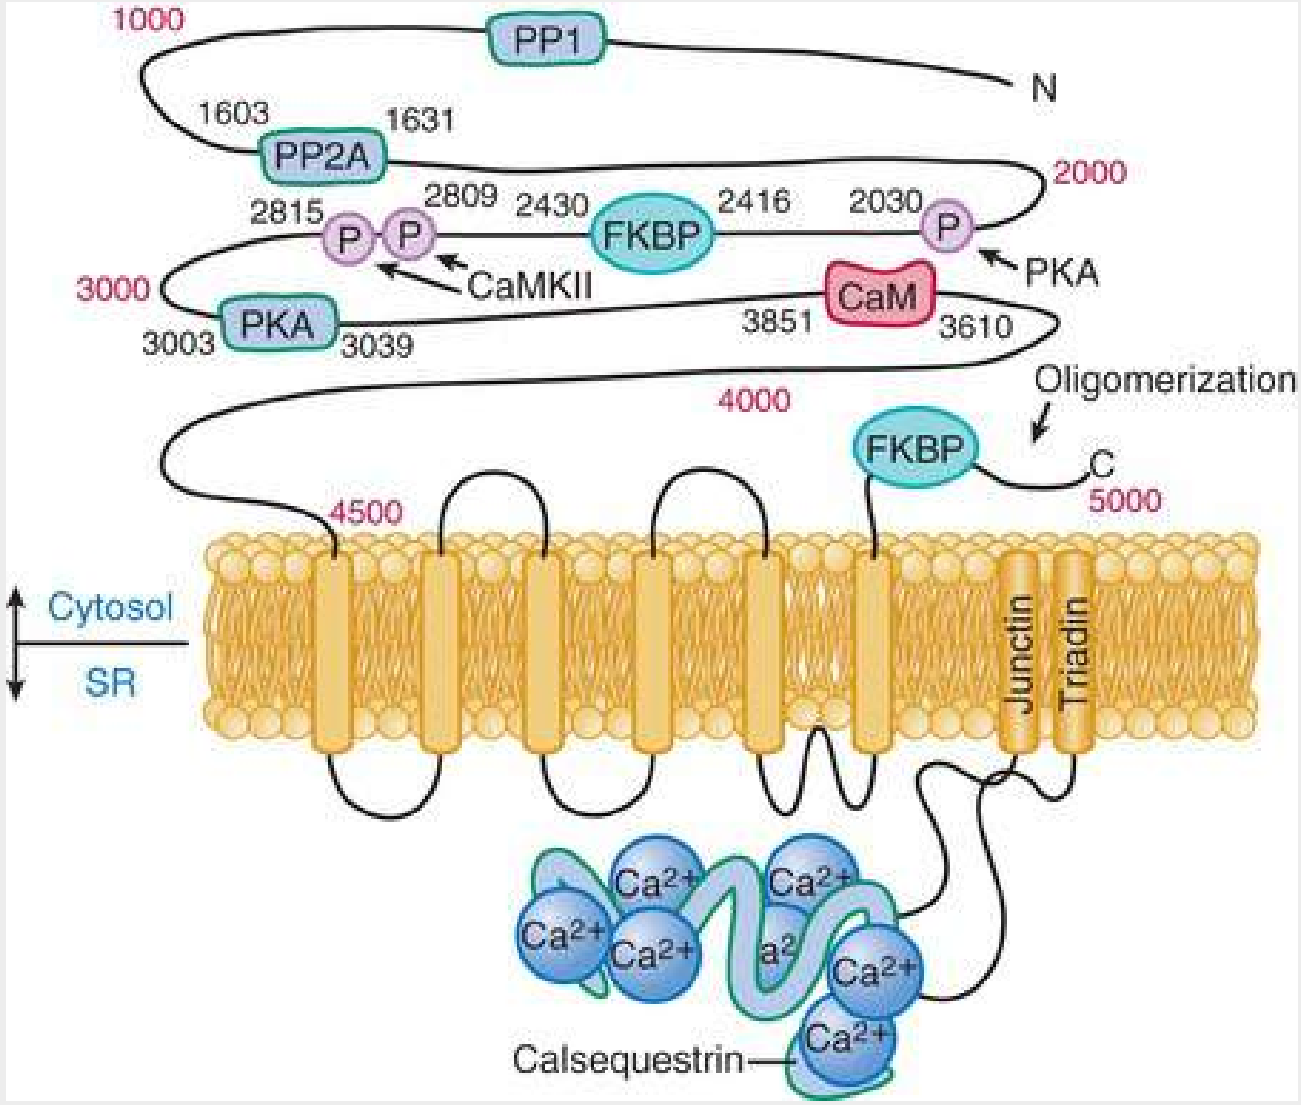
DADs and triggered activity have been demonstrated in Purkinje fibers, specialized atrial fibers and ventricular muscle fibers exposed to digitalis preparations, pulmonary veins, normal Purkinje fibers exposed to Na-free superfusates from the endocardium of the intact heart, ventricular myocardial cells from failing hearts and from mouse hearts with ankyrin-B mutations (**Fig. 34.12A**) during beta-adrenergic stimulation, and endocardial preparations 1 day after MI. When fibers in the rabbit, canine, simian, and human mitral valves and in the canine tricuspid valve and coronary sinus are superfused with norepinephrine, they exhibit the capability for sustained, triggered rhythmic activity.[1]

In vivo, atrial and ventricular arrhythmias apparently caused by triggered activity have been reported in the dog and possibly in humans. It is tempting to ascribe certain clinical arrhythmias to DADs, such as some arrhythmias precipitated by digitalis or some cases of AF arising from DADs in pulmonary veins. The accelerated idioventricular rhythm 1 day after experimental canine MI may be caused by DADs, and some evidence has suggested that certain ventricular tachycardias, such as those arising in the right ventricular outflow tract, may be caused by DADs, whereas other data suggest that EADs are responsible.[42]

Major Role of Intracellular Ca^{2+}-Handling Abnormalities in DAD Generation

It is well recognized that DADs result from the activation of a calcium-sensitive inward current elicited by spontaneous increases in the intracellular free calcium concentration. Acquired or inherited abnormalities in the properties of the SR calcium-release channels or SR calcium-binding proteins underlie these spontaneous calcium-release events.

Rapid mobilization of Ca^{2+} from the SR into the cytosol is mediated by the synchronous opening of ryanodine-sensitive Ca^{2+}-release channels (ryanodine receptors, RyRs). The cardiac RyR is composed of four equivalent subunits (homotetramer), each encoded by the *RYR2* gene. During cardiac systole, the small influx of calcium ions through L-type Cav channels triggers a massive release of Ca^{2+} from the SR via synchronous opening of RyR2 channels, a process called Ca^{2+}-induced Ca^{2+} release (**see Chapter 22**). During diastole, RyR2 channels close and Ca^{2+} is recycled into the SR via calcium pumps, thereby refilling SR Ca^{2+} stores for the next release cycle. The duration and amplitude of Ca^{2+} efflux from the SR are therefore tightly controlled by the gating of RyR2 channels. RyR2 interacts with a number of accessory proteins to form a macromolecular Ca^{2+}-release complex (**eFig. 34.21**). Proteins interact with RyR2 at multiple sites within the cytosolic domains of RyR2 and in the SR (e.g., calsequestrin, the major calcium-binding protein in the SR lumen). Among the cytosolic ligands, FKBP-12.6 (calstabin 2) has been implicated in stabilizing the closed state of the RyR2 channel and thus preventing diastolic Ca^{2+} leakage. [1]

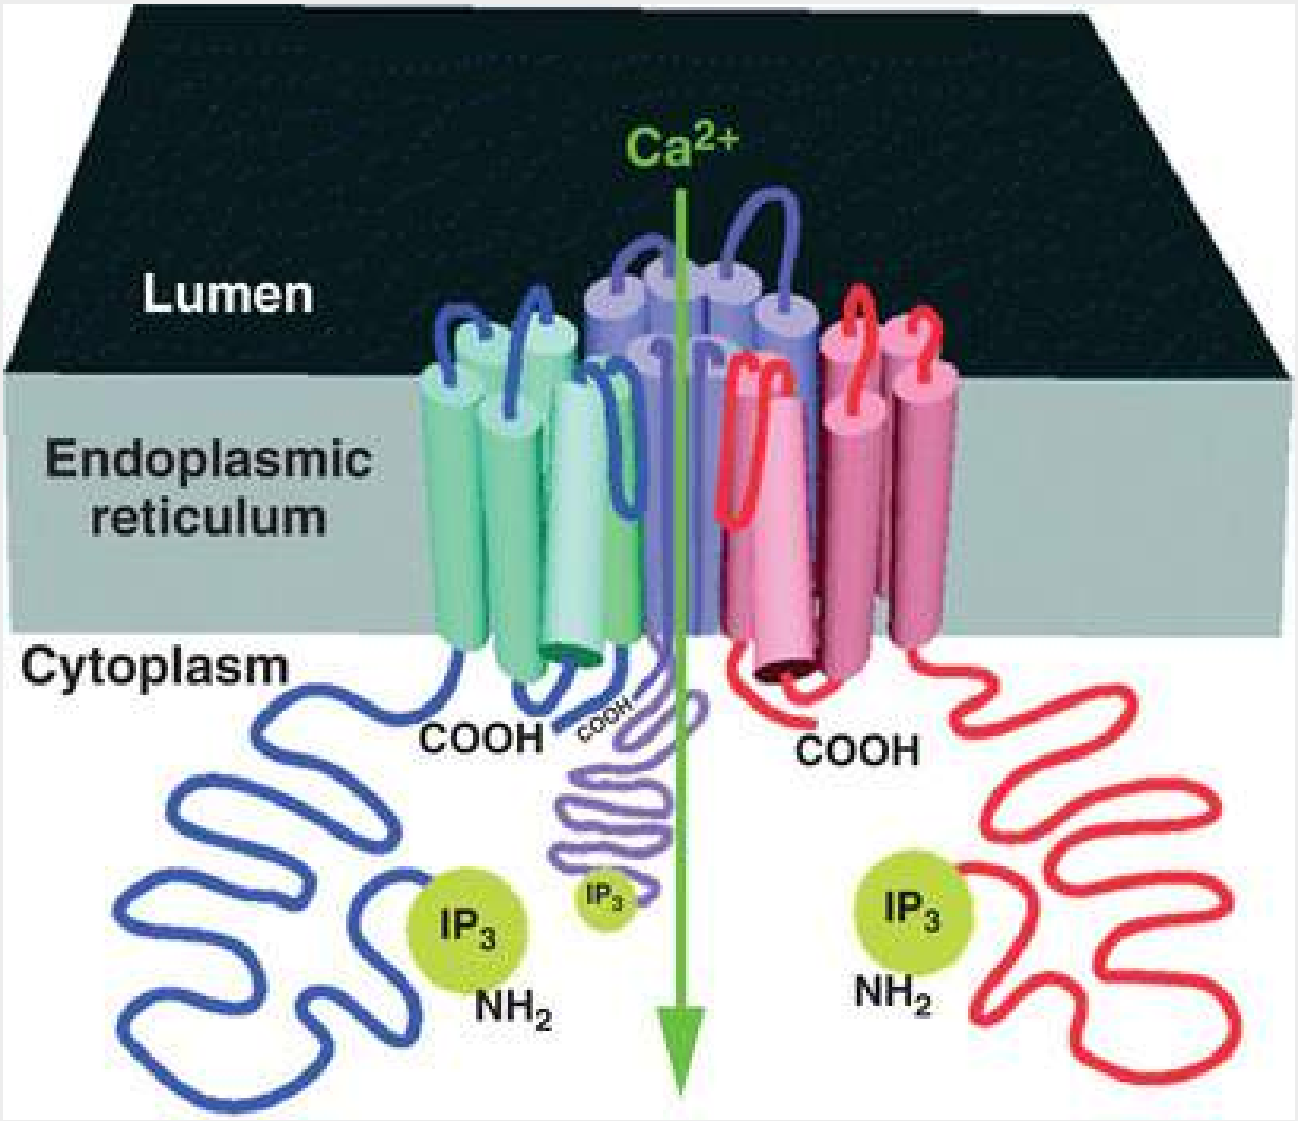


EFIGURE 34.21 Structure of the cardiac ryanodine receptor monomer subunit, RyR2, delineating the sites of interaction with auxiliary proteins and the phosphorylation sites (P). CaM, Calmodulin; CaMKII, calmodulin-dependent kinase II; FKBP, FK506-binding protein 12.6; PKA, protein kinase A; PP, protein phosphatase. Calsequestrin, junctin, and triadin are proteins that interact with RyR2 in the sarcoplasmic reticulum (SR). (From Bers DM. Macromolecular complexes regulating cardiac ryanodine receptor function. J Mol Cell Cardiol 2004;37:417.)

Mutations in the human *RYR2* gene and in *CASQ2*, which encodes calsequestrin, have been linked to CPVT. Experimental studies have revealed that the *RYR2* and *CASQ2* mutations that underlie CPVT cause an increase in the sensitivity of the RyR2 channel to luminal Ca^{2+} activation on adrenergic stimulation (e.g., from emotional or physical stress) and enhance the propensity for spontaneous, diastolic Ca^{2+} release from the SR and subsequent DAD-triggered arrhythmias. It is also possible that CPVT mutants exhibit reduced affinity for binding of the regulatory protein FKBP-12.6, thereby resulting in diastolic Ca^{2+} leakage from the SR. Reduced FKBP-12.6 binding caused by protein kinase A–mediated hyperphosphorylation has been implicated in cardiac arrhythmogenesis associated with heart failure. Polymorphic VT develops in FKBP-12.6–deficient mice on adrenergic stimulation. Treatment with the 1,4-benzothiazepine derivatives JTV519 and S107, which restore FKBP-12.6 affinity for RyR2, has been shown to suppress CPVT in FKBP-12.6–deficient mice.[1]

The IP_3 receptor (IP3R) is another Ca^{2+}-release channel in cardiomyocytes that is activated by binding of the second-messenger IP_3 and cytosolic Ca^{2+}. IP3R exists as a homotetramer or heterotetramer, each subunit encoded by the *ITPR1*, *ITPR2*, or *ITPR3* gene (**eFig. 34.22**). The type 2 IP3R is the predominant subtype in atrial myocytes, where they are located near RyR2 channels at the SR Ca^{2+}-release sites and

contribute to altered excitation-contraction coupling and arrhythmogenesis in the atria. In Purkinje myocytes, type 1 IP3Rs colocalize with type 3 RyR in the subsarcolemmal space to form a functional dyad that critically determines electrical excitability. IP_3-dependent Ca signaling has been implicated in cardiac arrhythmias attributable to ischemia and reperfusion injury, inflammation, and cardiac failure. IP3Rs are upregulated in heart failure and AF.[1,43] In atrial and Purkinje myocytes, IP_3 causes spontaneous $[Ca^{2+}]_i$ transients, Ca^{2+} waves, and Ca^{2+} alternans and facilitates the generation of afterdepolarizations.[44]



EFIGURE 34.22 Structure of the IP_3 receptor (IP3R). IP3Rs are intracellular membrane proteins that exist as homotetramers or heterotetramers. The Ca^{2+}-conducting pore is believed to be created at the central axis of the tetrameric structure. The drawing depicts three of four IP3R molecules (in different colors) in a single tetrameric channel structure. Part of the luminal loop (i.e., the loop facing the SR lumen) connecting transmembrane helices 5 and 6 of each monomer dips into the fourfold symmetric axis and creates the pathway for efflux of Ca^{2+} from the sarcoplasmic reticulum (SR) lumen. (From Foskett JK et al. Inositol trisphosphate receptor Ca^{2+} release channels. Physiol Rev 2007;87:593.)

The cascade of events linking cellular Ca^{2+}-handling abnormalities to cardiac arrhythmias is illustrated in **eFig. 34.20**. Ca^{2+} leaking through SR Ca^{2+}-release channels during diastole gives rise to localized increases in the cytosolic calcium level in a single cardiomyocyte. The focally elevated Ca^{2+} then causes a propagating Ca^{2+} wave that depolarizes the cardiomyocyte membrane and triggers a DAD through

transient activation of the inward Na^+/Ca^{2+}exchange current ($I_{Na/Ca}$). Inhibition of calmodulin kinase has a number of effects in the heart cell, including elimination of transient inward $I_{Na/Ca}$, indicating that activation of this enzyme plays an important role in cardiac arrhythmogenesis. In addition, drugs that reduce I_{Na} also reduce the transient inward current, relieve Ca^{2+} overload, and can abolish DADs. DADs most likely play a causative role in arrhythmogenesis in the failing heart, where upregulation of $I_{Na/Ca}$, in combination with downregulation of the inward rectifier K^+ current I_{K1}, facilitates DAD generation.[2]

Short coupling intervals and pacing at rates more rapid than the triggered activity rate (*overdrive pacing*) increase the amplitude and shorten the cycle length of the DAD after cessation of pacing (*overdrive acceleration*) rather than suppressing and delaying the escape rate of the afterdepolarization, as in normal automatic mechanisms. Premature stimulation exerts a similar effect: the shorter the premature interval, the larger the amplitude and the shorter the escape interval of the triggered event.

The clinical implication is that tachyarrhythmias caused by DAD-triggered activity may not be suppressed easily or indeed may be precipitated by rapid rates, either spontaneously, as with sinus tachycardia, or induced by pacing. Further, because a single premature stimulus can both initiate and terminate triggered activity, differentiation from reentry (see later) becomes difficult. The response to overdrive pacing may help separate triggered arrhythmias from reentrant arrhythmias.

Early Afterdepolarizations

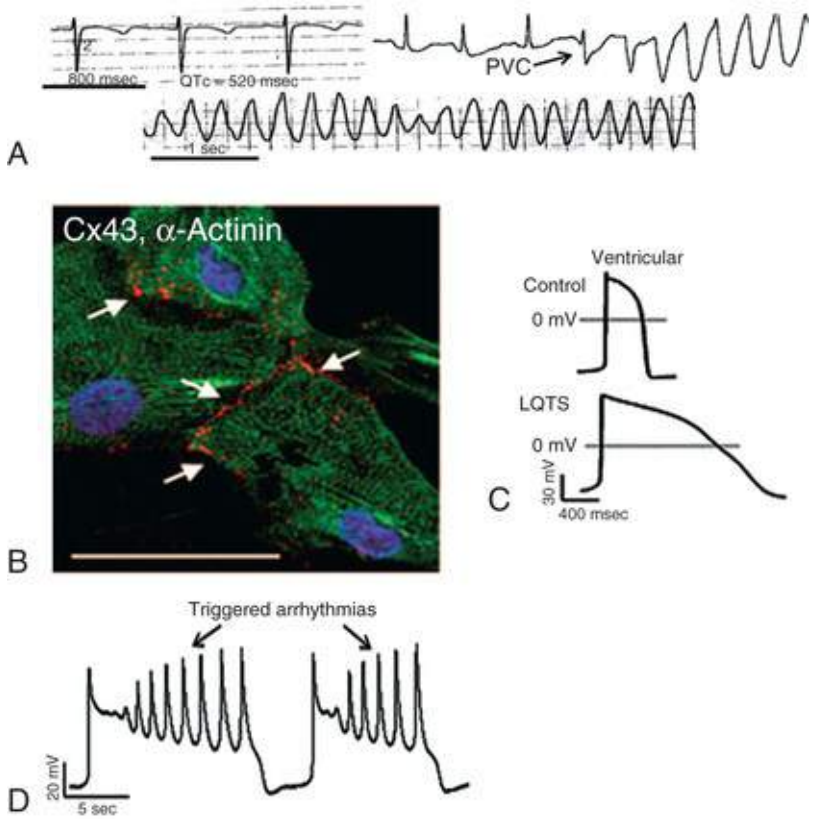
Various interventions, each of which results in an increase in intracellular positivity, can cause EADs. EADs may be responsible for the lengthened repolarization time and ventricular tachyarrhythmias seen in several clinical situations, such as the acquired and congenital forms of LQTS (**see Fig. 34.12 and Chapter 39**).

Long-QT Syndrome

Patients with heritable LQTS have an abnormally prolonged ventricular action potential duration and are at increased risk for SCD from ventricular tachyarrhythmias (**see Chapters 33 and 39**). The genesis of LQTS-associated VT or VF is uncertain. Evidence is mounting that an increased $[Ca^{2+}]_i$ related to spontaneous release of Ca^{2+} from the SR in cardiomyocytes, coupled with dispersion of repolarization, plays a causative role in LQTS-associated cardiac arrhythmia and SCD. Action potential prolongation may increase influx of Ca^{2+} through L-type Ca^{2+} channels during a cardiac cycle and cause excessive accumulation of Ca^{2+} in the SR and spontaneous release of Ca^{2+} from the SR. The ensuing elevation of intracellular free calcium can depolarize cardiomyocyte membrane potential by activation of Ca^{2+}-dependent chloride currents, the electrogenic Na^+/Ca^{2+} exchange current, or both, thereby evoking EADs. EADs can trigger a propagated response and thus elicit an extra beat, which can initiate a tachycardia.

Genetically modified mice have been used extensively to model congenital arrhythmogenic disorders, including LQTS. However, the usefulness of this approach is limited because of the profound differences in electrophysiologic properties between the murine and human heart. The ability to generate patient-specific human iPSCs offers a new paradigm for modeling human disease. Recently, several research groups have independently reported successful derivation of functional cardiomyocytes from LQTS patient–specific human iPSC lines. Electrophysiologic evaluation of LQTS cardiomyocytes demonstrated that they recapitulate the disease phenotype in vitro, including marked action potential prolongation and increased susceptibility to spontaneous or pharmacologically induced triggered activity.[45] A study of cardiomyocytes derived from LQTS patient–specific iPSCs is summarized in **eFig. 34.23**. Large-scale

production of human iPSC–derived cardiomyocytes has made it possible to generate sufficient numbers of uniform cardiac monolayers and higher-order three-dimensional models that can be used for the study of arrhythmia mechanisms in vitro.[46,47] Collectively, pluripotent stem cell technology now offers a unique platform to evaluate patient-specific arrhythmia mechanisms and to evaluate and optimize patient therapy.



EFIGURE 34.23 Recapitulation of long-QT syndrome (LQTS) via induced pluripotent stem cell (iPSC) technology. **A,** Surface ECG from a 28-year-old woman with familial type 2 LQTS as a result of a loss-of-function mutation in the *KCNH2* gene, which encodes the pore-forming subunit of the hERG potassium channel (see **Table 34.1**). Tracings were recorded during sinus rhythm (**upper left panel;** the QT interval corrected for heart rate is 520 milliseconds) and during initiation **(upper right panel)** and sustainment of torsades de pointes. **B,** iPSC-derived cardiomyocytes in culture express structural markers of the cardiac lineage. Dermal fibroblasts were obtained from the LQTS patient above and were reprogrammed to generate LQTS patient–specific human iPSCs via transduction with a cocktail of transcription factors. These iPSCs were then induced to differentiate into cardiomyocytes. Immunocytostaining revealed expression of sarcomeric alpha-actinin (*green*) and the gap junction protein connexin 43 (*red; arrows*) in LQTS cardiomyocytes. **C,** Transmembrane action potential recordings from LQTS ventricular cardiomyocytes revealed a markedly prolonged action potential duration relative to recordings obtained from healthy control patient iPSC–derived myocytes, consistent with a reduction in *KCNH2*-encoded I_{Kr} in the LQTS patient. **D,** Spontaneous development of repetitive early afterdepolarizations in LQTS cardiomyocytes. (From Itzhaki I et al. Modelling the long QT syndrome with induced pluripotent stem cells. Nature 2011;471:225.)

Experimental observations have also suggested an important role of transmural or longitudinal heterogeneity of repolarization. Marked transmural dispersion of repolarization can create a vulnerable window for the development of reentry. Direct experimental evidence of the existence of transmural dispersion in the action potential has been provided for the human heart. Normal hearts studied showed midmyocardial islands of cells that had distinctly long action potential durations (APDs) with steep local APD gradients. In contrast, failing hearts were observed to have significantly reduced transmural repolarization gradients and to lack islands of cells with delayed repolarization. The ionic mechanisms underlying transmural dispersion of repolarization in the human heart are currently unknown but may

involve spatial variations in expression of the transient outward potassium current I_{to} and the delayed rectifier potassium current I_{Ks} (**see Table 34.1**).[1]

Sympathetic stimulation, primarily left, can increase the EAD amplitude to provoke ventricular tachyarrhythmias. Alpha-adrenoceptor stimulation also increases the amplitude of cesium-induced EADs and the prevalence of ventricular tachyarrhythmias, both of which are suppressed by magnesium.

Acquired LQTS and torsades de pointes from drugs such as quinidine, *N*-acetylprocainamide, cisapride, erythromycin, and class III antiarrhythmic agents may be mediated by EADs (**see Chapters 8 and 36**). Such drugs easily elicit EADs experimentally and clinically, whereas magnesium suppresses them. Multiple drugs may additively prolong the action potential and provoke EADs and torsades de pointes in patients. Alternatively, drug-induced alterations in metabolism may increase the concentration of a compound that prolongs the action potential.[48] Activators of ATP-dependent potassium channels, such as pinacidil and nicorandil, can eliminate EADs.

Parasystole

Classically, parasystole has been likened to the function of a fixed-rate, asynchronously discharging pacemaker—its timing is generally not altered by the dominant rhythm, it produces depolarization when the myocardium is excitable, and the intervals between discharges are multiples of a basic interval (**see Chapters 35 and 39**). Complete *entrance block*, constant or intermittent, insulates and protects the parasystolic focus from surrounding electrical events and accounts for such behavior. On occasion, the focus can exhibit *exit block*, during which it may fail to depolarize excitable myocardium. In fact, the dominant cardiac rhythm may modulate parasystolic discharges to speed up or slow down its rate. Brief subthreshold depolarizations induced during the first half of the cardiac cycle of a spontaneously discharging pacemaker delay the subsequent discharge, whereas similar depolarizations induced in the second half of the cardiac cycle accelerate it.

Disorders of Impulse Conduction

Conduction delay and block can result in bradyarrhythmias or tachyarrhythmias. Bradyarrhythmias occur when the propagating impulse is blocked and is followed by asystole or a slow escape rhythm; tachyarrhythmias occur when the delay and block produce reentrant excitation (see later, Reentry). Various factors involving both active and passive membrane properties determine the conduction velocity of an impulse and whether conduction is successful. These factors include the stimulating efficacy of the propagating impulse, which is related to the amplitude and rate of rise of phase 0; the excitability of the tissue into which the impulse is conducted; and the geometry of the tissue.

Deceleration-Dependent Block

Diastolic depolarization has been suggested as a cause of conduction block at slow rates, so-called bradycardia- or deceleration-dependent block (**see Chapter 40**). However, excitability and the speed of impulse propagation *increase* as the membrane depolarizes until approximately −70 mV despite a reduction in action potential amplitude (*supernormal conduction*). This type of block has also been referred to as “phase 4 block,” but experiments in Purkinje fiber bundles have demonstrated that diastolic (phase 4) depolarization is not a necessary condition for the occurrence of deceleration-dependent block. Evidently, depolarization-induced inactivation of fast Na^+ channels is offset by other factors, such as a reduction in the difference between membrane potential and threshold potential and an increase in

membrane excitability.

Tachycardia-Dependent Block

More often, impulses are blocked at rapid rates or short cycle lengths as a result of incomplete recovery of refractoriness (postrepolarization refractoriness) caused by incomplete time- or voltage-dependent recovery of excitability. For example, such incomplete recovery is the usual mechanism responsible for a nonconducted premature P wave or one that conducts with a functional bundle branch block.

Decremental Conduction

"Decremental conduction" is a term commonly used in the clinical literature but is often misapplied to describe any Wenckebach-like conduction block, that is, responses similar to a block in the AV node during which progressive conduction delay precedes the nonconducted impulse. Correctly used, decremental conduction refers to a situation in which the properties of the fiber change along its length such that the action potential loses its efficacy as a stimulus to excite the fiber ahead of it. Thus the stimulating efficacy of the propagating action potential diminishes progressively, possibly as a result of its decreasing amplitude and slowed upstroke velocity.

Reentry

Electrical activity during each normal cardiac cycle begins in the sinoatrial node and continues until the entire heart has been activated. Each cell becomes activated in turn, and the cardiac impulse dies out when all fibers have been discharged and are completely refractory. During this absolute refractory period, the cardiac impulse has "no place to go." It must be extinguished and restarted by the next sinus impulse. If, however, a group of fibers not activated during the initial wave of depolarization recovers excitability in time to be reactivated before the impulse dies out, the fibers may serve as a link to reexcite areas that were just discharged and have now recovered from the initial depolarization. Such a process has been given various names—reentry, reentrant excitation, circus movement, reciprocal or echo beat, and reciprocating tachycardia—and all have approximately the same meaning.

Entrainment

Entraining a tachycardia (i.e., increasing the rate of the tachycardia by pacing), with resumption of the intrinsic rate of the tachycardia when pacing is stopped, establishes the presence of reentry (**Fig. 34.13A**). Entrainment represents capture or continuous resetting of the tachycardia by the pacing-induced activation. Each pacing stimulus creates a wavefront that travels in an anterograde direction (orthodromic) and resets the tachycardia to the pacing rate. A wavefront propagating retrogradely in the opposite direction (antidromic) collides with the orthodromic wavefront of the previous beat. As the right ventricular (RV) pacing rate is increased, the paced QRS morphology (**Fig. 34.13B-D**) changes, the result of more of the tachycardia circuit being captured by the anterograde activation wave, yet when pacing is stopped, the tachycardia is still present; this is referred to as *progressive fusion*. These wavefront interactions create electrocardiographic and electrophysiologic features that can be explained only by reentry. Therefore the criteria of entrainment can be used to prove the reentrant mechanism of a clinical tachycardia and form the basis for localizing the pathway traveled by the tachycardia wavefront. Such localization is essential for ablation therapy.

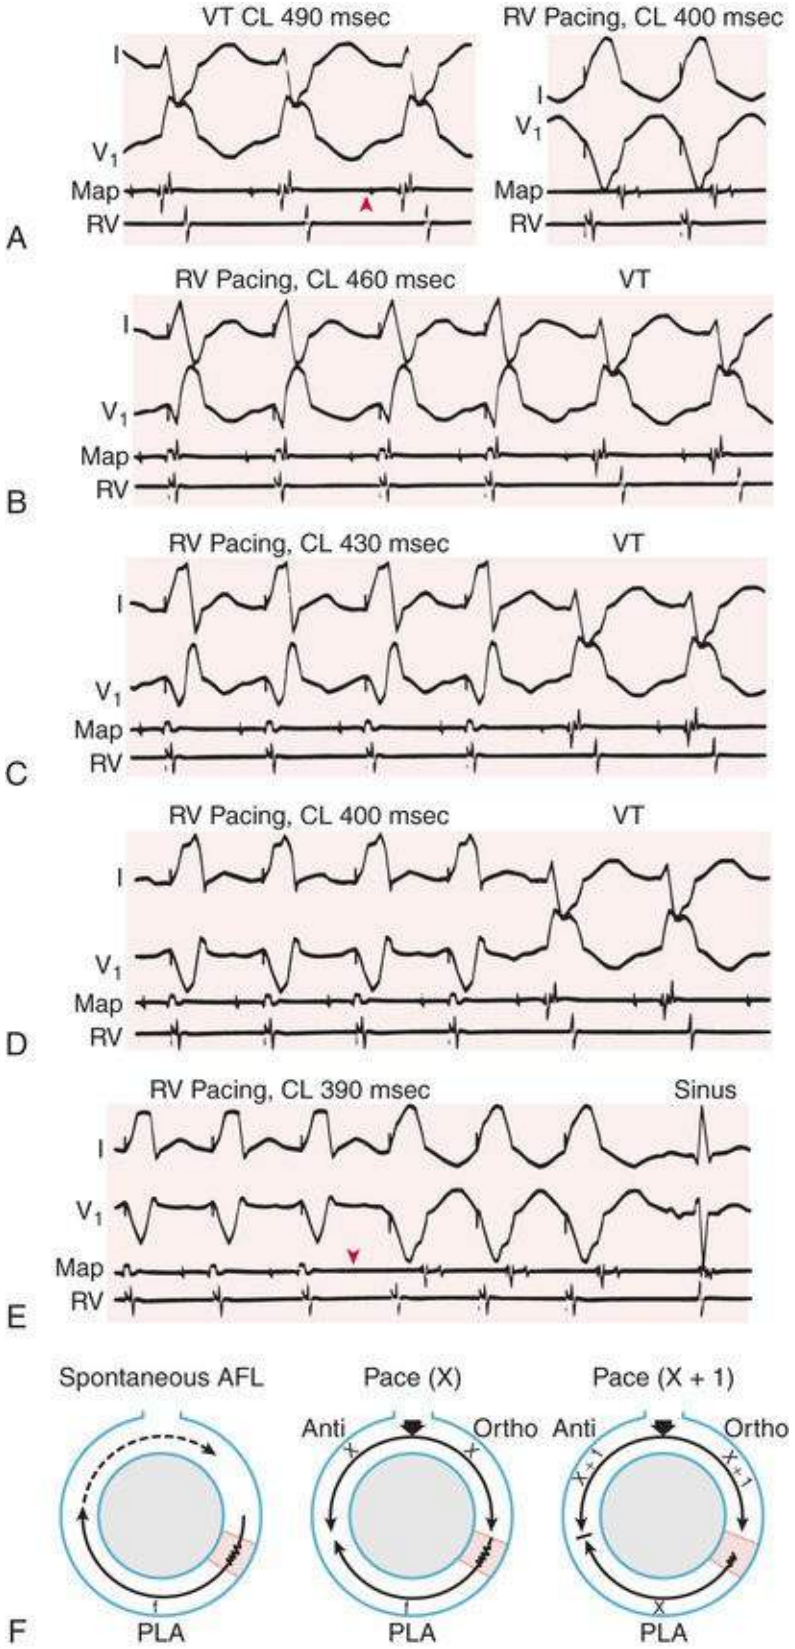


FIGURE 34.13 **A to E,** Criteria for entrainment exemplified in a case of postinfarction ventricular tachycardia (VT). **A, left,** Two leads of the ECG of a VT and intracardiac recordings from a mapping catheter (Map) at a left ventricular site critical for VT continuation, as well as from the right ventricular apex (RV). Note the diastolic potential (*red arrowhead*) during VT. Recordings are similarly arranged in all subsequent panels. **A, right,** RV pacing in the setting of sinus rhythm. **B,** RV pacing at a cycle length (CL) slightly shorter than VT produces a QRS complex that is a blend between fully VT and fully paced ("fusion") complexes. All recordings are accelerated to the paced CL, and after pacing ceases, the same VT resumes. Each fused QRS complex is identical, and the last beat is entrained, but surface fusion is absent. **C, D,** The same phenomena, but at shorter-paced CLs. Note that the fused QRS complex appears to be more similar to pacing than to VT as the pacing CL shortens. **B to D,** Progressive degrees of fusion on ECG. Map recording of **B, C,** and **D** also shows a progression of fusion, with both the morphology and timing of a portion of the electrogram changing with faster pacing. **E,** Finally, an even shorter-paced CL results in a sudden change in both map electrogram (block in small diastolic potential,

red arrowhead) and surface ECG, which is now fully paced. When pacing ceases, VT has been interrupted. **F,** Diagrammatic representation of the reentrant circuit during spontaneous atrial flutter (AFL) and transient entrainment of the AFL. **Left,** Reentrant circuit during spontaneous type I AFL; *f* = circulating wavefront of the AFL. **Center,** Introduction of the first pacing impulse (X) during rapid pacing from a high atrial site during AFL. The *black arrowhead* indicates entry of the pacing impulse into the reentrant circuit, where it is conducted orthodromically (Ortho) and antidromically (Anti). The antidromic wavefront of the pacing impulse (X) collides with the previous beat, in this case the circulating wave front of the spontaneous AFL (*f*), which results in an atrial fusion beat and, in effect, terminates the AFL. However, the orthodromic wavefront from the pacing impulse (X) continues the tachycardia and resets it to the pacing rate. **Right,** Introduction of the next pacing impulse (X + 1) during rapid pacing from the same high atrial site. The *black arrowhead* again indicates entry of the pacing impulse into the reentrant circuit, where it is conducted orthodromically and antidromically. Once again, the antidromic wavefront from the pacing impulse (X + 1) collides with the orthodromic wavefront of the previous beat. In this case, it is the orthodromic wavefront of the previous paced beat (X), and an atrial fusion beat results. The orthodromic wavefront from the pacing impulse (X + 1) continues the tachycardia and resets it to the pacing rate. In all three parts, *arrows* indicate the direction of spread of the impulses; the *serpentine line* indicates slow conduction through a presumed area of slow conduction (*stippled region*) in the reentrant circuit. (**A-E,** From Zipes DP. A century of cardiac arrhythmia: in search of Jason's golden fleece. J Am Coll Cardiol 1999;34:959; **F,** from Waldo AL. Atrial flutter: entrainment characteristics. J Cardiovasc Electrophysiol 1997;8:337.)

Anatomic Reentry

Studies on reentry have used models with anatomically defined separate pathways where it could be shown that they had an area of unidirectional block and recirculation of the impulse to its point of origin. An example of AV nodal reentry using different pathways is illustrated in **Fig. 34.14**. Because the two pathways have different electrophysiologic properties (e.g., shorter refractory period and slower conduction in one pathway versus a longer refractory period and faster conduction of the other), the impulse is first blocked anterogradely in the fast pathway with the longer refractory period and then propagates slowly in the adjacent slow pathway, whose refractory period is shorter (**Fig. 34.14A**). If conduction in this alternative route is sufficiently depressed, the slowly propagating impulse excites tissue beyond the blocked pathway and returns in the reverse direction along the pathway initially blocked, to reexcite tissue proximal to the site of block (**Fig. 34.14B**). A clinical arrhythmia caused by anatomic reentry is most likely to have a monomorphic contour (Video 34.2).

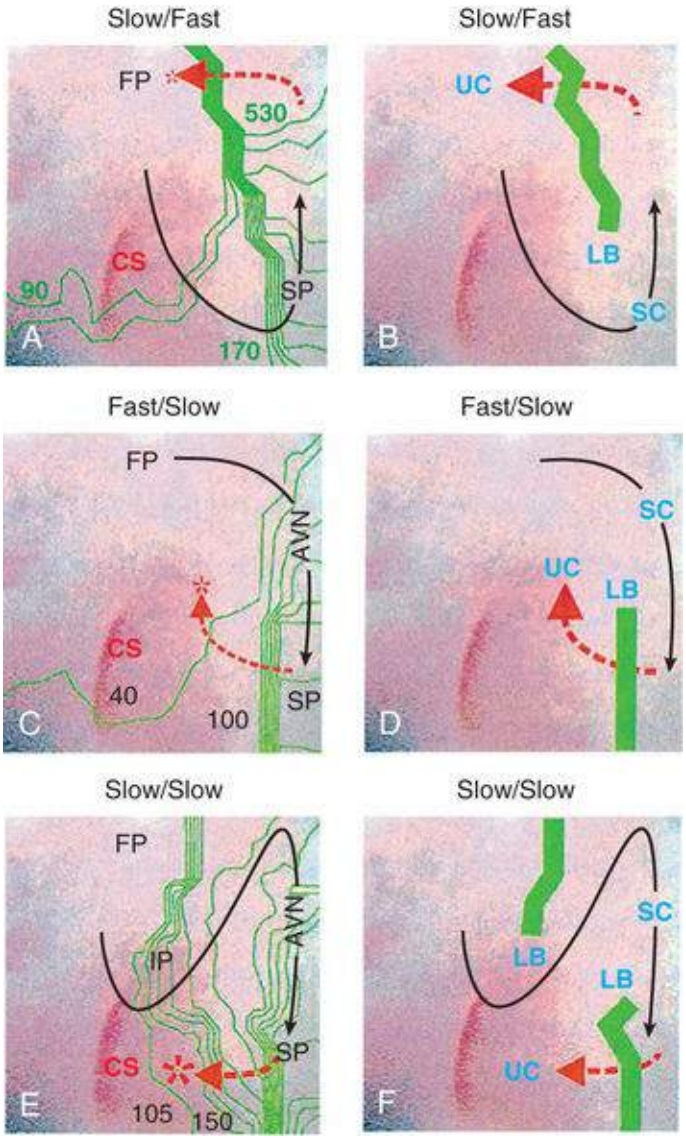

FIGURE 34.14 Reentrant circuits of different types of atrioventricular nodal reentrant tachycardia (AVNRT). Pictures of the optical activation maps of A_2 stimuli obtained from three different experiments at A_2 coupling intervals of 190, 220, and 190 milliseconds, respectively, were merged with the pictures of the mapping area to show the initiation of echo beats in **A** (Slow/Fast), **C** (Fast/Slow), and **E** (Slow/Slow) circuits. The numbers on the maps indicate the activation times in reference to the A_2 stimulus. The *black arrow* indicates anterograde conduction, and the *asterisk* and the *dashed red arrow* represent the site of earliest retrograde atrial activation. The corresponding locations of the lines of block (LB, *green*), slow anterograde conduction (SC, *black arrow*), and unidirectional conduction (UC, *red*) are shown in **B, D,** and **F,** respectively. *CS,* Coronary sinus; *FP,* fast pathway; *IP,* intermediate pathway; *SP,* slow pathway. (From Wu J, Zipes DP. Mechanisms underlying atrioventricular nodal conduction and the reentrant circuit of atrioventricular nodal reentrant tachycardia using optical mapping. J Cardiovasc Electrophysiol 2002;13:831.)

For anatomic reentry to occur, the time for conduction within the depressed but unblocked area and for excitation of the distal segments must exceed the refractory period of the initially blocked pathway and the tissue proximal to the site of block. Stated another way, continuous reentry requires the anatomic length of the circuit traveled to equal or exceed the reentrant wavelength (λ). The latter, λ, is equal to the mean conduction velocity of the impulse multiplied by the longest refractory period of the elements in the circuit. Both values can be different at different points along the reentry pathway, and thus a tachycardia does not have a single wavelength.

Conditions for Anatomic Reentry.

The length of the pathway is fixed and determined by the anatomy. Conditions that depress conduction velocity or abbreviate the refractory period promote the development of reentry in this model, whereas prolonging refractoriness and speeding conduction velocity can hinder it. For example, if conduction velocity (0.30 m/sec) and refractoriness (350 milliseconds) for ventricular muscle were normal, a pathway of 105 mm (0.30 m/sec × 0.35 sec) would be necessary for reentry to occur. However, under certain conditions, conduction velocity in ventricular muscle and Purkinje fibers can be very slow (0.03 m/sec), and if refractoriness is not greatly prolonged (600 milliseconds), a pathway of only 18 mm (0.03 m/sec × 0.60 sec) may be necessary. Such reentry frequently exhibits an *excitable gap*, that is, a time interval between the end of refractoriness from one cycle and the beginning of depolarization in the next, when tissue in the circuit is excitable. This condition results because the wavelength of the reentrant circuit is *less* than the length of the pathway. Electrical stimulation during this period can invade the reentrant circuit and reset its timing or terminate the tachycardia. Although "microanatomic" reentry (confinement of the reentrant circuit to a few adjacent myocytes) has been postulated to occur in fibrotic myocardium, its occurrence in intact heart muscle has not been demonstrated directly. This difficulty results from the inability unambiguously to distinguish microreentry from triggered activity with currently available techniques.

In reentrant circuits with an excitable gap, conduction velocity determines the revolution time of the impulse around the circuit and therefore the rate of the tachycardia. Prolongation of refractoriness, unless it is long enough to eliminate the excitable gap and make the impulse propagate in relatively refractory tissue, does not influence the revolution time around the circuit or the rate of the tachycardia. Anatomic reentry occurs in patients with Wolff-Parkinson-White (WPW) syndrome (**Fig. 34.15**), in AV nodal reentry, in some atrial flutters, and in some VTs.

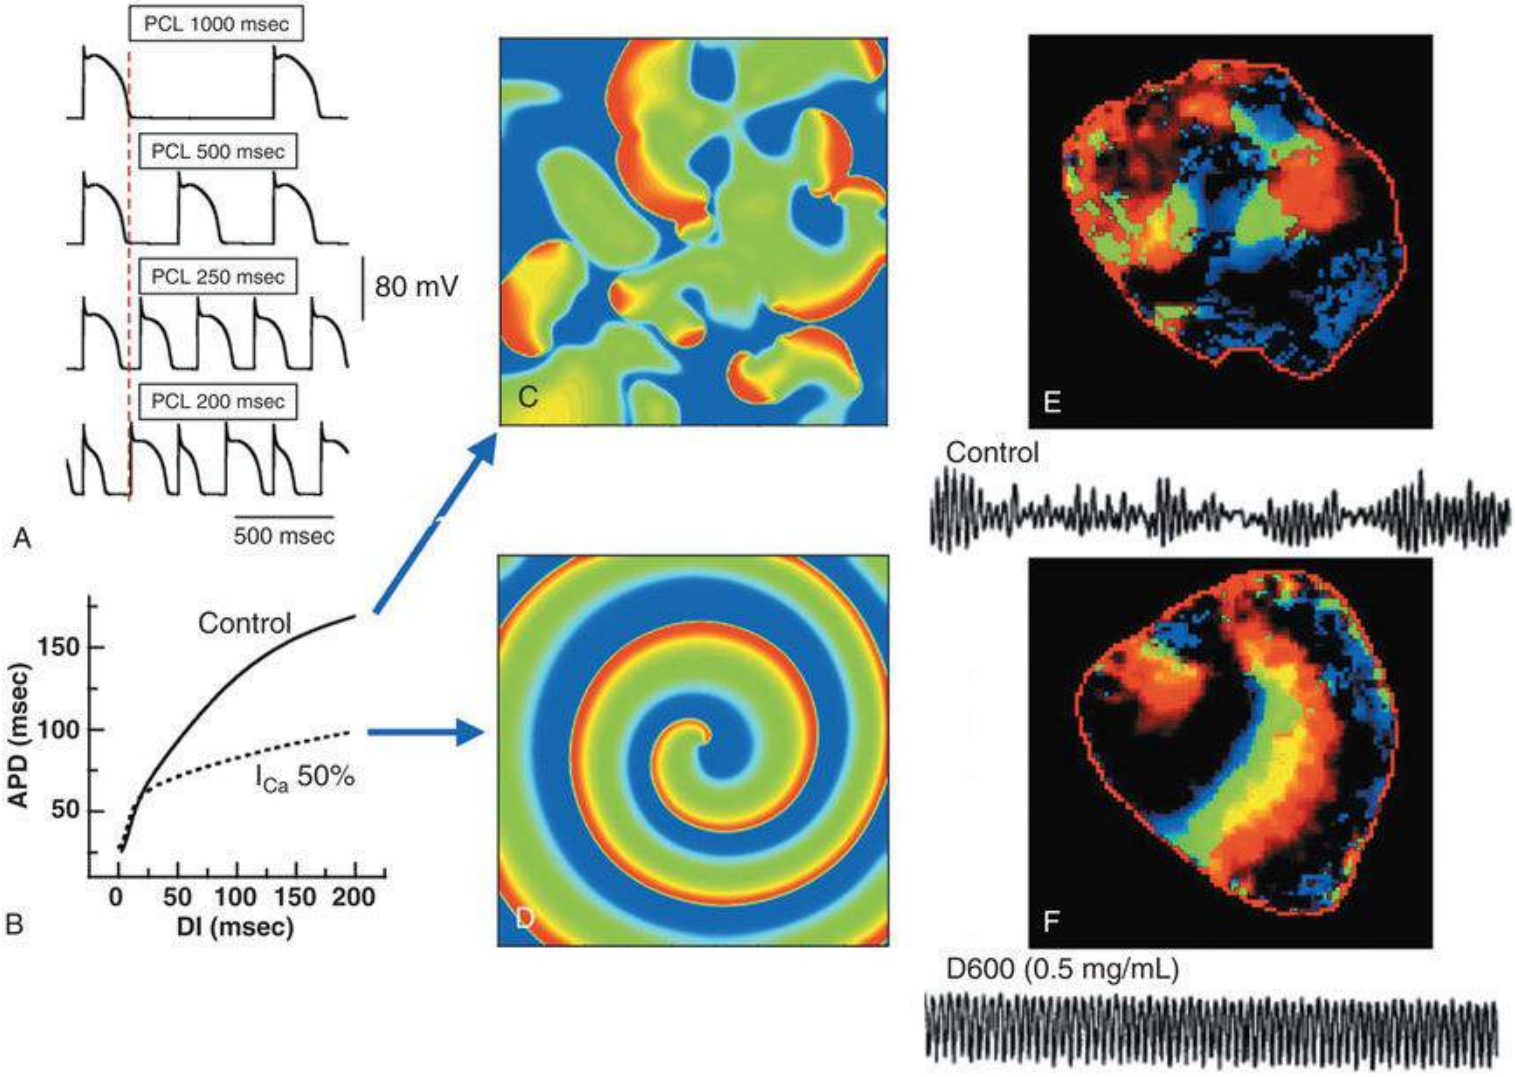
FIGURE 34.15 **A,** Wolff-Parkinson-White syndrome. Following high right atrial pacing at a cycle length of 500 milliseconds (S_1-S_1), premature stimulation at a coupling interval of 300 milliseconds (S_1-S_2) produces physiologic delay in AV nodal conduction, which results in an increase in the A-H interval from 100 to 140 milliseconds but no delay in the AV interval. Consequently, activation of the His bundle follows activation of the QRS complex (*second interrupted line*), and the QRS complex becomes more anomalous in appearance because of increased ventricular activation over the accessory pathway. **B,** Induction of reciprocating AV tachycardia. Premature stimulation at a coupling interval of 230 milliseconds prolongs the A_2-H_2 interval to 230 milliseconds and results in anterograde block in the accessory pathway and normalization of the QRS complex (a slight functional aberrancy in the nature of incomplete right bundle branch block occurs). Note that H_2 precedes onset of the QRS complex (*interrupted line*). Following V_2, the atria are excited retrogradely (A′) beginning in the distal coronary sinus, followed by atrial activation in leads recording from the proximal coronary sinus, His bundle, and high right atrium. A supraventricular tachycardia is initiated at a cycle length of 330 milliseconds. I, II, III, and V_1 indicate scalar electrocardiographic leads. A, H-V, atrial, His bundle, and ventricular activation during the drive train; A_2, H_2,V_2, atrial, His bundle, and ventricular activation during the premature stimulus; DCS, distal coronary sinus electrogram; HBE, His bundle electrogram; HRA, high right atrium; PCS, proximal coronary sinus electrogram; RV, right ventricular electrogram. Indiana Med 1986;89:432.)

Functional Reentry

Functional reentry lacks confining anatomic boundaries and can occur in contiguous fibers that exhibit functionally different electrophysiologic properties caused by local differences in transmembrane action potential (e.g., Purkinje-myocyte transition). Dispersion of excitability, refractoriness, or both, as well as anisotropic distributions of intercellular resistance, permit initiation and maintenance of reentry. Functional heterogeneities in the electrophysiologic properties of the myocardium have been shown to contribute to the generation and maintenance of tachycardia and fibrillation. These heterogeneities can be fixed, as in the case of spatial redistribution of gap junctions in the failing heart or infarct border zone, or with spatial gradients in the magnitude of the background K^+ current I_{K1}. They can also change dynamically, as in an acutely ischemic myocardium or in the presence of repolarization-prolonging agents.[1,49] A very important determinant of the dynamically induced component of heterogeneity has been identified as *electrical restitution*, or variation of the action potential duration and conduction velocity with the diastolic interval. It has been proposed that the breakup of periodic waves is precipitated by oscillations in the APD (APD alternans) of sufficiently large amplitude to cause conduction block along a spiral wavefront[50] (**eFig. 34.24**).



EFIGURE 34.24 Action potential duration (APD) restitution slope and rotor stability. **A,** APD shortening and APD alternans as the pacing cycle length (PCL) decreases (computer simulations). **B,** APD restitution curves with a slope greater than 1 (*solid line*) or less than 1 (*dashed line*, obtained with 50% block of the calcium current). **C, D,** Spiral wave behavior several seconds after initiating a rotor in homogeneous two-dimensional tissue. All myocytes are assumed to be identical, with either a steep **(C)** or shallow **(D)** APD restitution slope. **E, F,** Conversion of multiple-wavelet ventricular fibrillation (VF) to mother rotor VF. Optically measured surface voltage maps were obtained from an intact Langendorff-perfused rabbit heart before **(E)** and after **(F)** partially blocking the L-type calcium current to flatten the APD restitution slope to less than 1. In **E,** multiple wavefronts move in a complex VF pattern. In **F,** VF has converted to ventricular tachycardia, manifested as a stable rotor. *Black tracings* below the color panels in **E** and **F** are corresponding electrograms. *DI,* Diastolic interval. Tachycardias Caused by Reentry

Reentry is probably the cause of many tachyarrhythmias, including various types of supraventricular and ventricular tachycardias, flutter, and fibrillation (**see Chapters 37 and 39**).

Atrial Flutter

Reentry is the most likely cause of the usual form of atrial flutter, with the reentrant circuit being confined to the right atrium in typical atrial flutter, where it usually travels counterclockwise in a caudocranial direction in the interatrial septum and in a craniocaudal direction in the right atrial free wall. An area of slow conduction is present in the posterolateral to posteromedial inferior area of the right atrium, along

with a central area of block that can include an anatomic (IVC) and functional component. This area of slow conduction is rather constant and represents the site of successful ablation of typical atrial flutter. Ablation results are consistent with a macroreentry circuit.

Different reentrant circuits exist in patients with other types of atrial flutter, such as those that occur after surgery or ablation or that are associated with an atrial septal defect (**see Chapter 75**).

Atrial Fibrillation

Spatiotemporal Organization and Focal Discharge

According to the multiple-wavelet hypothesis, AF is characterized by fragmentation of the wavefront into multiple daughter wavelets (**see Chapter 38**). They wander randomly throughout the atrium and give rise to new wavelets that collide with each other and are mutually annihilated or that give rise to new wavelets in a perpetual activity.

The randomness of the irregular electrical activity during AF has been disputed on the basis of both statistical methods and experimental studies. A combination of high-resolution video imaging, ECG recordings, and spectral analysis was used to demonstrate that reentry in anatomically or functionally determined circuits forms the basis of spatiotemporal periodicity during acute AF. The cycle length of the source in the left atrium determines the dominant peak in the frequency spectra. The underlying periodicity may stem from a repetitive focal source of activity propagated from an individual pulmonary vein or left atrial site to the remainder of the atrium as fibrillating waves. If a single repetitive focal source of activity that undergoes fractionated conduction underlies the maintenance of AF, ablation of this focal source should interrupt AF. Indeed, delivery of radiofrequency energy to discrete sites in the distal pulmonary veins in humans has been shown to eliminate or reduce recurrence of AF. Alternatively, ablation of a discrete focus that serves as a trigger for AF would also reduce arrhythmia recurrence. In a large animal model of inducible AF associated with heart failure, it was recently demonstrated that AF dynamics is characterized by rapid repetitive activation (resulting from either microanatomic reentry or triggered activity) revolving around fibrotic obstacles in the posterior left atrium or pulmonary vein ostia. Furthermore, fibrillatory activity was maintained by intramural reentry centered on fibrotic patches and appeared as *endocardial breakthroughs* at the posterior left atrium (endocardial breakthroughs are considered sudden and unexpected appearances of localized electrical activity not related to activation or slow conduction in the surrounding regions). In atria with heart failure, AF waves changed the origin and direction of propagation on a beat-to-beat basis, whereas in normal left atria, the breakthrough sites and direction of activation of AF wavefronts were highly recurrent from one AF wave to the next (Video 34.3).

Several experimental models have been used to study the structural and basic electrophysiologic properties of pulmonary veins that are thought to play a role in initiation and maintenance of AF. Morphologic studies have demonstrated the presence of complex anatomic structures and phenotypically different cardiomyocytes in pulmonary veins.[1,51] Electrophysiologic studies have shown that a combination of reentrant and nonreentrant mechanisms (automaticity and triggered activity) is the underlying arrhythmogenic mechanism for initiation of AF from the pulmonary veins. Abnormal intracellular calcium handling probably plays a pivotal role in the pulmonary vein electrical activity.

Ion Channel Abnormalities in Atrial Fibrillation

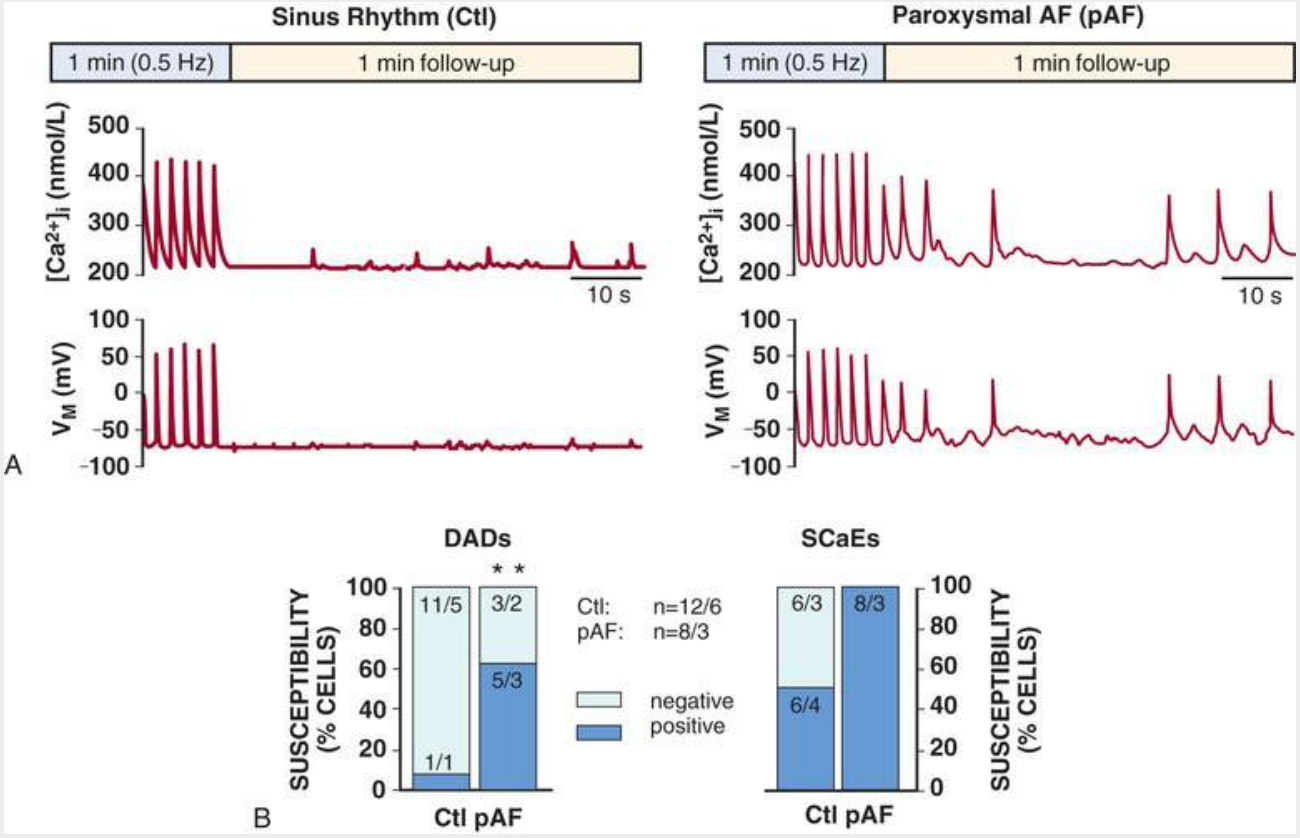
Monogenic (Familial) Atrial Fibrillation.

Although familial forms of AF are relatively rare, identification of mutations in AF kindreds has provided valuable insight into the molecular pathways underlying the arrhythmia. Most mutations linked to familial AF have been located in genes that encode sodium or potassium channel subunits. Functional analyses of these mutations have revealed either gain-of-function or loss-of-function effects. Mutations in genes encoding pore-forming alpha or auxiliary beta subunits of the delayed rectifier potassium channel and the voltage-gated sodium channel (I_{Ks} and I_{Na}, respectively; **see Table 34.1**) have been reported in familial AF. The mechanisms by which these mutations cause AF are not clearly understood. Gain-of-function mutations in I_{Ks} give rise to increased repolarizing currents, which then shorten the APD and atrial refractoriness, thereby facilitating fibrillatory activity. An augmented inward sodium current can induce triggered activity. Conversely, a reduced inward sodium current promotes reentry by abbreviating the action potential duration/refractoriness and thus the reentry wavelength. Other potassium channel mutations in the *KCNJ2* and *KCNA5* genes, which encode the inward rectifier and ultrarapid delayed rectifier potassium current, respectively, have been associated with AF (**see Table 34.1**). Finally, mutations in the *GJA5* gene, which encodes the gap junction channel subunit connexin 40, have been linked to familial AF. Functionally, abnormal intercellular electrical coupling can result in conduction heterogeneity and facilitate reentry.[52]

Genome-Wide Association Studies for Lone Atrial Fibrillation.

GWASs have identified variations in multiple genomic regions that are associated with lone AF. [19] These regions encode ion channels (e.g., calcium-activated potassium channel gene *KCNN3*, HCN channel gene *HCN4*), transcription factors related to cardiopulmonary development (e.g., homeodomain transcription factor PRRX1), and cell-signaling molecules (e.g., CAV1, a cellular membrane protein involved in signal transduction). The mechanistic links between these genetic variations and susceptibility to AF remain to be determined.

A number of experimental studies have probed the primary role of abnormalities in ion channel expression or properties in causing AF. In human tissue studies, diastolic Ca^{2+} leak and associated triggered activity in right atrial appendage myocytes were associated with paroxysmal AF[53] (**eFig. 34.25**). Genetically induced deficiency of Cav1.3 Ca^{2+} channels, or ablation of *KCNE1* (an auxiliary subunit of the pore-forming K^+ channel α subunit *KCNQ1*) or a small-conductance Ca^{2+}-dependent potassium (SK) channel impairs repolarization and increases atrial arrhythmias in mouse models.[1] SK channels participate in repolarization of human atrial myocytes and are dysregulated in chronic AF.[9]



EFIGURE 34.25 Atrial fibrillation (AF), delayed afterdepolarizations (DADs), spontaneous SR Ca^{2+}-release events (SCaEs) in human right atrial myocytes. **A,** Intracellular [Ca^{2+}] **(top)** and membrane potential **(bottom)** in control (Ctl) **(left)** and paroxysmal AF (pAF) **(right)** cardiomyocytes. Cellular and molecular mechanisms of atrial arrhythmogenesis in patients with paroxysmal atrial fibrillation. Circulation 2014;129:145.)

Electrical Remodeling of the Atria

Electrical remodeling of the atria appears to be a key determinant for maintenance of AF. Prolonged rapid atrial rates cause electrophysiologic alterations in the atria, including shortening and loss of the physiologic rate adaptation of refractoriness and a decrease in conduction velocity. Because abbreviation of the atrial refractory period is disproportionately larger than the reduction in conduction velocity, the wavelength of the reentrant wavelets shortens and thereby promotes reentrant activity.

The ionic basis of shortening of the refractory period and slowing of conduction may be a significant reduction in the density of the L-type Ca^{2+} and the fast Na^{+} currents. The electrophysiologic changes are paralleled by similar decreases in messenger RNA levels of Ca^{2+} and Na^{+} channel genes, which suggests alterations in gene expression as the underlying molecular mechanisms of atrial electrical remodeling. Changes in the density, spatial distribution, or both of various connexin types may also cause alterations in atrial impulse propagation. [54] In addition, autonomic remodeling appears to play a key role in both triggering and maintaining AF. Long-term selective vagal denervation of the atria and SA and AV nodes prevents induction of AF. Heterogeneous sympathetic denervation of the atria favors the development of sustained AF.[55]

Sinus Reentry

The SA node shares with the AV node electrophysiologic features such as the potential for dissociation of

conduction; that is, an impulse can be conducted in some nodal fibers but not in others, thereby permitting reentry to occur (**see Chapter 37**). The reentrant circuit can be located entirely within the SA node or may involve both the SA node and atrium. Supraventricular tachycardias caused by sinus node reentry are generally less symptomatic than other SVTs because of slower rates. Ablation of the SA node may occasionally be necessary for refractory tachycardia.

Atrial Reentry

Reentry within the atrium, unrelated to the SA node, can be a cause of SVT in humans. Distinguishing atrial tachycardia (AT) caused by automaticity or afterdepolarizations from AT sustained by reentry over small areas (i.e., microanatomic reentry) is difficult.

Atrioventricular Nodal Reentry

Differences in the electrical properties of the various tissue types that contribute to the AV node are responsible for AV nodal reentrant tachycardia (AVNRT; **see Fig. 34.9 and eFig. 34.12**). Optical mapping of AV nodal transmembrane action potentials during echo beats reveals the reentrant pathways underlying the various types of AVNRT (**see Fig. 34.14**). The reentrant pathway of the slow-fast type starts counterclockwise with block in the fast pathway (transitional zone; **see Fig. 34.9**), delay in conduction across the slow pathway (inferior nodal extension, INE) to the compact AV node (CN), exit from the AV node to the fast pathway, and rapid return to the slow pathway through atrial tissue located at the base of the triangle of Koch. The reentrant circuit of the fast-slow type is clockwise. In the slow-slow type, anterograde conduction is over the intermediate pathway and retrograde conduction is over the slow pathway. Because slow-pathway conduction is involved in each type of AVNRT, ablation of the slow pathway is effective for all types of AVNRT. These results also demonstrate that atrial tissue surrounding the triangle of Koch is clearly involved in all three types of AV nodal reentry described.

Preexcitation Syndrome

In most patients who have reciprocating tachycardias associated with WPW syndrome, the accessory pathway conducts more rapidly than the normal AV node but takes a longer time to recover excitability; that is, the anterograde refractory period of the accessory pathway exceeds that of the AV node at long cycles. Consequently, a premature atrial complex (PAC) that occurs sufficiently early is blocked anterogradely in the accessory pathway and continues to the ventricle over the normal AV node and His bundle. After the ventricles have been excited, the impulse is able to enter the accessory pathway retrogradely and return to the atrium. A continuous conduction loop of this type establishes the circuit for the tachycardia. The usual (orthodromic) activation wave during such a reciprocating tachycardia in a patient with an accessory pathway occurs anterogradely over the normal AV node–His-Purkinje system and retrogradely over the accessory pathway, which results in a normal-duration QRS complex (**see Fig. 34.15**).

Because the circuit requires both atria and ventricles, the term “supraventricular tachycardia” is not precisely correct, and the tachycardia is more accurately termed *atrioventricular reciprocating tachycardia* (AVRT). The reentrant loop can be interrupted by ablation of the normal AV node–His bundle pathway *or* the accessory pathway. On occasion, the activation wave travels in a reverse (antidromic) direction to the ventricles over the accessory pathway and to the atria retrogradely up the AV node. Two accessory pathways can form the circuit in some patients with antidromic AVRT. In some patients the accessory pathway may be capable of only retrograde conduction (“concealed”), but the circuit and

mechanism of AVRT remain the same. Less frequently, the accessory pathway can conduct only anterogradely. The pathway can be localized by ECG analysis. Patients can have AF as well as AVRT. Developmental studies in mice have demonstrated that myocardium-specific inactivation of T-box 2 (Tbx2), a transcription factor essential for AV canal patterning, leads to the formation of fast-conducting accessory pathways, malformation of the annulus fibrosus, and ventricular preexcitation in mice.[56]

Unusual accessory pathways with AV node–like electrophysiologic properties, that is, nodofascicular or nodoventricular fibers, can be part of the circuit for reciprocating tachycardias in patients who have variant forms of WPW syndrome. Tachycardia in patients with nodoventricular fibers can be caused by reentry, with these fibers being used as the anterograde pathway, and the His-Purkinje fibers and a portion of the AV node being used retrogradely. In the Lown-Ganong-Levine syndrome (short PR interval and normal QRS complex), conduction over a James fiber that connects the atrium to the distal portion of the AV node and His bundle has been proposed, although little functional evidence exists to support the presence of this entity.

Ventricular Tachycardia Caused by Reentry

Reentry in the ventricle, both anatomic and functional, as a cause of sustained VT has been supported by many animal and clinical studies (**see Chapter 37**). Reentry in ventricular muscle, with or without contributions from specialized tissue, is responsible for many or most VTs in patients with ischemic heart disease. The area of microreentry appears to be small, and less often a macroreentry circuit is found around the infarct scar. Surviving myocardial tissue separated by connective tissue provides serpentine routes of activation traversing infarcted areas that can establish reentry pathways. Bundle branch reentry, macroreentry using the specialized conduction system, can cause sustained ventricular tachycardia, particularly in patients with dilated cardiomyopathy.

Both figure-of-8 and single-circle reentrant loops have been described as circulating around an area of functional block in a manner consistent with the “leading circle” hypothesis or as conducting slowly across an apparent area of block created by anisotropy. When intramural myocardium survives, it can form part of the reentrant loop. Structural discontinuities that separate muscle bundles—as a result of the naturally occurring myocardial fiber orientation and anisotropic conduction, as well as collagen matrices formed from the fibrosis after MI—establish the basis for slowed conduction and fragmented electrograms, which can lead to reentry. After MI, the surviving epicardial border zone undergoes substantial electrical remodeling, including reduced conduction velocity and increased anisotropy associated with the occurrence of reentrant circuits and VT. Slowing of conduction arises from alterations in the spatial distribution and electrophysiologic properties of connexin 43 gap junctions, as well as from reduced voltage-gated sodium current. Whether myocyte depolarization secondary to electrotonic coupling to adjacent myofibroblasts (which typically have a much more depolarized potential) plays a role in electrical remodeling in postinfarction border-zone myocardium remains to be seen. During acute ischemia, various factors, including elevated $[K^+]_o$ and reduced pH, combine to create depressed action potentials in ischemic cells that impede conduction and can lead to reentry. Indeed, optical mapping studies in arterially perfused canine wedge preparations during global no-flow ischemia have demonstrated initiation of reentry during initial ischemia and subsequent reperfusion caused by the unidirectional block of conduction resulting from the spatiotemporal dispersion in tissue responses to stimulation. The rapidly changing combination of transmural dispersion in response to endocardial pacing stimuli and the velocity of conduction creates a dynamic substrate in which reentry can be initiated and sustained.

Brugada Syndrome

Phase 2 reentry has been implicated in the genesis of VT-VF associated with Brugada syndrome, which is characterized by ST-segment elevation (unrelated to ischemia, electrolyte abnormalities, or structural heart disease) in the right precordial (V_1 to V_3) leads of the ECG, often but not always accompanied by an apparent right bundle branch block. The hereditary nature of the syndrome is well established; however, it is apparent that simple mendelian transmission does not explain the phenotypic expression in many cases.[10] Brugada syndrome has been linked to loss-of-function mutations in *SCN5A*, which encodes the pore-forming cardiac sodium channel alpha subunit Nav1.5, and mutations in *SCN1B*, *SCN2B*, and *SCN3B*, which encode the function-modifying sodium channel beta subunits (**see Chapter 33**). Although Na^+ channel mutations are most common, mutations in the α and β subunits of the Ca^{2+} channel and several potassium channel genes have been found in some patients with Brugada syndrome, as have mutations in the glycerol-3-phosphate dehydrogenase 1–like (*GPD1L*) and other genes that encode proteins that regulate the functional expression of the Na^+ current I_{Na}. Brugada syndrome–associated gene defects cause a reduction or loss of sodium or calcium current in combination with altered functional properties of voltage-gated sodium channels.[57] Alterations in the sodium current can cause heterogeneous loss of the action potential dome during the plateau phase (phase 2) in the right ventricular epicardium, which leads to a marked dispersion of repolarization and refractoriness and the potential for phase 2 reentry. Ablation of RV epicardium eliminated ventricular arrhythmias in an animal model of pharmacologically induced Brugada syndrome. However, ablation in humans has been shown to eliminate the electrocardiographic changes but does not totally eliminate the risk of recurrent ventricular arrhythmias.[58]

Catecholaminergic Polymorphic Ventricular Tachycardia

CPVT is an inherited arrhythmogenic syndrome characterized by stress-induced, adrenergically-mediated polymorphic ventricular tachycardia occurring in structurally normal hearts. Heterozygous missense mutations in the gene encoding the RyR2 have been reported in most patients with CPVT, although mutations in the calsequestrin gene can also cause CPVT. A common mechanism underlying RyR2-associated CPVT is increased leakage of Ca^{2+} from the SR during diastole, leading to intracellular Ca^{2+} waves and triggered activity. Carvedilol, a beta blocker used for prevention of ventricular tachyarrhythmias in heart failure, and flecainide, a blocker of voltage-gated sodium channels, have recently been shown to suppress CPVT by direct inhibition of cardiac ryanodine receptor–mediated Ca^{2+} release, thus indicating that these agents possess pharmacologic properties that can be exploited for the treatment of Ca^{2+}-dependent arrhythmias in the clinical setting.[1,59] Although the mechanism of action of flecainide in CPVT has been debated, some studies suggest block of a noncardiac Nav channel in the dyad.[5,60]

Arrhythmogenic Right Ventricular Cardiomyopathy

Arrhythmogenic right ventricular cardiomyopathy (ARVC) is an inherited myopathy characterized by sustained monomorphic ventricular tachycardia and sudden death (**see Chapter 77**). Previous studies have linked ARVC with mutations in proteins of the cardiac desmosome, a component of the intercalated disc essential for mechanical coupling between cardiomyocytes. Mutations in multiple genes, including desmoplakin, desmoglein 2, desmocollin 2, plakophilin 2, plakoglobin (*JUP*, also called gamma-catenin), ryanodine receptor 2, laminin receptor 1, and transforming growth factor-beta 3, have been identified in patients with ARVC. Approximately 40% of the pathogenic mutations linked to ARVC are in the gene encoding plakophilin 2 (*PKP2*), which interacts with other cytoskeletal proteins to stabilize the

desmosome.[30] In vitro studies have demonstrated that loss of *PKP2* expression reduces the voltage-gated sodium current and connexin 43 expression at the intercalated disc and thus results in slowed action potential propagation. Shared phenotypic, genetic and functional features have suggested the possibility of pathogenic links between ARVC and Brugada syndrome.[28,61]

Ventricular Fibrillation: Initiation and Maintenance

Previous experimental and simulation investigations have suggested that VF is maintained solely by reentry (**see Chapter 39**). This reentry was thought to be unstable and to be maintained by wandering wavelets of activation following constantly changing paths of activation and exhibiting frequent conduction block caused by nonuniform dispersion of refractoriness. More recent investigations have suggested other mechanisms of maintenance of VF and have introduced the concepts of restitution kinetics, wavefront, wave break, focal discharge, and rotors as replacement for the classic reentry theory.[50,62] (For a demonstration of wavefront dynamics during fibrillation, see Video 34.4.)

The hallmark of cardiac fibrillation is ongoing wave break (or wave splitting). Wave break is caused by conduction block occurring at a specific site along the wavefront while the remaining portions of the front continue to propagate. This localized block, wave break, causes splitting of the mother wavefront into two daughter wavelets. Two hypotheses exist regarding the genesis of wave breaks during fibrillation. The “mother rotor” hypothesis states that VF is maintained by a single, stationary, intramural stable reentrant circuit (i.e., the mother rotor) in a dominant domain, which has the shortest refractory period from which activations propagate into the more slowly activating domains with longer refractory periods. Wave breaks result from Wenckebach-like conduction as high-frequency impulses emanating from the dominant domain are unable to sustain 1 : 1 conduction through heterogeneous tissue. In this case, the fastest activating (i.e., dominating) rotor rather than ongoing wave break is the engine driving cardiac fibrillation, and wave break occurs only secondarily. Evidence supporting this concept is that frequency domain analyses have shown (1) single, stable (both in space and time), dominant frequencies in the power spectra of membrane voltage signals obtained from various regions of the heart; (2) correlation of dominant frequencies and the frequency of reentry; (3) relative infrequency of reentry on the surface of the heart during fibrillation, with an intramural location of the mother rotor being favored, such as the Purkinje network; and (4) Wenckebach-like conduction at the borders between different dominant frequency domains. These borders can result from preexisting structural or functional heterogeneities. For example, high-resolution electrical mapping has suggested that fast activation during VF is driven by Purkinje fibers. Spatial heterogeneity in the magnitude of ionic currents has been implicated in the generation of spatial gradients in activation rates and in maintaining rotor stability in the fastest activating regions. For example, the magnitude of the inward rectifying K^+ current I_{K1} (**see Table 34.1**) was larger in the rapidly activating LV myocytes than in the slower activating RV myocytes. Furthermore, regions with larger I_{K1} had faster activation rates and more stable rotors than did regions with smaller I_{K1}.[1]

In contrast to the stable mother rotor theory, other experimental evidence has supported the idea that dynamic wave break plays a fundamental role in the initiation and maintenance of short-duration VF (“wandering wavelet” hypothesis).[1,62] According to this hypothesis, VF is maintained by wandering wavelets with constantly changing, evanescent, reentrant circuits. Experimental evidence favoring the multiple-wavelet hypothesis includes (1) an inability to detect a single dominant frequency in the power

spectra of mapping data from fibrillating hearts; (2) spatiotemporal instability of frequency domain distributions during VF, with the exception of anatomic borders, such as the Purkinje-myocyte transition; (3) failure to demonstrate stable intramural reentry at higher frequencies than at the surface; and (4) boundaries dynamically generated by wavelet behavior rather than by anatomic conduction block. To reproduce the dynamic spatiotemporal instability of dominant frequency domains, a combination of dynamically changing and fixed-tissue heterogeneity is required. The most important determinant of the dynamically induced component of heterogeneity has been identified as electrical restitution, or variation of the action potential duration and conduction velocity with the diastolic interval. For example, it has been proposed that the breakup of periodic waves is precipitated by APD alternans sufficiently large to cause conduction block along the spiral wavefront. Simulations have shown that a reentrant rotor becomes unstable and breaks down into multiple rotors when the slope of the restitution curve for the APD versus the diastolic interval is greater than 1. Pharmacologic blockade of the L-type calcium current can terminate VF by reducing the APD restitution slope (**see eFig. 34.24**). If it is occurring in a spatially discordant pattern, alternans is considered a key arrhythmogenic factor predisposing the heart to reentry and fibrillation.[1] At the cellular level, the origin of APD alternans appears to be determined primarily by alternations in cardiomyocyte calcium transient amplitude or duration (calcium alternans).[63]

During spatially discordant alternans, the APD alternates out of phase in different regions of the heart, thereby increasing dispersion of refractoriness so that ectopic beats have a high probability of inducing reentry. This mechanism is illustrated in **Fig. 34.16**; some regions of the heart alternate in a long-short-long pattern, whereas other regions at the same time alternate in a short-long-short pattern. These out-of-phase regions are separated by a nodal line in which no alternans is present, but spatial gradients in the APD are steepest along this line. Thus, spatially discordant alternans creates gradients in tissue refractoriness, which in turn favor the development of reentry by a premature beat (**Fig. 34.16B**). At the cellular level, the steepness of the APD restitution curve and intracellular calcium level ($[Ca^{2+}]_i$) dynamics cause the APD and $[Ca^{2+}]_i$ transient to alternate. Given the bidirectional coupling between changes in $[Ca^{2+}]_i$ and membrane potential—for example, the membrane potential determines the activity of L-type Ca channels, and conversely, the $[Ca^{2+}]_i$ transient amplitude strongly modulates the APD through its effects on Ca^{2+}-sensitive currents (e.g., $I_{Na/Ca}$ and I_{Ca}) during the action potential plateau—an alternation in $[Ca^{2+}]_i$ transient amplitude can cause a secondary alternation in the APD. Indeed, experimental evidence has strongly suggested that the onset of APD alternans is primarily attributable to instabilities in $[Ca^{2+}]_i$ cycling dynamics, thus defining a causal role of intracellular Ca^{2+}-handling abnormalities in initiating electrical instability. At the tissue level, alternans combines with instabilities in conduction velocity to cause alternans to become spatially discordant.

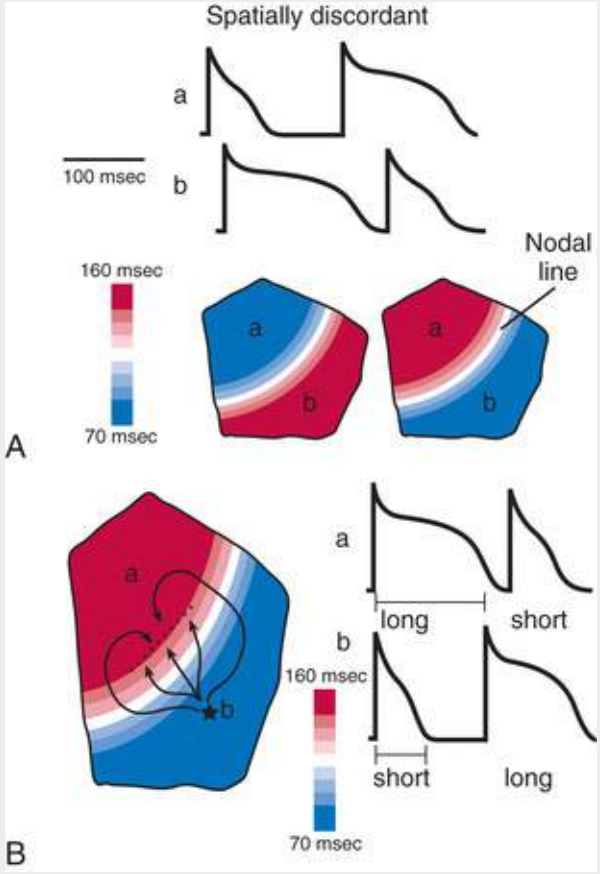


FIGURE 34.16 Initiation of reentry by a premature beat during spatially discordant alternans. **A, upper panel,** At rapid rates, action potentials at site **a** alternate short-long, whereas at the same time, action potentials at site **b** alternate long-short, thereby creating a steep gradient of action potential duration (APD) distribution with a nodal line that has no APD alternation separating the out-of-phase regions **a** and **b (lower panel). B,** A premature beat (*asterisk*) occurring in region **b** blocks (*dotted line*) as it propagates across the nodal line into the region with a long APD **(a).** The premature beat propagates laterally along the nodal line while waiting for the long APD region to repolarize and then reenters the blocked region to initiate figure-of-8 reentry. (From Weiss JN et al. From pulsus to pulseless: the saga of cardiac alternans. Circ Res 2006;98:1244.)

Ventricular Tachycardias Caused by Nonreentrant Mechanisms

In some VTs, especially in patients without coronary artery disease, nonreentrant mechanisms are important causes. In many patients, however, the mechanism of the VT remains unknown.

Triggered Activity

A group of VTs occurring in the absence of structural heart disease can be initiated and terminated by programmed stimulation. These are catecholamine dependent and can be terminated by the Valsalva maneuver, adenosine, or verapamil. These VTs are generally but not exclusively located in the RV outflow tract and may be caused by triggered activity, possibly DADs that are cAMP dependent. [42] EADs have been recorded in this VT as well. LV fascicular tachycardias can be suppressed by verapamil but not generally by adenosine, and some may be caused by triggered activity and others by reentry. EADs and triggered activity may be responsible for torsades de pointes.

Automaticity

Automatic discharge can be responsible for some VTs and does not appear to be suppressed by adenosine. Unless invasive studies are undertaken, mechanisms of VT can only be conjectured.

Diagnosis of Cardiac Arrhythmias

John M. Miller, Gordon F. Tomaselli, Douglas P. Zipes

In managing clinical arrhythmias, physicians must evaluate and treat the entire patient, not just the rhythm disturbance.[1] Some arrhythmias are hazardous to the patient regardless of the clinical setting, such as

ventricular fibrillation, whereas others are hazardous because of the clinical setting, such as rapidly conducted atrial fibrillation (AF) in a patient with severe coronary artery stenoses. Some rhythm abnormalities, such as premature ventricular complexes (PVCs), may be highly symptomatic but not associated with any adverse outcomes, whereas other patients with PVCs may have no palpitations but develop heart failure related to the PVCs. Some patients with AF have no symptoms but may still be at significant risk for stroke or heart failure from the rapid ventricular rate, whereas others are highly symptomatic with palpitations but have low risk for stroke or heart failure. Evaluation of the patient begins with a careful history and physical examination and should usually progress from the simplest to the most complex test, from the least invasive and safest to the most invasive and risky, and from the least expensive out-of-hospital evaluations to those that require hospitalization and sophisticated, costly, and potentially risky procedures. On occasion, depending on the clinical circumstances, the physician may choose to proceed directly to an expensive procedure associated with some risk, such as an electrophysiologic study (EPS), before obtaining a 24-hour electrocardiographic recording. In most cases, management of arrhythmia has a dual purpose: evaluation and treatment must address not only the patient's symptoms, but also whatever risks the arrhythmia poses to the individual.

Patient History

Patients with disturbances in cardiac rhythm can have various complaints, but symptoms such as palpitations, syncope, presyncope, or dyspnea commonly cause them to seek a physician's help. Their awareness of palpitations and a regular or irregular cardiac rhythm varies greatly. Some patients perceive slight variations in their heart rhythm with uncommon accuracy, whereas others are oblivious to even sustained episodes of ventricular tachycardia (VT); still others complain of palpitations when they actually have regular sinus rhythm.

In assessing a patient with a known or suspected arrhythmia, several key pieces of information should be obtained that can help determine a diagnosis or guide further diagnostic testing. The *mode of onset* of an episode can provide clues about the type of arrhythmia or preferred treatment option. For example, palpitations that occur in the setting of exercise, fright, or anger are often caused by catecholamine-sensitive automatic or triggered tachycardias that may respond to adrenergic blocking agents (**see Chapter 36**); palpitations that occur at rest or that awaken the patient can be caused by vagal initiation, such as AF. Lightheadedness or syncope occurring in the setting of a tightly fitting collar, shaving the neck, or turning the head suggests carotid sinus hypersensitivity. The triggering event may help establish the presence of an inherited ion channel abnormality (**see Chapter 33**). The *mode of termination* of episodes can also be helpful: palpitations that are reliably terminated by breath-holding or by Valsalva or other vagal maneuvers probably involve the atrioventricular (AV) node as an integral part of a tachycardia circuit; on occasion, focal atrial tachycardias or VTs can be terminated with vagal maneuvers, as can VT originating in the right ventricular outflow tract. Patients should be asked about the frequency and duration of episodes and the severity of symptoms. In some women the features of their episodes vary according to the menstrual cycle. These features can help guide how aggressively and quickly the physician needs to pursue a diagnostic or therapeutic plan (a patient with daily episodes associated with near-syncope or severe dyspnea warrants a more expeditious evaluation than does one with infrequent episodes of mild palpitations and no other symptoms). Patients should be encouraged to report their heart rate during an episode (either rapid or slow, regular or irregular) by counting the pulse directly or by using an automatic blood pressure or heart rate monitor or smart phone application; these may or may not provide reliable

data. Characteristics of the mode of onset and frequency of episodes can guide the choice of diagnostic tests (see later).

A careful drug and dietary history should also be sought; some nasal decongestants can provoke tachycardia episodes, whereas beta-adrenergic blocking eye drops for the treatment of glaucoma can drain into tear ducts, be absorbed systemically, and precipitate syncope secondary to bradycardia. Dietary supplements, particularly those containing stimulants such as ephedrine (generally removed from the market), can cause arrhythmias. A growing list of drugs can directly or indirectly affect ventricular repolarization and produce or exacerbate long-QT interval–related tachyarrhythmias (**see Chapter 8**). The patient should be questioned about the presence of systemic illnesses that may be associated with arrhythmias, such as chronic obstructive pulmonary disease, thyrotoxicosis (**see Chapter 86**), pericarditis (**Chapter 83**), and chronic heart failure (**Chapters 24 and 25**), as well as previous chest injury, surgery, or radiation therapy or chemotherapy. A family history of rhythm disturbances is often present in those with long-QT syndrome, AF or other inherited arrhythmia syndromes, hypertrophic cardiomyopathy (**see Chapter 78**), and muscular or myotonic dystrophy (**Chapter 97**).

Physical Examination

Examination of a patient during an arrhythmia episode can be revealing. Heart rate and blood pressure should be evaluated, as well as how ill the person appears. Assessment of jugular venous pressure and waveform can disclose the rapid oscillations of atrial flutter or “cannon” A waves indicative of contraction of the right atrium against a closed tricuspid valve in patients with AV dissociation, such as in complete heart block or VT. Variations in the intensity of the first heart sound and systolic blood pressure have the same implications.

Physical maneuvers during tachycardia can have diagnostic and therapeutic value. As noted, the Valsalva maneuver[2] (as well as carotid sinus massage) causes a transient increase in vagal tone; tachyarrhythmias that depend on the AV node for continuation can terminate or slow with these maneuvers but may also show no change. Even though focal atrial and VTs occasionally terminate in response to vagal stimulation, sinus tachycardia slows slightly but returns to its original rate soon thereafter; the ventricular response during atrial flutter and AF and other atrial tachycardias can decrease briefly. During wide-QRS tachycardias with a 1 : 1 relationship between P waves and QRS complexes, vagal influence can terminate or slow a supraventricular tachycardia (SVT) that depends on the AV node for perpetuation; on the other hand, vagal effects on the AV node can transiently block retrograde conduction and thus establish the diagnosis of VT by demonstrating AV dissociation. Because the effect of either of these physical maneuvers typically lasts only seconds, clinicians must be ready to observe or record any changes in rhythm on an electrocardiogram (ECG) when the maneuver is performed or the response may be missed.

Carotid massage is performed with the patient supine and comfortable and the head turned slightly away from the side being stimulated.[3] Careful auscultation for carotid bruits must always precede any attempt at carotid massage (embolic events have been associated with massage). The area of the carotid sinus, at the artery's bifurcation, is palpated with two fingers at the angle of the jaw until a good pulse is felt. Even this minimal amount of pressure can induce a hypersensitive response in susceptible individuals. If no initial effect is noted, a side-to-side or rotating motion of the fingers over the site is performed for up to 5 seconds. A negative response is lack of effect on the ECG after 5 seconds of pressure adequate to cause mild discomfort. Because responses to carotid massage may differ on the two

sides, the maneuver can be repeated on the opposite side; however, both sides should never be stimulated simultaneously. Findings may not be readily reproducible, even within minutes of a prior attempt.

Physical findings can suggest the presence of structural heart disease (and thus generally a clinically more serious situation with a worse overall prognosis), even in the absence of an arrhythmia episode. For example, a laterally displaced or dyskinetic apical impulse, a regurgitant or stenotic murmur, or a third heart sound in an older adult can denote significant myocardial or valvular dysfunction or damage (**see Chapter 10**). Even facial features may suggest an associated rhythm disorder (e.g., cataracts and early balding with myotonic dystrophy, micrognathia and low-set ears in Andersen-Tawil syndrome).

Electrocardiogram

The ECG is the primary tool for analysis of arrhythmias (**see Chapter 12**); an EPS, in which intracardiac electrode catheters are used to record activity from several regions of the heart at one time, is more definitive but not always immediately available. Initially, a 12-lead ECG is recorded. In addition, a long continuous recording with use of a lead that shows distinct P waves is often helpful for closer analysis; typically, this is one of the inferior leads (2, 3, aVF), V_1, or aVR. The ECG obtained during an arrhythmia episode may be diagnostic by itself and obviate the need for further diagnostic testing. **Fig. 35.1** depicts an algorithm for the diagnosis of specific tachyarrhythmias from the 12-lead ECG (**see Chapters 37 and 39**). A major branch point in the differential diagnosis concerns the QRS duration: wide-QRS (>0.12 second) tachycardias are often VTs, and narrow-QRS (≤0.12 second) tachycardias are almost always SVTs, but there is some overlap (**Table 35.1**). Next, the most important questions to answer, regardless of QRS width, concern the characteristics of P waves. If P waves are not clearly visible on the regular ECG, atrial activity can occasionally be discerned by placing the right and left arm leads in various anterior chest positions (so-called Lewis leads), by recording atrial electrograms using intracardiac right atrial recordings (via permanent or temporary transvenous pacing leads), or by using esophageal electrodes or an echocardiogram; the last methods are not readily available in most clinical situations and consume valuable time when dealing with a sick patient. A long rhythm strip can usually be obtained and can yield important clues by revealing P waves if perturbations occur during the arrhythmia (e.g., changes in rate, premature complexes, sudden termination, and effect of physical maneuvers, as noted earlier).

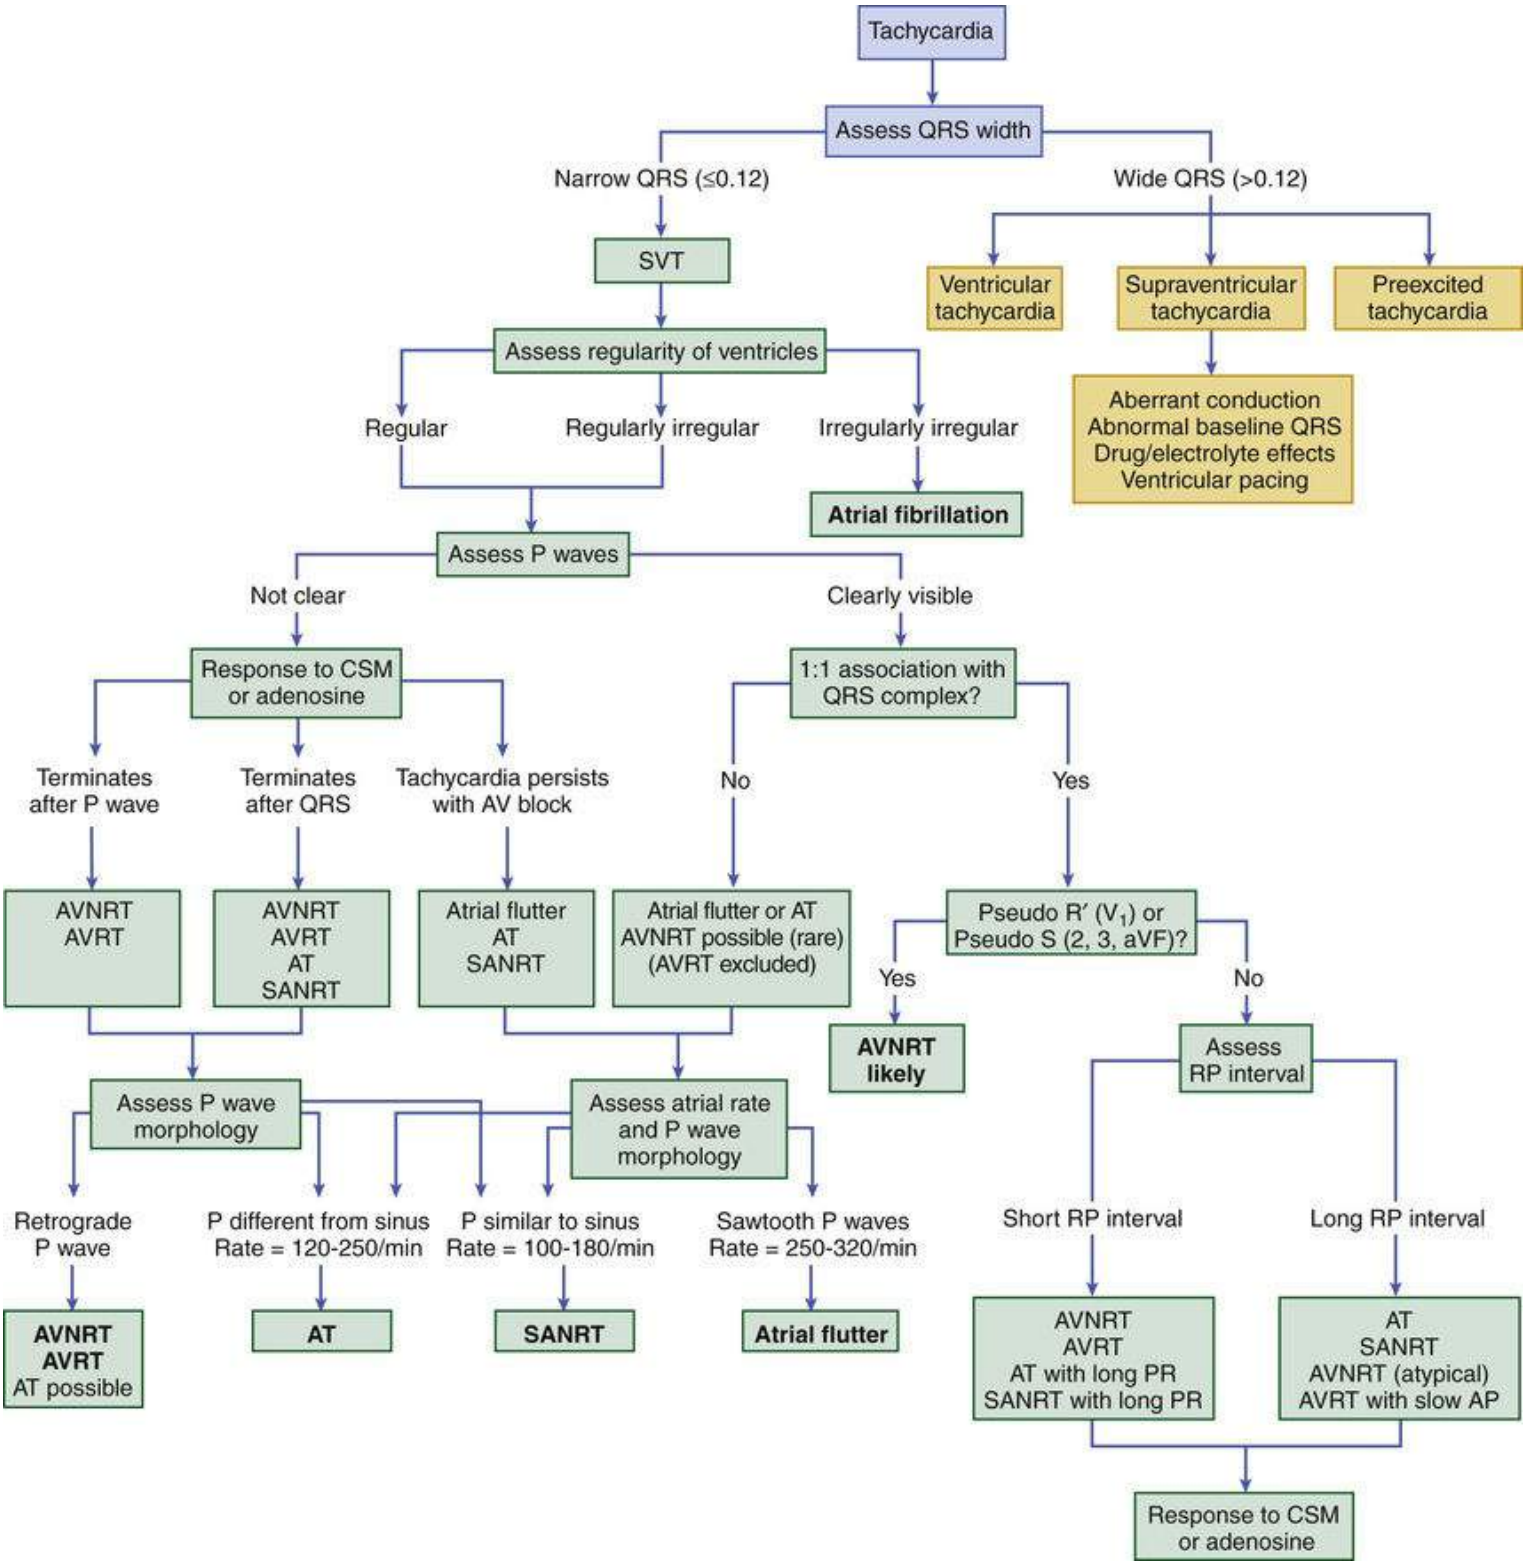

FIGURE 35.1 Stepwise approach to diagnosis of the type of tachycardia based on a 12-lead ECG during the episode. The initial step is to determine whether the tachycardia has a wide or narrow QRS complex. For wide-complex tachycardia, see Table 35.1; the remainder of the algorithm is helpful in diagnosis of the type of narrow-complex tachycardia. *AP,* Accessory pathway; *AT,* atrial tachycardia; *AVNRT,* atrioventricular nodal reentrant tachycardia; *AVRT,* atrioventricular reciprocating tachycardia; *CSM,* carotid sinus massage; *SANRT,* sinoatrial nodal reentry tachycardia.

TABLE 35.1

Electrocardiographic Distinctions for Diagnosis of Wide–QRS Complex Tachycardia

FAVOR SUPRAVENTRICULAR TACHYCARDIA	FAVOR VENTRICULAR TACHYCARDIA
Initiation with a premature P wave	Initiation with a premature QRS complex
Tachycardia complexes identical to those in resting rhythm	Tachycardia beats identical to PVCs during sinus rhythm
"Long-short" sequence preceding initiation	"Short-long" sequence preceding initiation
Changes in the P-P interval preceding changes in the R-R interval	Changes in the R-R interval preceding changes in the P-P interval
QRS contours consistent with aberrant conduction (V_1, V_6)	QRS contours inconsistent with aberrant conduction (V_1, V_6)
Slowing or termination with vagal maneuvers	AV dissociation or other non-1 : 1 AV relationship
Onset of the QRS to its peak (positive or negative) <50 msec	Onset of the QRS to its peak (positive or negative) ≥50 msec
	Fusion beats, capture beats
QRS duration ≤0.14 sec	QRS duration >0.14 sec
Normal QRS axis (0 to +90 degrees)	Left axis deviation (especially −90 to 180 degrees)
	Concordant R wave progression pattern
	Contralateral bundle branch block pattern from the resting rhythm
	Initial R, q, or r >40 msec or notched Q in aVR
	Absence of an "rS" complex in any precordial lead

AV, Atrioventricular; *PVC,* premature ventricular complexes.

Each arrhythmia should be approached in a systematic manner to answer several key questions; as suggested earlier, many of these questions relate to P wave characteristics and underscore the importance of assessing the ECG carefully for them. If P waves are visible, are the atrial and ventricular rates identical? Are the P-P and R-R intervals regular or irregular? If irregular, is it a consistent, repeating irregularity? Is there a P wave related to each QRS complex? Does the P wave seem to precede (long RP interval) or follow (short RP interval) the QRS complex (**Fig. 35.2**)? Are the resultant RP and PR intervals constant? Are all P waves and QRS complexes identical? Is the P wave vector normal or abnormal? Are P, PR, QRS, and QT durations normal? Once these questions have been addressed, the clinician needs to assess the significance of the arrhythmia in view of the clinical setting. Should it be treated, and if so, how? For SVTs with a normal QRS complex, a branching decision tree such as that shown in Fig. 35.1 may be useful.[4]

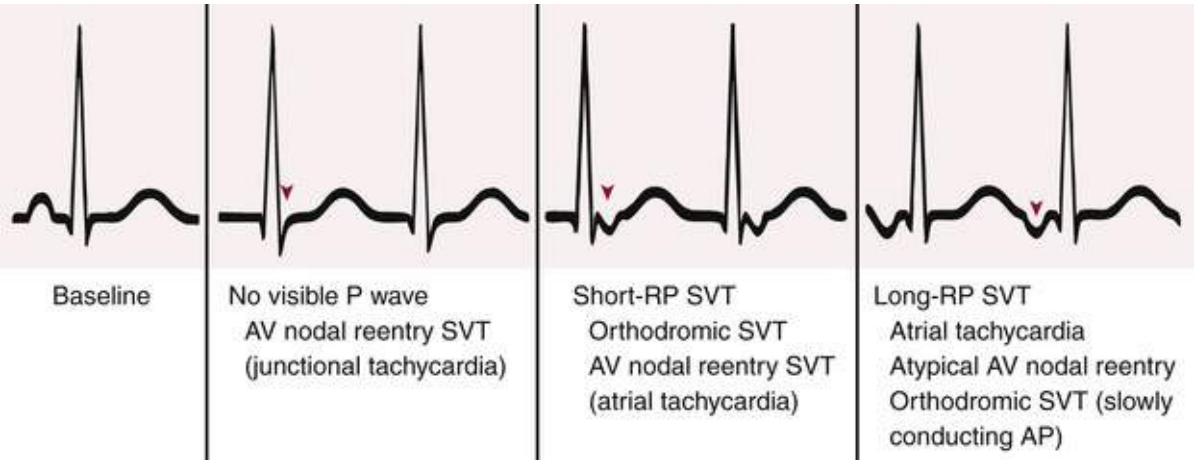

FIGURE 35.2 Differential diagnosis of different types of supraventricular tachycardia (SVT) based on timing of atrial activity (RP and PR intervals). **Left,** Normal beat. Different types of tachycardia are listed below the representative electrocardiographic patterns that they can produce, as categorized by P wave position relative to the QRS complex. An *arrowhead* shows the location of the P wave in each example. Diagnoses in parentheses are rare causes of the noted findings. *AP,* Accessory pathway.

The Ladder Diagram.

A ladder diagram, derived from the ECG, is used to depict depolarization and conduction schematically to aid in understanding the rhythm. Straight or slightly slanting lines drawn on a tiered framework beneath an ECG represent electrical events occurring in the various cardiac structures (**Fig. 35.3**). Because the ECG and therefore the ladder diagram represent electrical activity as a function of time along the *x* axis, conduction is indicated by the lines of the ladder diagram sloping in a left-to-right direction. A steep line represents rapid conduction; more slanting lines depict slower conduction. A short bar drawn perpendicular to a sloping line represents blocked conduction. Activity originating in an ectopic site such as the ventricle is indicated by lines emanating from that tier. Sinus nodal discharge and conduction and, under certain circumstances, AV junctional discharge and conduction can only be inferred; their activity is not directly recorded on the ECG.

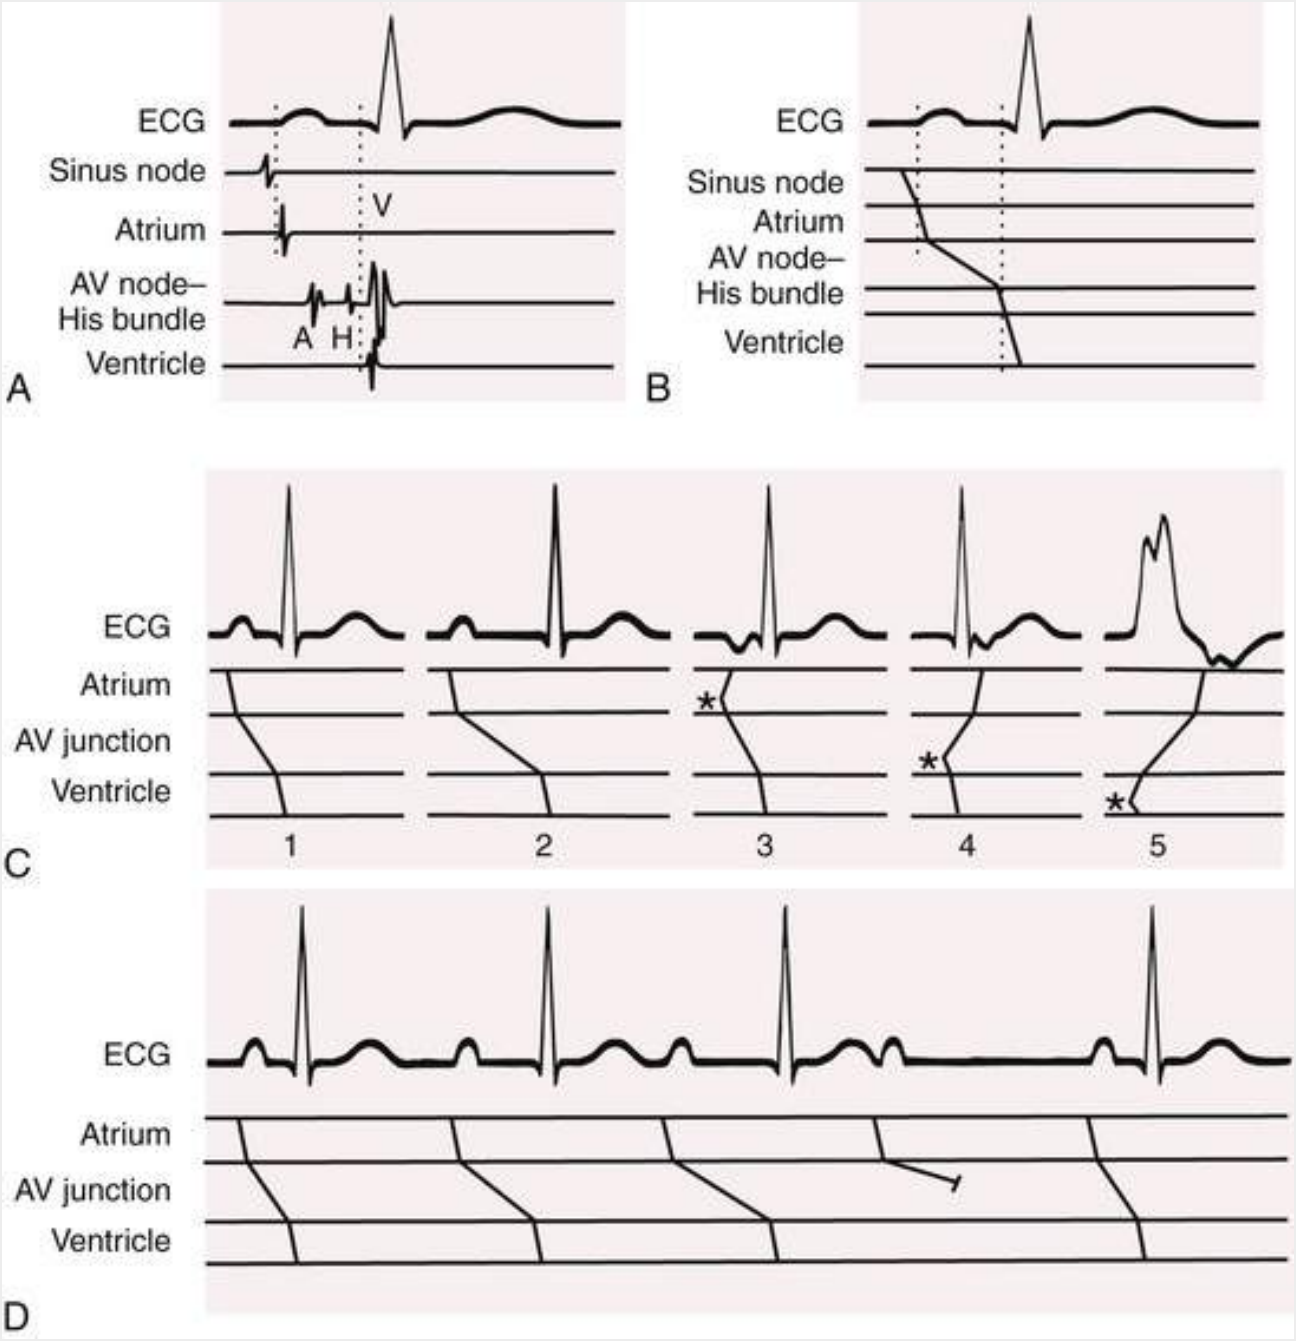

FIGURE 35.3 Intracardiac signals and ladder diagrams. **A,** A single beat is shown with accompanying intracardiac signals from the sinus node, right atrium, atrioventricular (AV) nodal and His bundle regions, and right ventricle. **B,** The same beat is shown with the accompanying ladder diagram below. Cardiac regions have been divided into tiers separated by horizontal lines. Vertical *dotted lines* denote onset of the P wave and QRS complexes. Note the relatively steep lines (rapid conduction through the atrium, His bundle, and ventricular muscle) and more gently sloping lines as the impulse traverses the sinus and AV nodes (signifying slow conduction). **C,** Several different situations are depicted with accompanying explanatory ladder diagrams. Beat 1 is normal, as in **B**; beat 2 shows first-degree AV delay, with the more gradual slope than normal in the AV nodal tier signifying very slow conduction in this region. In beat 3 an atrial premature complex is shown (starting in the atrial tier at the *asterisk*) and is producing an inverted P wave on the ECG. In beat 4 an ectopic impulse arises in the His bundle (*asterisk*) and propagates to the ventricle, as well as retrogradely through the AV node to the atrium. In beat 5 a ventricular ectopic complex (*asterisk*) conducts retrogradely through the His bundle and AV node and eventually to the atrium. **D,** Wenckebach AV cycle (type I second-degree block). As the PR interval progressively increases from left to right in the figure, the slope of the line in the AV nodal region is progressively less steep until it fails to propagate at all after the fourth P wave (small line perpendicular to the sloping AV nodal conduction line), after which the cycle repeats. *A,* Atrial recording; *H,* His recording; *V,* ventricular recording.

Additional Tests

Most patients have only occasional episodes of arrhythmia and spend most of the time in their baseline rhythm (e.g., sinus, AF). The ECG during the patient's resting rhythm can provide clues about the presence of a substrate for arrhythmia (i.e., structural or physiologic abnormalities from which arrhythmias can arise). Several of these abnormalities are shown in **Fig. 35.4**. Recently, the common finding on the ECG of early repolarization (in the lateral precordial and inferior leads) has been observed in some patients with primary ventricular fibrillation (VF) (i.e., without identifiable structural heart disease) (**see Chapter 39**). In most patients with SVT, except those with Wolff-Parkinson-White (WPW) syndrome, findings on the resting ECG are normal. This is also true for many patients with ventricular tachyarrhythmias. Thus, although it is capable of showing an abnormality with possible arrhythmic implications, the resting ECG is not a very sensitive tool. In light of this, the following additional tests can be used to evaluate patients who have cardiac arrhythmias. The physician's choice of which test to use depends on the clinical circumstances. For example, a patient with multiple daily episodes of presyncope is likely to have an event recorded on a 24-hour ambulatory electrocardiographic (Holter) monitor, whereas in a patient who complains of infrequent exercise-induced palpitations, exercise stress testing may be more likely to provide a diagnosis.

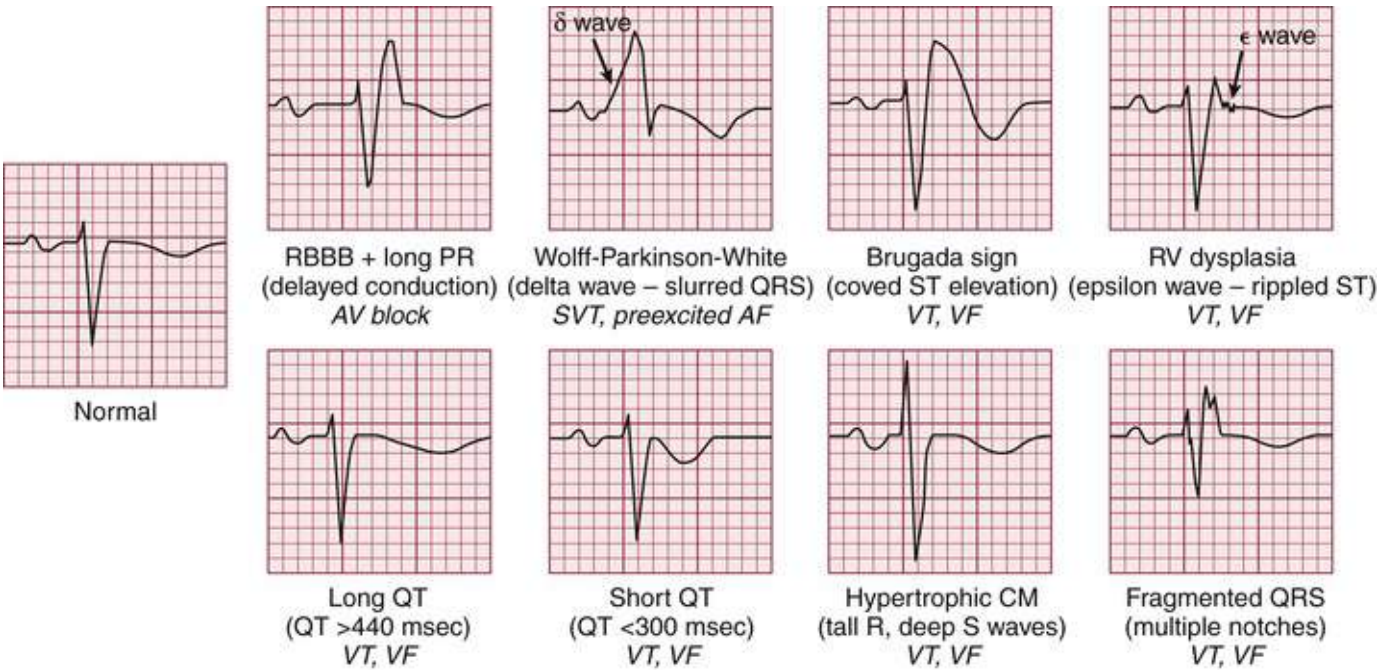

FIGURE 35.4 Electrocardiographic abnormalities in resting rhythm that suggest potential for arrhythmia. Lead V_1 is shown in each example; a normal complex is presented at *left* for reference. *CM,* Cardiomyopathy; *RBBB,* right bundle branch block; *RV,* right ventricular.

Exercise Testing

Exercise can induce various types of supraventricular and ventricular tachyarrhythmias and, infrequently, bradyarrhythmias (**see Chapter 13**). Ventricular ectopy develops in approximately one third of normal individuals in response to exercise testing. Ectopy is more likely to occur at faster heart rates, as occasional PVCs of constant morphology or even pairs of PVCs, and is often not reproducible from one stress test to the next. Three to six beats of nonsustained VT can occur in normal patients, especially elderly persons, and its occurrence neither implicates ischemia or other forms of heart disease nor predicts increased cardiovascular morbidity or mortality. PVCs are often more common during exercise

than at rest and increase in frequency with age. A persistent elevation in heart rate after the end of exercise (delay in return to baseline) is associated with a worse cardiovascular prognosis, as is a rapid resting heart rate.

Premature ventricular complexes develop in approximately 50% of patients with coronary artery disease in response to exercise testing and do so at lower heart rates (<130 beats/min) than in normal individuals, and often in recovery. Frequent (>7 PVCs/min) or complex ectopy is associated with a worse prognosis. Exercise reproduces sustained VT or VF in less than 10% of patients with spontaneous VT or VF late after myocardial infarction (MI), and these patients have a worse prognosis. The relationship of exercise to ventricular arrhythmia in patients with structurally normal hearts and no primary electrical disease has no prognostic implications.

Patients who have symptoms consistent with an arrhythmia induced by exercise (e.g., syncope, sustained palpitations) should be considered for stress testing. Stress testing may be indicated to provoke supraventricular and ventricular arrhythmias, to determine the relationship of the arrhythmia to activity, to aid in choosing antiarrhythmic therapy and uncovering proarrhythmic responses, and possibly to provide some insight into the mechanism of the tachycardia. The test can be performed safely; however, prolonged ambulatory recording is more sensitive than exercise testing in detecting most arrhythmias. Because either technique can uncover serious arrhythmias that the other technique misses, both examinations may be indicated for selected patients. Stress testing is frequently useful in patients with long-QT syndrome and catecholaminergic monomorphic and polymorphic VT[5] (**see Chapters 13 and 33**).

In-Hospital Electrocardiographic Recording

Electrocardiographic monitoring systems are used in increasing proportions of inpatients regardless of history or suspicion of arrhythmias. These systems can provide valuable information about rhythm abnormalities, including mode of onset and termination, and allow prompt acquisition of a full 12-lead ECG for more detail. Telemetry can disclose intermittent heart block in a patient with presyncope that may warrant consideration of pacemaker implantation or reveal nonsustained VT in a patient with previous MI and left ventricular dysfunction and prompt an electrophysiology study for further assessment of risk. Although telemetry is helpful in many cases, it can be misleading: artifact can simulate VT or VF, heart block, or asystole. Careful scrutiny is necessary to avoid unnecessary tests and procedures in patients with these artifactual arrhythmias (**Fig. 35.5**).

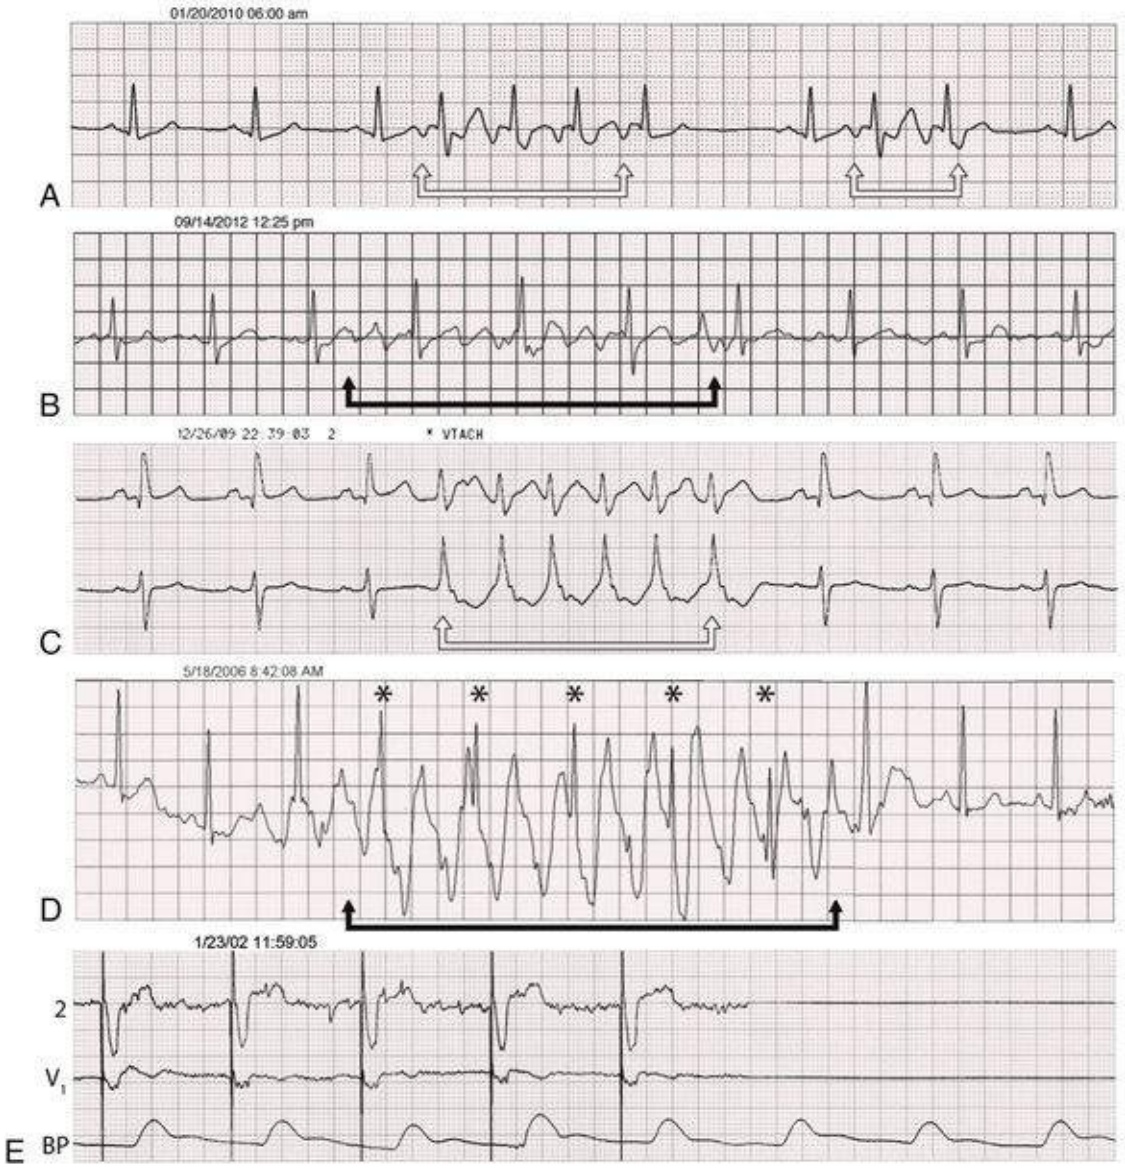

FIGURE 35.5 Electrocardiographic events and artifacts. **A,** Sinus rhythm punctuated by short episodes of atrial tachycardia with a more rapid ventricular rate (between the *white arrows*). **B,** Pseudo–atrial arrhythmia. Sinus rhythm is present throughout (no variation in the R-R interval) despite the appearance of a short episode of atrial flutter or fibrillation (between the *black arrows*). **C,** Nonsustained VT (between the *white arrows*) with wide rapid QRS complexes not preceded by a P wave and seen in two monitor leads. **D,** Pseudo-VT. Despite the appearance of VT (between the *black arrows*), sinus rhythm is present throughout (including complexes indicated by *asterisks*). **E,** Pseudo–pacemaker failure. After the first five paced complexes, the ECG is flat in *both* monitor leads, thus suggesting failure of pacemaker output; however, the pulse contour on the blood pressure (BP) tracing indicates that the heart is still contracting and the pacemaker is still working whereas the ECG monitor is not.

Long-Term Electrocardiographic Recording

Prolonged electrocardiographic recording in patients engaged in normal daily activities is the most useful noninvasive method to document and quantitate the frequency and complexity of an arrhythmia, to correlate the arrhythmia with the patient's symptoms, and to evaluate the effect of antiarrhythmic therapy on spontaneous arrhythmia. For example, recording normal sinus rhythm during the patient's typical symptomatic episode effectively excludes cardiac arrhythmia as a cause.

Ambulatory Electrocardiographic (Holter) Recording

Continuous electrocardiographic recorders represent the traditional Holter monitor and digitally record

three or more electrocardiographic channels for 24 to 48 hours. Computers scan the recording media, with human oversight, to provide a report with snapshot recordings of symptomatic events and other important findings (asymptomatic arrhythmias, ST-segment changes). From 25% to 50% of patients experience a complaint during a 24-hour recording; in 2% to 15% the complaint is caused by an arrhythmia (**Fig. 35.6**). The ability to correlate symptoms temporally with abnormalities on the ECG is one of the strengths of this technique.

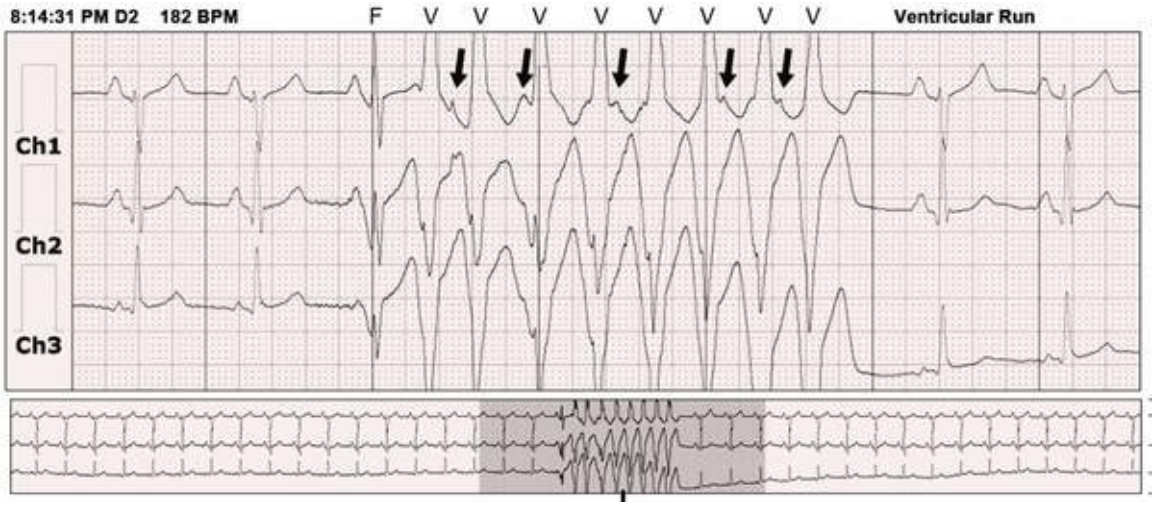

FIGURE 35.6 Long-term electrocardiographic recording in a patient with palpitations. A three-channel monitor shows sinus rhythm followed by nine wide QRS complexes of VT (labeled "V"); the complex that precedes these is a fusion between the normal complex and wide ("F"). *Arrows* indicate retrograde P waves during tachycardia. The presence of fewer P waves than QRS complexes and a fusion complex at the outset confirm the diagnosis of VT (which correlated with the patient's palpitations).

Significant rhythm disturbances are uncommon in healthy young persons. Sinus bradycardia with heart rates of 35 to 40 beats/min, sinus arrhythmia with pauses exceeding 3 seconds, sinoatrial exit block, type I (Wenckebach) second-degree AV block (often during sleep), wandering atrial pacemaker, junctional escape complexes, and premature atrial complexes and PVCs can be observed and are not necessarily abnormal. Frequent and complex atrial and ventricular rhythm disturbances are less frequently observed, however, and type II second-degree AV conduction disturbances (**see Chapter 40**) are not recorded in normal patients. Elderly patients have a higher prevalence of arrhythmias, some of which may be responsible for neurologic symptoms (**Fig. 35.7**; **see Chapters 88 and 97**). It is worth repeating that the long-term prognosis of even frequent and complex PVCs in asymptomatic healthy patients is very good, without an increased risk for death. However, frequent PVCs (>15% of the total) have been shown to produce a cardiomyopathy and heart failure in some people, which can be reversed following elimination of the PVCs.

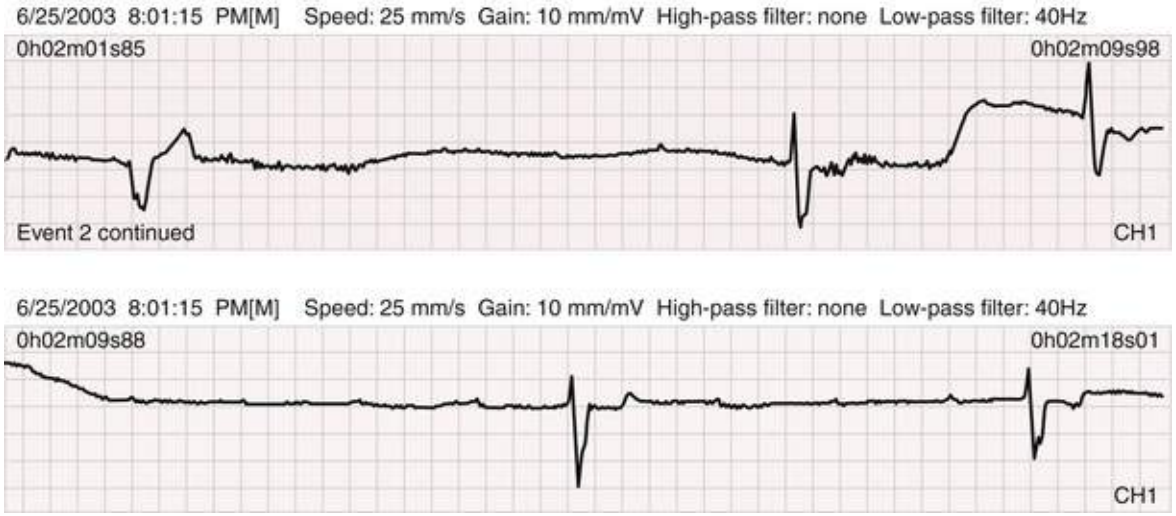

FIGURE 35.7 Continuous electrocardiographic recording from a patient-activated event monitor during an episode of lightheadedness. Sinus rhythm at 75 beats/min with sudden AV block is present with pauses of longer than 4 seconds, and in the *bottom strip* there is an effective heart rate of approximately 8 beats/min.

Most patients with ischemic heart disease, particularly after MI (**see Chapters 58 to 60**), exhibit PVCs when they are monitored for 24 hours. The frequency of PVCs progressively increases during the first several weeks and then decreases at about 6 months after infarction. Frequent and complex PVCs are associated with a twofold to fivefold increased risk for cardiac or sudden death in patients after MI, but treating these PVCs may not improve the prognosis. The Cardiac Arrhythmia Suppression Trial (CAST) showed that PVCs identified patients at increased risk for sudden death, but that successful suppression of PVCs with flecainide, encainide, or moricizine was associated with increased mortality compared with placebo. Recent data indicate that ablation of PVCs after MI may improve previously depressed ventricular function.

Long-term recording of the ECG has also exposed potentially serious arrhythmias and complex ventricular ectopy in patients with left ventricular hypertrophy, as well as in those with hypertrophic, dilated, and ischemic cardiomyopathy; in those with mitral valve prolapse (**see Chapter 69**); in those with otherwise unexplained syncope (**Chapter 43**) or transient vague cerebrovascular symptoms or stroke; and in those with conduction disturbances, sinus node dysfunction, bradycardia-tachycardia syndrome, WPW syndrome (**Chapter 37**), and pacemaker malfunction (**Chapter 41**). It has been shown that asymptomatic AF occurs far more often than symptomatic episodes in patients with AF.

Variations of Holter recording have been used for particular applications. Some monitoring systems are able to reconstruct a full 12-lead ECG from a seven-electrode recording system. This is especially useful in trying to document the electrocardiographic morphology of VT before an ablation procedure or a consistent morphology of PVCs that may arise from an ablatable focus of VT or VF. Most Holter recording and analysis systems can place a clearly recognizable deflection on the recording when a pacemaker stimulus is detected, facilitating diagnosis of potential pacemaker malfunction. On occasion, artifacts on the ECG can mimic bradycardias or tachycardias and lead to erroneous therapy. Finally, most systems can also provide heart rate variability and QT data (see later). Use of these systems for detection of myocardial ischemia (ST-segment analysis) has yielded mixed results (in both specificity and sensitivity).

Event Recording

In many patients, the 24- or 48-hour snapshot provided by the Holter recording is incapable of

documenting the cause of the patient's symptoms. Longer-term monitoring, such as with an event recorder, is necessary in these cases, which occur frequently. These devices come in various forms and are kept by the patient for 30 days. During that time, digital recordings can be made during symptomatic episodes and can be transmitted to a receiving station by telephone at the patient's convenience (**see Fig. 35.7**). Some of these recorders store more than 30 seconds of the ECG before the patient activates the recording. These loop recorders record continuously, but only a small window of time is present in memory at any moment; when the patient presses the event button, the current window is frozen while the device continues recording for another 30 to 60 seconds, depending on how it is configured. Event recorders are highly effective in documenting infrequent events, but the quality of the recordings is more subject to motion artifact than with Holter recorders, and usually only one channel can be recorded. With most systems, the device automatically begins recording the rhythm when the heart rate increases or decreases outside preset parameters. Some systems incorporate cell phone technology that automatically notifies a central monitoring facility when certain conditions are met (e.g., extreme bradycardia or tachycardia). This can significantly shorten the time between occurrence and effective treatment of serious arrhythmias (**see Chapter 32**).

Most currently available pacemakers and implantable defibrillators are capable of providing Holter-like data when premature beats or tachycardia episodes occur and can store electrograms of these events from the implanted leads[6] (**Fig. 35.8**). The device can then be interrogated and the electrograms printed for analysis. Many implanted device systems incorporate remote monitoring so that if symptoms develop, patients can perform device interrogation at home; the information is then transmitted via the Internet to the physician's office and thus enables more prompt diagnosis and treatment than if the patient had to schedule an outpatient visit. For serious rhythm disturbances, such as sustained VT, this information can lead to timely changes in therapy; in other cases, such as incidentally discovered AF, therapeutic implications (e.g., initiation of anticoagulation) are less clear.

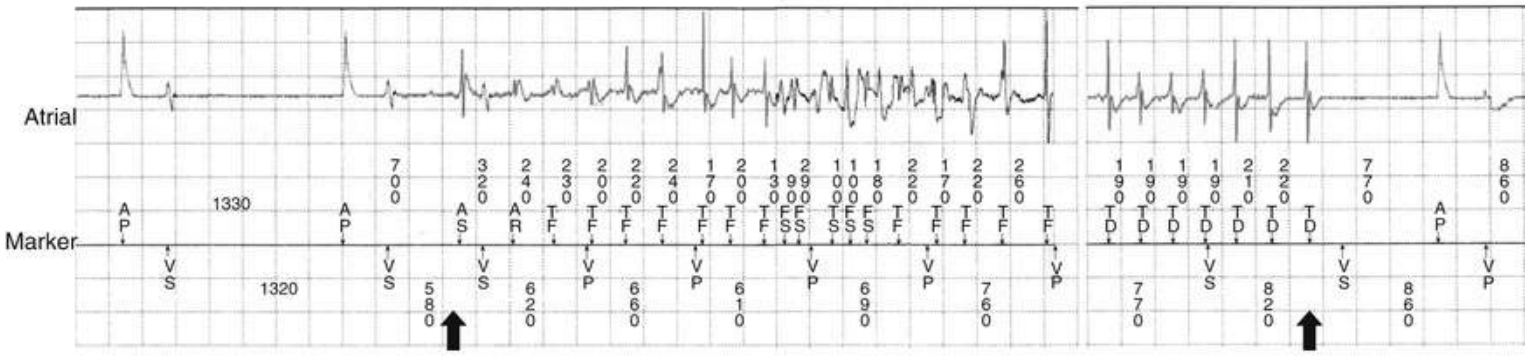

FIGURE 35.8 Recordings from a pacemaker log showing an episode of AF at its onset (*left arrow*) and termination (*right arrow*), more than 4 days later. Two atrial paced complexes ("AP") are followed by an episode of AF characterized by rapid erratic deflections. When the episode ends, atrial pacing resumes. The patient was unaware of the episode, but when discovered at a routine office follow-up visit, this information prompted initiation of anticoagulation in light of an elevated stroke risk and newly discovered AF.

Implantable Loop Recorder

For patients with very infrequent symptoms, neither Holter recorders nor 30-day event recorders may yield diagnostic information. In such patients an implantable loop recorder can be used. These devices (smaller than a pack of chewing gum) are inserted under the skin at about the level of the anterior second

rib on the left chest and are activated by passing a special magnet over the device. It is capable of recording several minutes of a single channel of the ECG before and after a symptomatic event and can have a service life of 2 to 3 years. Both P waves and QRS complexes can usually be identified. The devices can be configured to store patient-activated episodes, automatically activated recordings (heart rate outside preset parameters), or a combination of these. In patients with unexplained syncope, a diagnosis can be made in up to 80% by long-term monitoring, many only after a long period (up to 18 months). Detection of AF as a possible cause of cerebral symptoms has become a common indication for implantable monitors.[7]

Various additional noninvasive tests have been developed primarily to assess the risk for arrhythmic death in different groups of patients; although each has some applicability, none has enjoyed widespread use because of suboptimal sensitivity and specificity. Several of these tests are discussed in the following sections.

Heart Rate Variability

Heart rate variability is used to evaluate vagal and sympathetic influences on the sinus node (inferring that the same activity is also occurring in the ventricles) and to identify patients at risk for a cardiovascular event or death. Frequency domain analysis resolves parasympathetic and sympathetic influences better than time domain analysis does, but both types of analysis are useful. R-R variability predicts all-cause mortality, as well as left ventricular ejection fraction or nonsustained VT in patients after MI, and can be added to other measures of risk to enhance predictive accuracy.[8] Similar results have been obtained in patients with dilated cardiomyopathy (**see Chapters 25 and 77**). High-frequency components of R-R interval variability reflect tonic vagal activity. Reduced R-R interval variability, a marker of increased risk, indicates loss or reduction of the physiologic periodic sinus node fluctuations, which has many potential causes and may not necessarily represent a significant shift in autonomic modulation. New indices of heart rate variability are continually being evaluated. Even the simple measure of resting heart rate has been shown to be an independent cardiovascular risk factor (although a target "safe" heart rate has not been established), as has the heart rate obtained during and after exercise.

Heart Rate Turbulence

Heart rate turbulence is an index of changes in the sinus discharge rate after a PVC that is followed by a compensatory pause.[9] In normal individuals the sinus rate initially accelerates and then slows; this phenomenon is blunted or absent in patients with various heart diseases. Heart rate turbulence is a measure of reflex vagal control of the heart, whereas heart rate variability is more indicative of overall vagal tone. Abnormal heart rate turbulence is a strong independent predictor of mortality in patients with coronary artery disease and dilated cardiomyopathy; abnormal indices in some patients can be improved or normalized after treatment with beta blockers and statin drugs.

QRS and QT Dispersion and T Wave Abnormalities

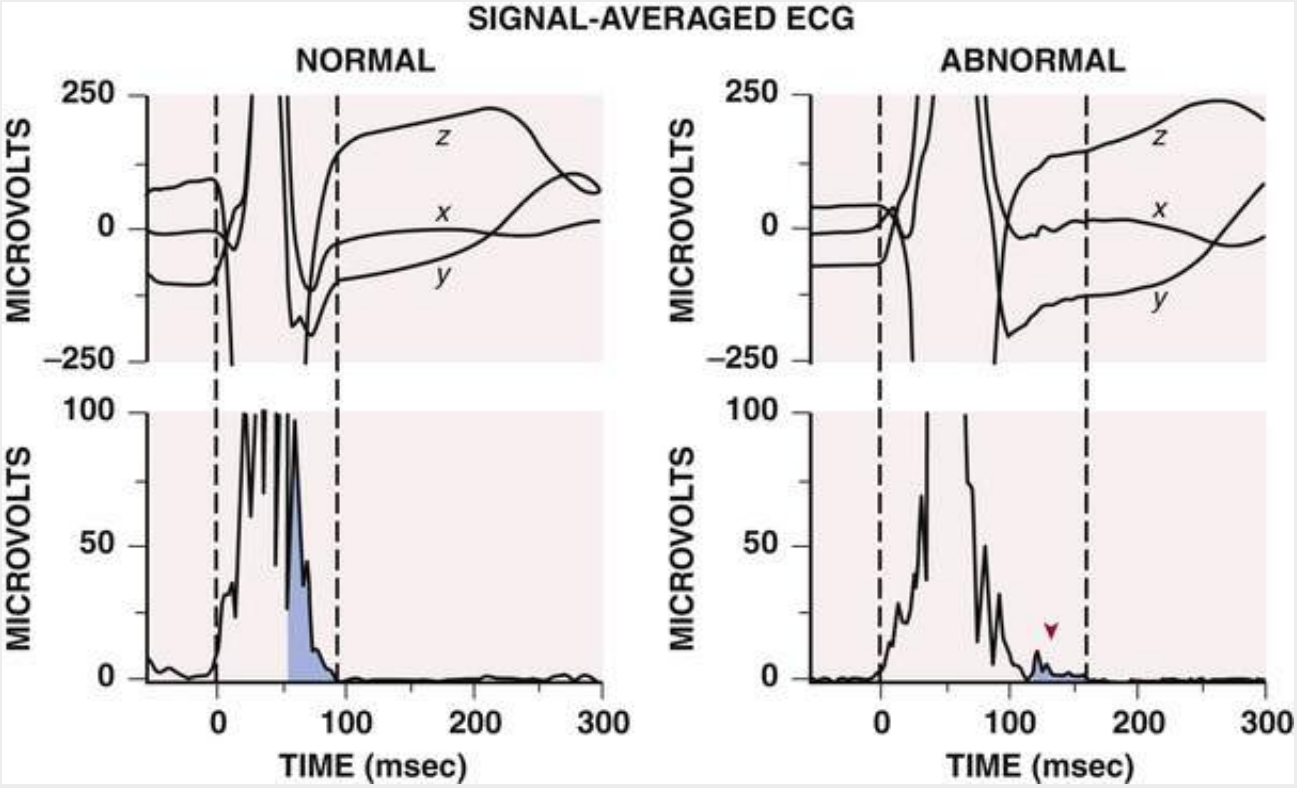
Heterogeneity in refractoriness and conduction velocity is a hallmark of reentrant arrhythmias. One index of the heterogeneity of ventricular conduction is derived from the QRS complex duration on surface ECG leads, while heterogeneity of ventricular refractoriness can be found in differences in the length of the QT interval. Dispersion indices usually measure the maximum difference (shortest to longest) in the intervals of interest, which may be adjusted for heart rate and the number of leads sampled (e.g., when the T wave is flat in some leads for QT dispersion). Abnormally high QRS and QT dispersion have been correlated

with risk for overall mortality and arrhythmic death in patients with various disorders, although the results are not consistent. Different techniques exist for determining dispersion (including automated algorithms), and the results of one study are often difficult to compare with those of another; in addition, the tests are sensitive to a variety of factors, including age, time of day, season of year, and even body position. More recently, T wave morphology and assessment of the interval from T wave peak to end in lead V_5 have been correlated with increased sudden death risk.[10] Overall, assessments of these indices have not gained popularity as useful clinical tools. Other details of the QRS complex, such as fragmentation of the conducted complex[11] (multiple notches in the QRS; **see Fig. 35.4**) and the simple width of PVCs,[12] have been associated with increased cardiovascular risk.

Signal-Averaged Electrocardiography and Late Potentials

Signal averaging is a method that improves the signal-to-noise ratio when the signals are recurrent and the noise is random. In conjunction with appropriate filtering and other methods of noise reduction, signal averaging can detect cardiac signals of a few microvolts in amplitude and reduce noise amplitude, such as muscle potentials, which are typically 5 to 25 mV, to less than 1 mV. With this method, very-low-amplitude electrical potentials generated by the sinus and AV nodes, His bundle, and bundle branches can be detected at the body surface.

One constituent of reentrant ventricular arrhythmias in patients with previous myocardial damage is slow conduction. Direct cardiac mapping techniques can record the myocardial activation from damaged areas that occurs after the end of the surface electrocardiographic QRS complex during sinus rhythm. These delayed signals have a very low amplitude that cannot be discerned by routine electrocardiography and correspond to the delayed and fragmented conduction in the ventricles recorded with direct mapping techniques (**eFig. 35.1**). Signal averaging has been applied clinically most often to detect such late ventricular potentials of 1 to 25 µV. Criteria for late potentials are the following: (1) filtered QRS complex duration longer than 114 to 120 milliseconds, (2) less than 20 µV of the root mean square signal amplitude in the last 40 milliseconds of the filtered QRS complex, and (3) terminal filtered QRS complex remaining below 40 µV for longer than 39 milliseconds. Such late potentials have been recorded in more than 70% of patients with spontaneous sustained and inducible VT after MI, but in only 0% to 6% of normal volunteers. Patients with bundle branch block or paced ventricular rhythms already have wide QRS complexes, thus rendering the technique less useful in these cases.

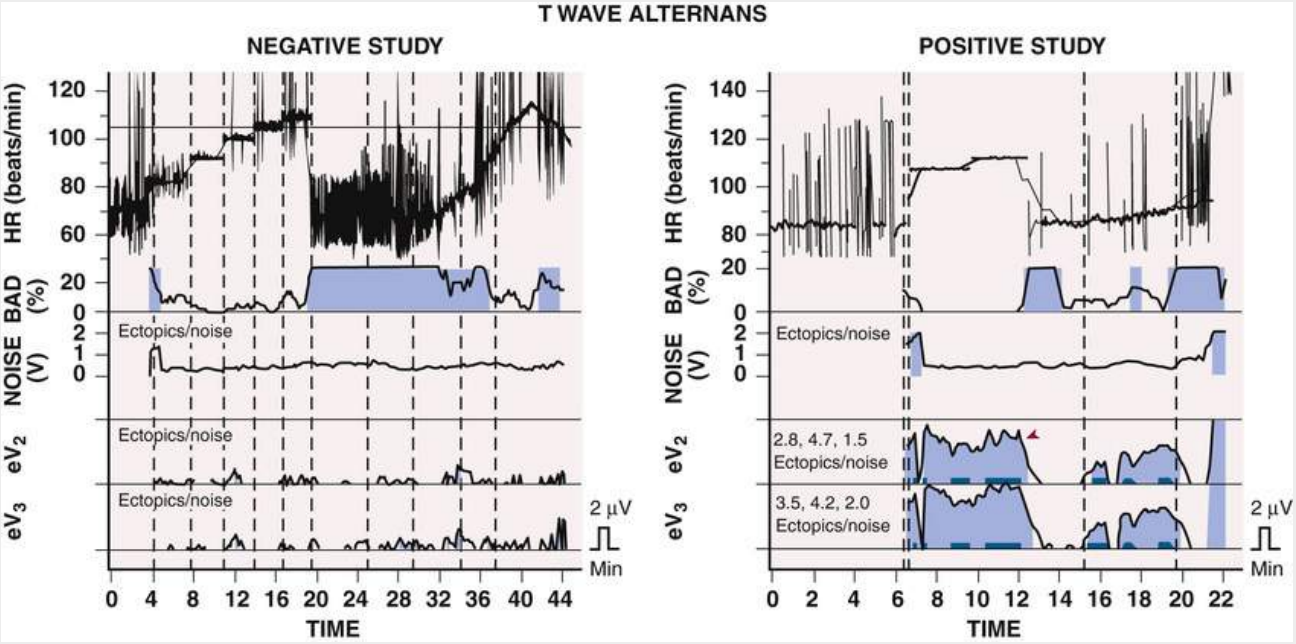


EFIGURE 35.1 Signal-averaged ECG. Normal **(left)** and abnormal **(right)** results are shown from a patient with previous myocardial infarction and VT. **Bottom panels,** *Shaded blue areas* at the end of each tracing represent the voltage content of the last 40 milliseconds of the filtered QRS integral. The small shaded area (*red arrowhead*) in the abnormal study denotes prolonged, slow conduction and suggests the potential for reentrant ventricular arrhythmias.

Late potentials have also been recorded in patients with VT not related to ischemia, such as in those with dilated cardiomyopathy. The presence of a late potential is a sensitive but not specific marker of arrhythmic risk, and therefore its prognostic use is limited. In specific situations it can be helpful, as in a patient suspected of having arrhythmogenic right ventricular cardiomyopathy.

T Wave Alternans

Beat-to-beat alternation in the amplitude or morphology of the electrocardiographic recording of ventricular repolarization, the ST segment and T wave, has been found in conditions favoring the development of ventricular tachyarrhythmias, such as ischemia and long-QT syndrome, and in patients with ventricular arrhythmias. The electrophysiologic basis appears to be the alternation of repolarization of ventricular myocytes. In the presence of a long QT interval, the cellular basis of alternation may be beat-to-beat repolarization changes in midmyocardial cells. Whether this mechanism applies to different disease states is not known. Detection of T wave alternans requires exercise or atrial pacing to achieve a heart rate of 100 to 120 beats/min with relatively little atrial or ventricular ectopic activity. The test is less useful in patients with a wide QRS complex (>120 msec). A positive T wave alternans test result (**eFig. 35.2**) has been associated with a worse arrhythmic prognosis in various disorders, including ischemic heart disease and nonischemic cardiomyopathy. Although the predictive value of a positive test result varies greatly, depending on the population studied, a negative test result strongly predicts freedom from VT and VF in all groups studied thus far, at least during a short follow-up period. T wave alternans may represent a fundamental marker of an electrically unstable myocardium prone to the development of VT or VF, but because of its relatively minor incremental value in defining arrhythmic risk, it is infrequently used at present.



EFIGURE 35.2 T wave alternans. Reports of T wave alternans analysis from two patients are shown and display the heart rate in beats per minute (HR BPM), proportion of beats rejected from analysis (% BAD), ECG noise level (in microvolts), and selected precordial leads (eV_2 and eV_3) as a function of time. **Left panel,** Records from a patient with no structural heart disease; the amplitude of T wave alternans was minimal. **Right panel,** Records from a patient hospitalized for sustained VT after myocardial infarction show T wave alternans (*blue shaded area, arrowhead*).

Baroreceptor Reflex Sensitivity Testing

Acute blood pressure elevation triggers a baroreceptor reflex that augments vagal tone to the heart and slows the sinus rate. The increase in sinus cycle length per millimeter mercury increase in systolic blood pressure is a measure of the sensitivity of the baroreceptor reflex and, when reduced, can identify patients susceptible to the development of VT and VF. The mechanism of the reduction in baroreceptor reflex sensitivity is uncertain. Although this test may be useful to identify patients at risk for developing a serious ventricular arrhythmia after MI, it is rarely used.

Body Surface Mapping

Isopotential body surface maps are used to provide a complete picture of the effects of currents from the heart on the body surface. The potential distributions are represented by contour lines of equal potential, and each distribution is displayed instant by instant throughout activation, recovery, or both.

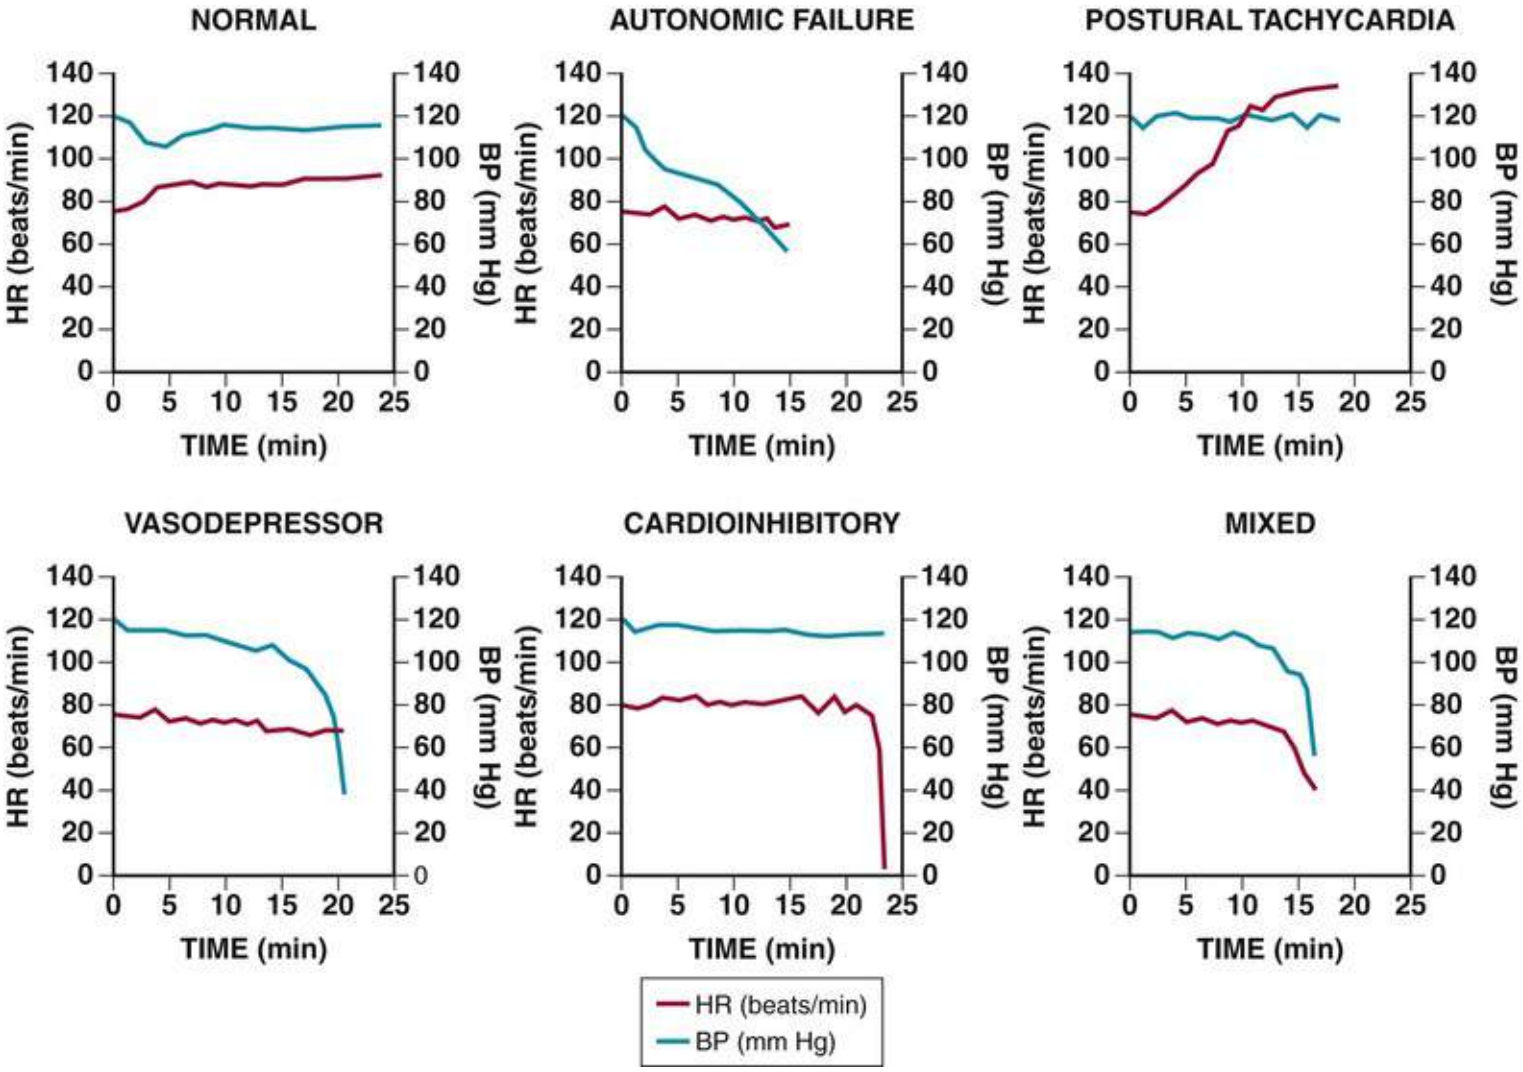
Body surface maps have been used clinically to localize and size areas of myocardial ischemia, to localize ectopic foci or accessory pathways, to differentiate aberrant supraventricular conduction from ventricular origin, to recognize patients at risk for the development of arrhythmias, and possibly to understand the mechanisms involved. Although these procedures are of interest, their clinical usefulness has not yet been established. In addition, the technique is cumbersome and the analysis complex.

Electrocardiographic Imaging

Another promising technology is electrocardiographic imaging, in which cardiac electrical activity recorded at the skin surface is spatially integrated with imaging data (currently, cardiac computed tomography scanning). Using complex mathematical processing of electrical data collected from 224 electrodes on the skin surface, this technique can plot or project atrial and ventricular electrical activity on an epicardial “shell” of the patient's own heart and thereby follow the course of activation or repolarization during sinus rhythm or an arrhythmia. Clinical experience is limited thus far, but both SVTs and VTs (especially focal) have been localized with this method.[13]

Upright Tilt-Table Testing

The tilt-table test is used to identify patients who have a vasodepressor or cardioinhibitory response as a cause of syncope (**see Chapter 43**). Patients are placed on a tilt table in the supine position and tilted upright to a maximum of 60 to 80 degrees for 20 to 45 minutes or longer if necessary (**eFig. 35.3**). Isoproterenol, administered as a bolus or infusion, may provoke syncope in patients whose initial upright tilt-table test result shows no abnormalities or, after a few minutes of tilt, may shorten the time needed to produce a positive response on the test. An initial intravenous isoproterenol dose of 1 µg/min can be increased in 0.5-µg/min steps until symptoms occur or a maximum of 4 µg/min is given. Isoproterenol induces a vasodepressor response in upright susceptible patients (decrease in heart rate and blood pressure along with near-syncope or syncope). Tilt-table test results are positive in two thirds to three fourths of patients susceptible to neurally mediated syncope and are reproducible in approximately 80% but have a 10% to 15% false-positive response rate. A positive test result is more meaningful when it reproduces symptoms that have occurred spontaneously. Positive responses can be divided into cardioinhibitory, vasodepressor, and mixed categories. Therapy with beta blockers, disopyramide, theophylline, selective serotonin reuptake inhibitors, midodrine, fludrocortisone, salt loading, and thigh-high support stockings, alone or in combination, has been reported to be successful but not with reliable reproducibility. Tilt training, in which the patient leans against a wall for prolonged periods to increase tolerance to this body position, may help, as may isometric muscle flexing to abort or lessen an episode. Permanent pacing has been useful in a subset of patients with significant bradycardia provoked on tilt testing.



EFIGURE 35.3 Head-up tilt-table testing. Responses to tilt-table testing are shown; heart rate (HR) and systolic blood pressure (BP) are plotted as time functions. **Top panels**, A normal response is an early, slight drop in BP with a compensatory increase in HR mediated by the autonomic nervous system. With autonomic dysfunction, a progressive fall in BP is not counteracted by an increase in HR. In postural tachycardia syndrome, an exaggerated increase in HR is seen. **Bottom panels,** Findings with neurocardiogenic syncope. A pure vasodepressor response is a relatively sudden drop in BP without a marked change in HR, whereas a pure cardioinhibitory response shows a sudden decrease in HR without a change in BP. A mixed response shows decreases in both HR and BP.

A variant of the neurocardiogenic response, postural orthostatic tachycardia syndrome (POTS), is characterized by dramatic increases in heart rate during the first 10 minutes of tilt-table testing. POTS appears to be distinct from simple orthostatic hypotension, as well as from standard neurocardiogenic responses, and is thought to be caused by various forms of autonomic imbalance. Relief of symptoms has been effected with fludrocortisone, beta blockers, pyridostigmine, or combinations, although randomized controlled trials (RCTs) often show no consistent improvement with these drugs.

Esophageal Electrocardiography

Esophageal electrocardiography is a useful noninvasive technique for diagnosing arrhythmias. The esophagus is located immediately behind the left atrium, between the left and right pulmonary veins. An electrode in the lumen of the esophagus can record atrial potentials. Bipolar recording is superior to unipolar recording because far-field ventricular events can lead to possible diagnostic confusion with unipolar recording. In addition, atrial and occasionally ventricular pacing can be performed by means of

a catheter electrode inserted into the esophagus, and tachycardias can be initiated and terminated. Optimal electrode position for atrial pacing correlates with the patient's height and is within about 1 cm of the site at which the maximum amplitude of the atrial electrogram is recorded. When it is recorded simultaneously with the surface ECG, the esophageal atrial electrogram can be used to differentiate SVT with aberrancy from VT and to define the mechanism of SVTs. Complications of transesophageal recording and pacing are uncommon, but the technique is cumbersome and uncomfortable for most patients, and it is therefore infrequently used.

Invasive Electrophysiologic Studies

An invasive EPS involves introducing multipolar electrode catheters into the venous or arterial system and positioning them at various intracardiac or intrapericardial sites to record or stimulate cardiac electrical activity. Assessment of AV conduction at rest is done by positioning electrodes along the septal leaflet of the tricuspid valve and measuring the atrial-His interval (an estimate of AV nodal conduction time; normally, 60 to 125 milliseconds) and the His-ventricular (H-V) interval (a measure of infranodal conduction; normally, 35 to 55 milliseconds). The heart is stimulated from portions of the atria or ventricles and from the region of the His bundle, bundle branches, accessory pathways, and other structures. EP studies are performed *diagnostically* to provide information about the type of clinical rhythm disturbance and insight into its electrophysiologic mechanism. EPSs are used *therapeutically* to terminate a tachycardia by electrical stimulation or electroshock, to evaluate the effects of therapy by determining whether a particular intervention modifies or prevents electrical induction of a tachycardia or whether an electrical device properly senses and terminates an induced tachyarrhythmia, and to ablate myocardium involved in the tachycardia and prevent further episodes. EPSs have also been used prognostically to identify patients at risk for sudden cardiac death. The study can be helpful in patients with AV block, intraventricular conduction disturbance, sinus node dysfunction, tachycardia, and unexplained syncope or palpitations (**see Chapter 43**).

An EPS is usually effective at initiating VT and SVT when these tachyarrhythmias have occurred spontaneously. This enables the use of similar stimulation techniques after an intervention (e.g., drug therapy or catheter or surgical ablation) to assess the efficacy of treatment. However, false-negative responses (not finding a particular electrical abnormality known to be present) and false-positive responses (induction of a nonclinical arrhythmia) may complicate interpretation of the results because many lack reproducibility. Altered autonomic tone in a supine patient undergoing study, hemodynamic or ischemic influences, changing anatomy (e.g., new infarction) after the study, day-to-day variability, and the use of an artificial trigger (electrical stimulation) to induce the arrhythmia are several of many factors that can explain the occasional disparity between test results and spontaneous occurrence of arrhythmia. Overall, the diagnostic validity and reproducibility of these studies are good, and they are safe when performed by skilled clinical electrophysiologists.

Atrioventricular Block

In patients with AV block, the site of block usually dictates the clinical course of the patient and whether a pacemaker is needed (**see Chapter 40**). In general, the site of AV block can be determined from analysis of the regular ECG. When the site of block cannot be determined from such an analysis and when knowing the site of block is imperative for management of the patient, an invasive EPS is indicated. Candidates include symptomatic patients in whom His-Purkinje block is suspected but not established and patients

with AV block treated with a pacemaker who continue to be symptomatic and in whom a causal ventricular tachyarrhythmia is suspected. Possible candidates are those with second- or third-degree AV block, for whom information about the site of block or its mechanism may help direct therapy or assess prognosis, and patients suspected of having concealed His bundle extrasystoles. Patients with block in the His-Purkinje system become symptomatic because of periods of bradycardia or asystole and require pacemaker implantation more often than do patients who have AV nodal block. Type I (Wenckebach) AV block in older patients can have clinical implications similar to those for type II AV block. However, the results of EPS for evaluating the conduction system must be interpreted with caution. In rare cases the process of recording conduction intervals alters their values. For example, catheter pressure on the AV node or His bundle can cause prolongation of the atrial-His or H-V interval and could lead to erroneous diagnosis and therapy.

Intraventricular Conduction Disturbance

For patients with an intraventricular conduction disturbance, an EPS provides information about the duration of the H-V interval, which can be prolonged with a normal PR interval, or normal with a prolonged PR interval. A prolonged H-V interval (>55 msec) is associated with a greater likelihood for the development of complete AV block (but the rate of progression is slow, 2% to 3% annually) and for having structural disease and with higher mortality.[14] The finding of very long H-V intervals (>80 to 90 msec) identifies patients at increased risk for the development of AV block. The H-V interval has high specificity (approximately 80%) but low sensitivity (66%) for predicting the development of complete AV block. During an EPS, atrial pacing is used to uncover abnormal His-Purkinje conduction. A positive response is provocation of distal His block during 1 : 1 AV nodal conduction at rates of 135 beats/min or less. Again, sensitivity is low but specificity is high. Drug infusion, such as with procainamide or ajmaline, sometimes exposes abnormal His-Purkinje conduction (**Fig. 35.9**). Ajmaline (not available in the United States) can cause arrhythmias and should be used cautiously.

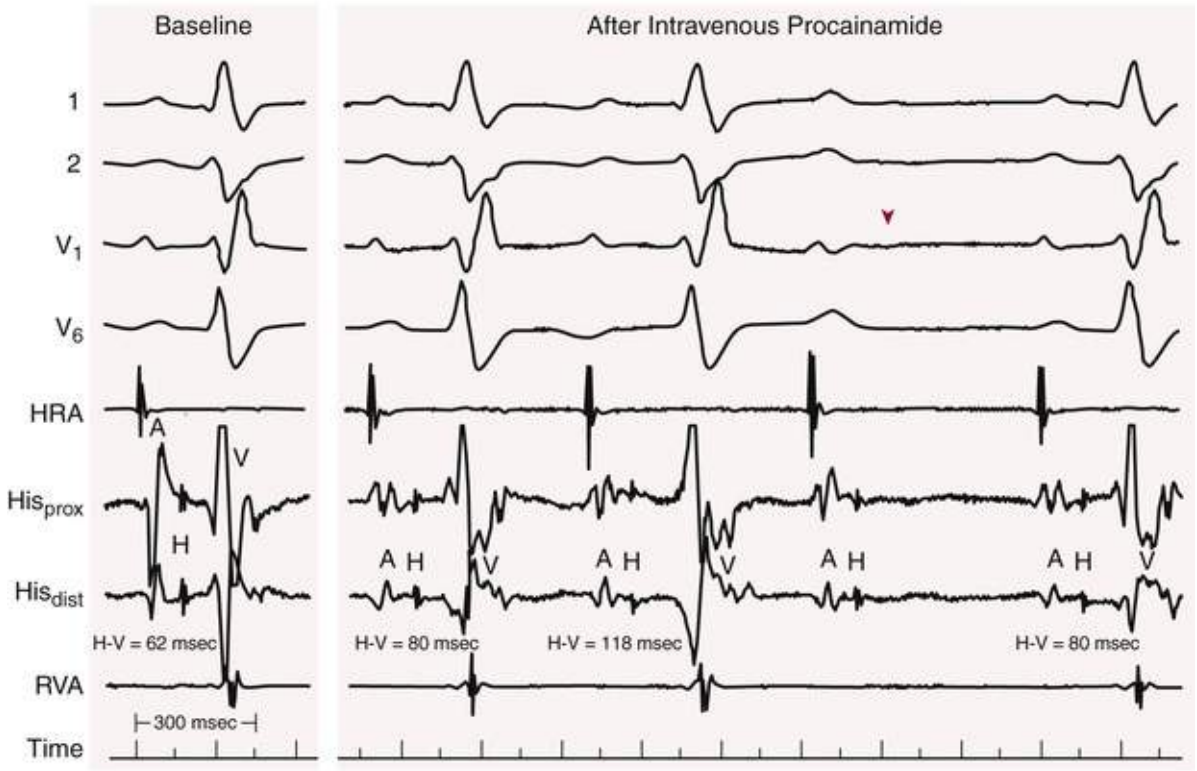


FIGURE 35.9 Testing the His-Purkinje system. A 43-year-old woman with sarcoid underwent EPS after a syncopal episode. Surface leads 1, 2, V_1, and V_6 are shown, with intracardiac recordings from catheters in the high right atrium (*HRA*), the proximal (His_{prox}) and distal (His_{dist}) electrode pairs of a catheter at the AV junction to record the His potential, and right ventricular apex (*RVA*). During baseline recording, the H-V interval is only slightly prolonged (62 milliseconds). After infusion of intravenous procainamide, the H-V interval is longer and an infra-His Wenckebach block is present. The *arrowhead* denotes the missing QRS complex caused by infra-His block. *A,* Atrial electrogram; *H,* His potential; *V,* ventricular electrogram.

An EPS is indicated in patients with symptoms (syncope or presyncope) that appear to be related to a bradyarrhythmia or tachyarrhythmia when no other cause of symptoms is found, including with prolonged ECG monitoring. For many of these patients, ventricular tachyarrhythmias rather than AV block can be the cause of their symptoms, with obvious therapeutic implications.

Sinus Node Dysfunction

Demonstration of slow sinus rates, sinus exit block, or sinus pauses on ECG temporally related to symptoms suggests a causal relationship and usually obviates the need for further diagnostic studies (**see Chapter 37**). Carotid sinus pressure that results in several seconds of complete asystole or AV block and reproduces the patient's usual symptoms exposes the presence of a hypersensitive carotid sinus reflex. Carotid sinus massage must be done cautiously; rarely it can precipitate a stroke. Neurohumoral agents, adenosine, or stress testing can be used to evaluate the effects of autonomic tone on sinus node automaticity and sinoatrial conduction time.

Sinus Node Recovery Time.

Sinus node recovery time (SNRT) is a technique that can be useful for evaluating sinus node function. The interval between the last paced high right atrial response and the first spontaneous (sinus) high right atrial response after termination of pacing is measured to determine SNRT. Because the spontaneous sinus rate influences SNRT, the value is corrected by subtracting the spontaneous sinus node cycle length

(before pacing) from the SNRT (**Fig. 35.10**). This value, the corrected SNRT (CSNRT), is generally shorter than 525 milliseconds. A prolonged CSNRT has been found in patients suspected of having sinus node dysfunction. After cessation of pacing, the first return sinus cycle can be normal but can be followed by secondary pauses (a strong indicator of sinus node dysfunction). It is important to evaluate AV node and His-Purkinje function in patients with sinus node dysfunction because many also exhibit impaired AV conduction.

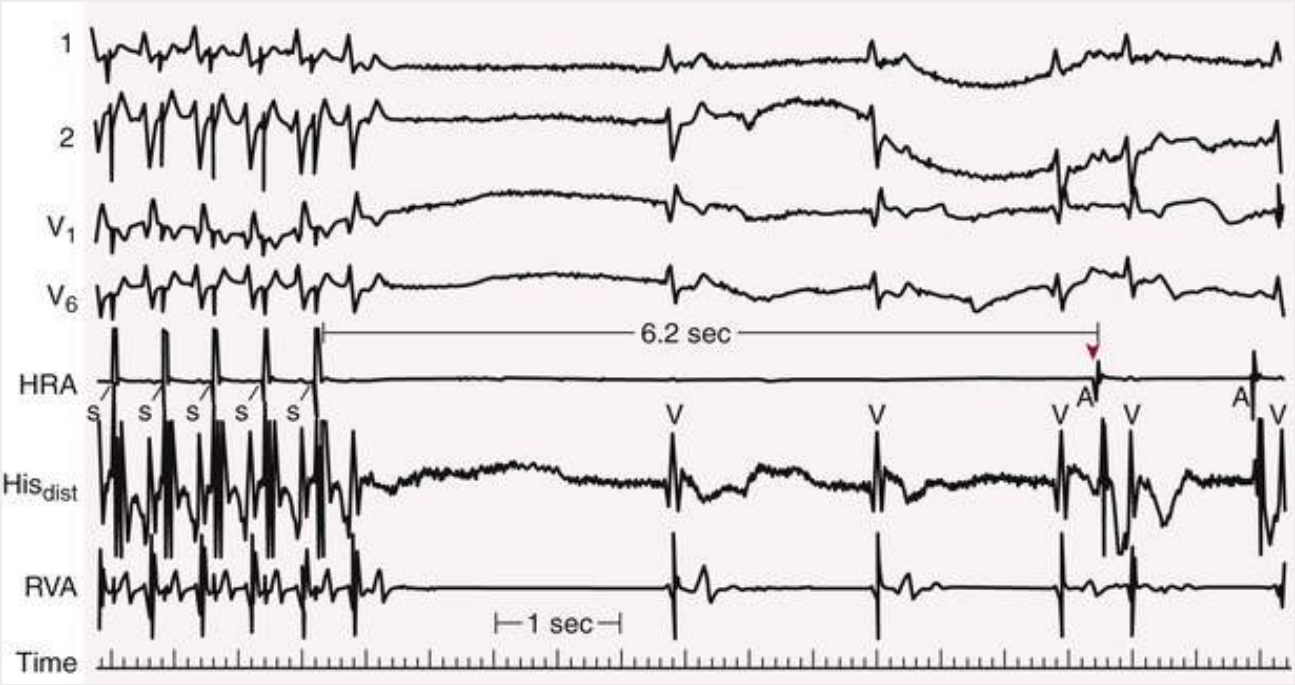

FIGURE 35.10 Abnormal sinus node function. Recordings are similar to those in Fig. 35.9. The last five complexes of a 1-minute burst of atrial pacing (*S*) at a cycle length of 400 milliseconds are shown, after which pacing is stopped. The sinus node does not spontaneously discharge (SNRT) until 6.2 seconds later (*arrowhead*). Three junctional escape beats occurred before this time. His_{dist}, Distal electrode pair; *HRA,* high right atrium; *RVA,* right ventricular apex.

Sinoatrial Conduction Time.

Sinoatrial conduction time (SACT) can be estimated by simple pacing techniques based on the assumptions that (1) conduction times into and out of the sinus node are equal, (2) no depression of sinus node automaticity occurs, and (3) the pacemaker site does not shift after premature stimulation. These assumptions can be erroneous, particularly in patients with sinus node dysfunction. The sensitivity of the SACT and SNRT tests is only approximately 50% for each test alone and 65% when combined. The specificity, combined, is approximately 88%, with a low predictive value. Thus, if these test results are abnormal, the likelihood of the patient having sinus node dysfunction is great. However, normal results do not exclude the possibility of sinus node disease. Candidates for invasive EPS to evaluate sinus node function are symptomatic patients in whom sinus node dysfunction is suspected but has not yet been established as a cause of the symptoms. Potential candidates are patients with clinical sinus node dysfunction in whom other causes of symptoms (e.g., tachyarrhythmias) are to be excluded.

Tachycardia

In patients with tachycardias, an EPS can be used to diagnose the arrhythmia, to determine and deliver therapy, to establish the anatomic sites involved in the tachycardia, to identify patients at high risk for the

development of serious arrhythmias, and to gain insight into the mechanisms responsible for the arrhythmia (**see Chapter 37**). The study can differentiate aberrant supraventricular conduction from ventricular tachyarrhythmias when standard electrocardiographic criteria are equivocal.

An SVT is recognized electrophysiologically by an H-V interval equaling or exceeding that recorded during normal sinus rhythm (**Fig. 35.11**). In contrast, during VT, the H-V interval is shorter than normal, or the His deflection cannot be recorded clearly because of superimposition of the larger ventricular electrogram. Only two situations exist in which a consistently short H-V interval occurs: during retrograde activation of the His bundle from activation originating in the ventricle (i.e., PVC, ventricular pacing, or VT) and during AV conduction over an accessory pathway (preexcitation syndrome). Atrial pacing at rates exceeding the tachycardia rate can demonstrate the ventricular origin of the wide-QRS tachycardia by producing fusion and capture beats and normalization of the H-V interval. The only VT that exhibits an H-V interval equal to or slightly exceeding the normal sinus H-V interval is bundle branch reentry, but His activation will be in the retrograde direction.

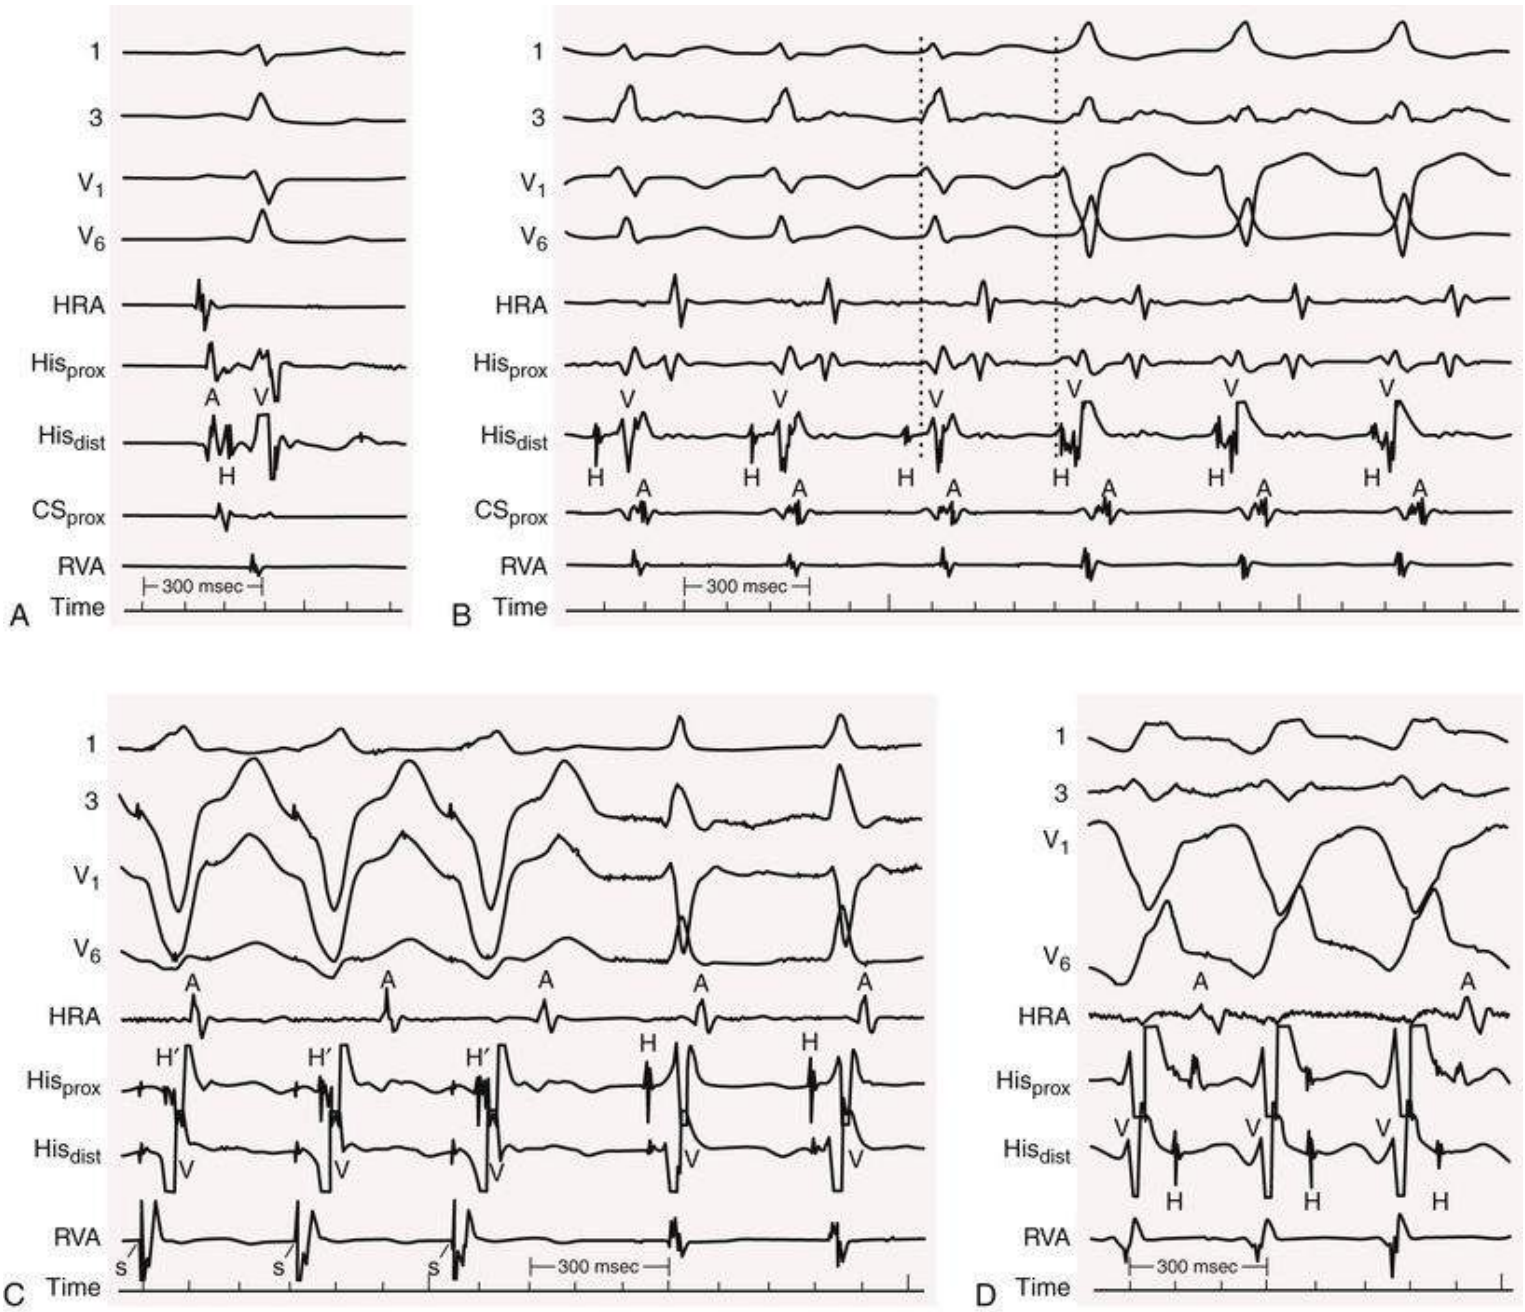

FIGURE 35.11 Bundle of His recordings in different situations similar to those in Figs. 35.9 and 35.10. **A,** Baseline sinus rhythm with normal AV conduction. **B,** Orthodromic SVT with retrograde conduction over a left-sided accessory pathway throughout the tracing. The first three beats have a narrow QRS complex with a normal H-V interval; the last three QRS complexes represent a fusion of conduction over the AV node–His bundle and a slowly conducting right-sided accessory pathway. The His potential occurs after onset of the wide QRS complex (*dashed lines*). **C,** Three paced ventricular beats are shown with a retrograde His potential (H′), followed by initiation of AV node reentrant SVT (atrial depolarization near the end of the QRS complex, as seen in the HRA tracing). **D,** VT with delayed activation of the His potential and complete retrograde AV node block (dissociated atrial complexes). *CS_{prox}*, Proximal coronary sinus; *His_{dist}*, distal electrode pair; *His_{prox}*, proximal electrode pair; *HRA,* high right atrium; *RVA,* right ventricular apex.

An EPS should be considered for the following circumstances: (1) in patients who have symptomatic, recurrent, or drug-resistant supraventricular or ventricular tachyarrhythmias to help select optimal therapy; (2) in patients with tachyarrhythmias occurring too infrequently to permit adequate diagnostic or therapeutic assessment; (3) for differentiation of SVT and aberrant conduction from VT; (4) whenever nonpharmacologic therapy, such as the use of electrical devices, catheter ablation, or surgery, is contemplated; (5) in patients surviving an episode of cardiac arrest occurring more than 48 hours after acute MI or without evidence of an acute Q wave MI; and (6) for assessment of the risk for sustained VT

in patients with a previous MI, ejection fraction of 0.3 to 0.4, and nonsustained VT on an ECG. In general, EPS is not indicated in patients with long-QT syndrome and torsades de pointes.

The process of initiation and termination of SVT or VT with programmed electrical stimulation to establish precise diagnoses and help select sites for catheter ablation is the most common application of EPS in patients with tachycardia. The role of drug therapy in clinically significant arrhythmias continues to diminish; although EPS was once widely used to predict the efficacy of drug therapy in suppressing spontaneous tachycardia recurrences, the technique is now rarely used for this purpose. Noninvasive stimulation from an implanted pacemaker or defibrillator can be used to test the effects of drug therapy given in an attempt to decrease the frequency of arrhythmias, as well as to test the ICD's ability to detect and treat VT that has been slowed or otherwise altered by drug effect.

Unexplained Syncope

The three common arrhythmic causes of syncope are sinus node dysfunction, AV block, and tachyarrhythmias (**see Chapter 43**). Of the three, tachyarrhythmias are most reliably evaluated in the electrophysiology laboratory, followed by sinus node abnormalities and His-Purkinje block.

The cause of syncope remains uncertain in up to 50% of patients, depending in part on the extent of the evaluation. A careful, accurately performed history and physical examination begin the evaluation, followed by noninvasive tests, including a 12-lead ECG, and can lead to a diagnosis in 50% or more of patients. In a small percentage (<5%) of patients, an arrhythmia develops coincident with syncope or presyncope during 24- or 48-hour ECG monitoring, whereas a larger percentage (15%) have symptoms without an arrhythmia, thereby excluding an arrhythmic cause. Prolonged ECG monitoring with patient-activated transtelephonic event recorders that have memory loops may increase the yield. Tilt-table and stress testing can be useful for selected patients.

An EPS helps explain the cause of syncope or palpitations when it induces an arrhythmia that replicates the patient's symptoms or is associated with significant hypotension. Patients with a single episode of syncope and no evidence of structural heart disease, as well as those with a nondiagnostic EPS, have a low incidence of sudden death and an 80% remission rate over the ensuing 10 years. In those with recurrent syncope, the test is falsely negative in 20%, usually because of failure to find AV block or sinus node dysfunction. On the other hand, in many patients with structural heart disease, several abnormalities may be present that could account for syncope and can be diagnosed at EPS. Deciding which among these abnormalities is responsible for syncope and therefore requires therapy, and of what type, can be difficult (**Fig. 35.12**). Mortality and the incidence of sudden cardiac death are determined mainly by the presence of underlying heart disease (**see Chapter 42**).

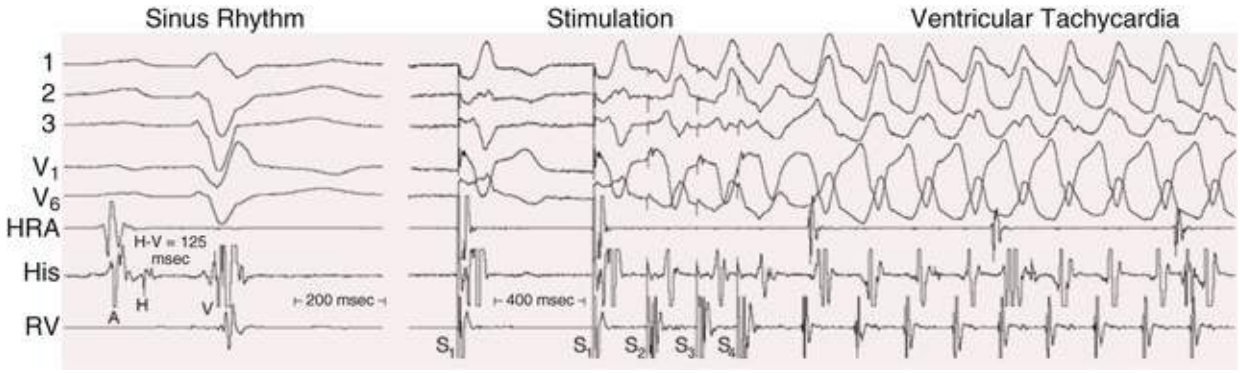

FIGURE 35.12 Multiple abnormalities in a patient with prior myocardial infarction and syncope. Recordings are similar to previous figures. In **left panel,** a sinus rhythm complex shows a right bundle branch block and left axis deviation, with a very prolonged H-V interval of 125 milliseconds (normal, 35 to 55); thus heart block could have caused syncope. However, in **right panel,** ventricular stimulation with three extrastimuli (S_2, S_3, S_4) induces sustained VT, another potential cause of syncope (note the different time scales in the two panels).

Syncopal patients considered for an EPS are those whose spells remain undiagnosed despite general, neurologic, and noninvasive cardiac evaluation, particularly if the patient has structural heart disease.[15] The diagnostic yield is approximately 70% in that group but only 12% in patients without structural heart disease. Therapy for a putative cause found during EPS prevents recurrence of syncope in approximately 80% of patients. Among arrhythmic causes of syncope, intermittent conduction disturbances are the most difficult to diagnose. EPSs are poor in establishing this diagnosis despite an array of provocative tests that can be used. When tachyarrhythmias have been thoroughly sought and excluded and clinical suspicion for intermittent heart block is high (e.g., bundle branch block or long H-V interval), empiric permanent pacing may be justified.

In patients with a nondiagnostic EPS, injection of adenosine triphosphate (different from plain adenosine) distinguishes patients who may benefit from permanent pacing (those with longer than a 10-second sinus pause or AV block) from those who do not. Some have suggested that this test be performed before EPS in some cases or after a negative EPS but before an implantable loop recorder is placed.

Palpitations

An EPS is indicated in patients with palpitations who have had a pulse documented by medical personnel to be inappropriately rapid or slow without an electrocardiographic recording and in those suspected of having clinically significant arrhythmias without electrocardiographic documentation.

In patients with syncope or palpitations, the sensitivity of EPS may be low but can be increased at the expense of specificity. For example, more aggressive pacing techniques (e.g., use of three or four premature stimuli), administration of drugs (e.g., isoproterenol), or left ventricular pacing can increase the likelihood of induction of ventricular arrhythmias by precipitating nonclinical ventricular tachyarrhythmias, such as nonsustained polymorphic VT or VF. Similarly, aggressive techniques during atrial pacing can induce nonspecific episodes of AF or atrial flutter. A diagnostic dilemma arises when the patient's clinical, symptom-producing arrhythmia is one of these nonspecific arrhythmias that can be produced in a normal patient who has no arrhythmia. In most patients, these arrhythmias are regarded as *nonclinical* (i.e., nonspecific responses to intense stimulation). In other patients, such as those with hypertrophic or dilated nonischemic cardiomyopathy, they may be clinically relevant arrhythmias. However, induction of sustained SVT (e.g., AV nodal reentry, AV reciprocating tachycardia) or monomorphic VT is almost never an artifact of stimulation, no matter how intense. Initiation of these arrhythmias in patients who have not had known spontaneous episodes of these tachycardias is uncommon

and provides important information; for example, the induced tachyarrhythmia may be clinically significant and responsible for the patient's symptoms. In addition, inducible SVT episodes can have important implications for patients with implantable cardioverter-defibrillators (ICDs) that may deliver inappropriate therapy for such arrhythmias. In general, other abnormalities, such as prolonged sinus pauses after overdrive atrial pacing or His-Purkinje AV block, are not induced in patients who do not or may not experience these abnormalities spontaneously. Provocation of these abnormalities has a high degree of specificity for clinical relevance.

Complications of Electrophysiologic Studies

The risks associated with undergoing only an EPS are small. Myocardial perforation with cardiac tamponade, pseudoaneurysms at arterial access sites, and provocation of nonclinical arrhythmias can occur, each with less than a 1/500 incidence; the addition of therapeutic maneuvers (e.g., ablation) to the procedure increases the incidence of complications. In many centers, diagnostic EPS and even ablation procedures are performed on an outpatient basis (i.e., same-day discharge). With the increasing use of extensive ablation in the left atrium to treat AF, an increase in systemic thromboembolic complications has been observed, as have pericardial effusion and tamponade, valve damage, and phrenic nerve injury[16] (**see Chapter 37**).

Direct Cardiac Mapping: Recording Potentials Directly From the Heart

Cardiac mapping is a method whereby potentials recorded directly from the heart are spatially depicted as a function of time in an integrated manner (**Fig. 35.13**). The location of recording electrodes (e.g., epicardial, intramural, or endocardial) and the recording mode used (unipolar versus bipolar), as well as the method of display (isopotential, isochronal, unipolar, or bipolar voltage maps), depend on the problem under consideration.

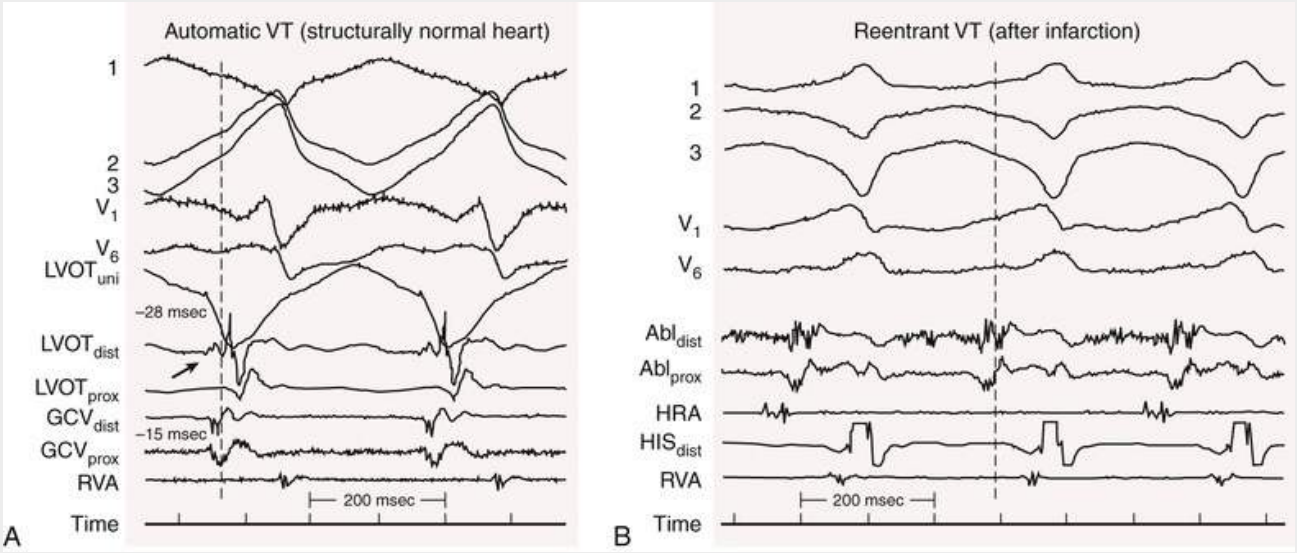

FIGURE 35.13 Endocardial catheter recordings during VT in two patients. *Dashed lines* denote onset of the QRS complexes. **A,** Woman without structural heart disease had a sustained VT arising from the left ventricular outflow tract (*LVOT*). Note the unipolar (uni) electrogram with a sharp "QS" complex and onset (*arrow*) of the distal bipolar recording ($LVOT_{dist}$) preceding the right ventricular recording, as well as recordings from a multielectrode catheter in the great cardiac vein (GCV_{dist} and GCV_{prox}) on the epicardial surface opposite the endocardial recording. Ablation at this site (LVOT) terminated the VT. **B,** Patient with reentrant VT caused by a previous inferior wall infarction. The ablation catheter (Abl_{dist}) on the inferomedial wall shows a prolonged, fragmented electrogram indicative of slow conduction that spans the entire diastolic interval between QRS complexes. Ablation at this site eliminated the VT. Abl_{prox}, Proximal ablation catheter electrodes.

Direct cardiac mapping by catheter electrodes or less frequently at cardiac surgery can be used to identify and localize the areas responsible for rhythm disturbances in patients with supraventricular and ventricular tachyarrhythmias for catheter or surgical ablation, isolation, or resection. Conditions amenable to this approach include accessory pathways associated with WPW syndrome, the pathways in AV node reentry, AV node–His bundle ablation, sites of origin of focal atrial tachycardia (AT) and VTs, isolated pathways essential for the maintenance of reentrant ATs or VTs, and various substrates responsible for episodes of AF (Videos 35.1 and 35.2) (**see Chapter 38**). Mapping can also be used to delineate the anatomic course of the His bundle and phrenic nerve to avoid injury during catheter ablation or open heart surgery for repair of congenital heart disease.

Early efforts at mapping involved moving an electrode from location to location, acquiring data from a single point at a time, and comparing the timing of local activation with some reference recording, as well as other mapped sites. Knowing when enough data points had been obtained to determine where ablation should be performed relied heavily on the memory of the operator. Specialized mapping systems have now been developed that use computers to log not only the activation times and electrogram amplitude (voltage) at various points in the heart, but also the physical locations from which they were obtained. The mapping information acquired in this way can be displayed on a screen to show relative activation times in a color-coded sequence. Using such systems, dozens or even hundreds of sites can be sampled relatively quickly, thereby leading to a clear picture of cardiac activation and potential target sites for ablation (**Figs. 35.14 and 35.15**). These systems can also record the signal amplitude at each site sampled to allow differentiation of normal from scarred myocardium, which can help in planning ablation strategies (**Fig. 35.16**). Other mapping systems can acquire data from several thousand points simultaneously by using a multipolar electrode array. This may be useful for hemodynamically unstable tachycardias or those that terminate spontaneously within seconds, which precludes detailed point-to-point mapping.

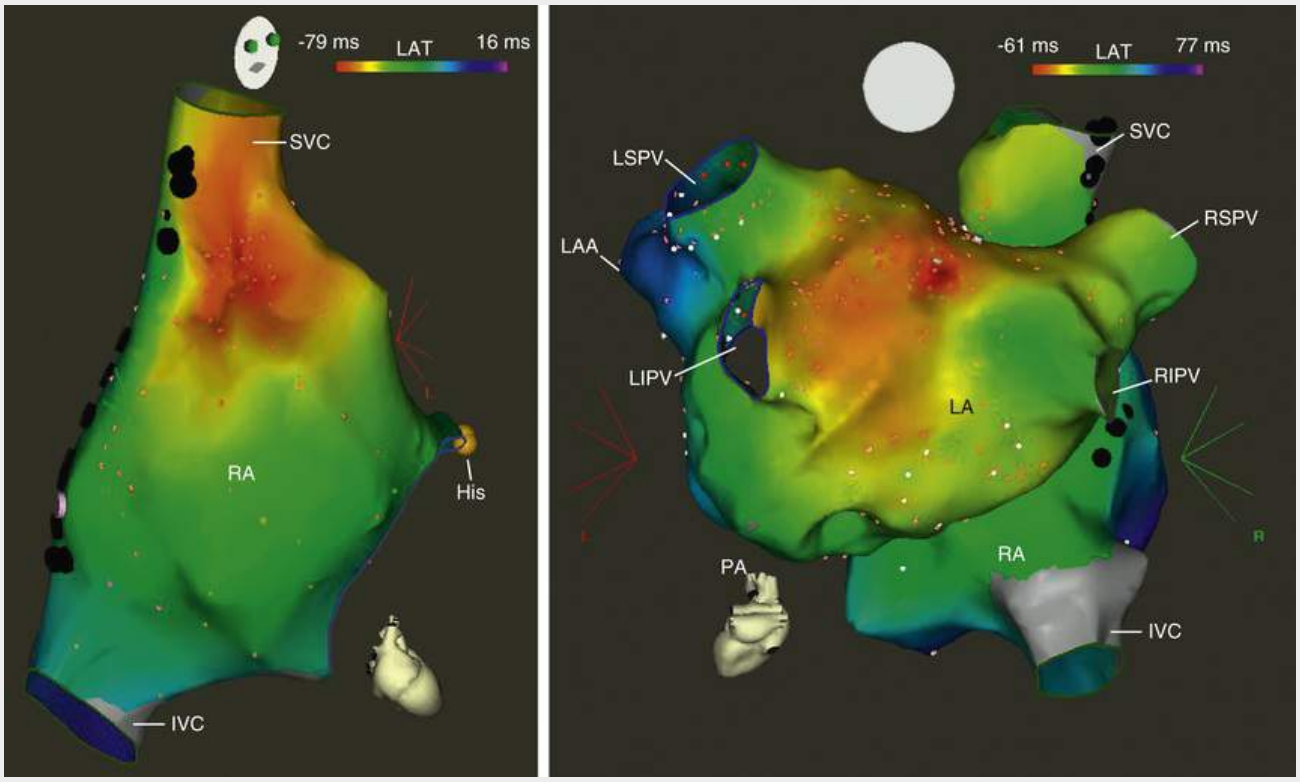

FIGURE 35.14 Electroanatomic maps of focal atrial tachycardias. **Left,** A focal right atrial tachycardia is shown from an almost right lateral view. A color-coded time scale of activation is shown at the right; *red* indicates earliest activation and *purple,* latest. This atrial tachycardia arose in the anterolateral right atrium (*RA*), slightly anterior to where the sinus node resides; ablation here eliminated tachycardia while leaving sinus node function unaffected. **Right,** A left atrial focal tachycardia is shown, with both RA and left atrium (*LA*) viewed from posteriorly. The tachycardia arose from the region of the *small red spot* at top center of the LA, with all other areas activated centrifugally. Ablation at this site eliminated the tachycardia. *SVC,* Superior vena cava; *IVC,* inferior vena cava; *His,* His bundle area (*orange dots*); *LIPV,* left inferior pulmonary vein (PV); *LSPV,* left superior PV; *RSPV,* right superior PV; *RIPV,* right inferior PV.

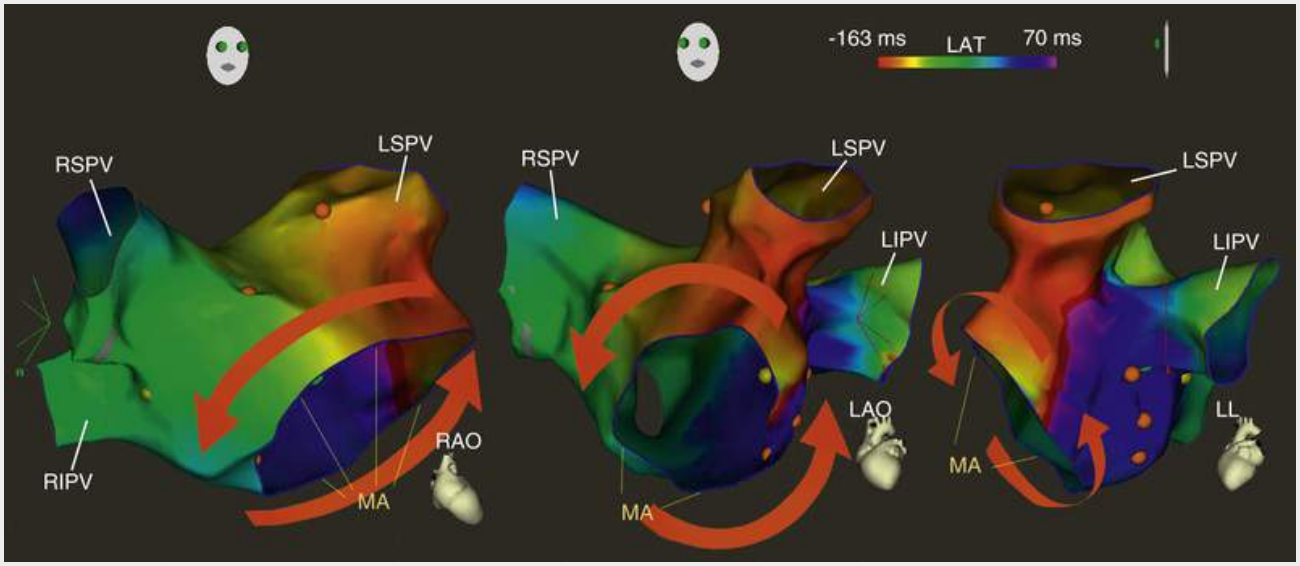

FIGURE 35.15 Electroanatomic activation map of "perimitral" reentrant atrial flutter. Three views of the left atrium are shown: right anterior oblique (*RAO*), left anterior oblique (*LAO*), and left lateral (*LL*). The electrical wave front propagates around the mitral annulus (*MA*) in a "counterclockwise" direction as indicated by *orange arrows*; in this complete circuit, early activation (*red*) abuts late activation (*purple*) at the lateral mitral annulus. The cycle length of the tachycardia was 235 milliseconds, almost completely described by the points shown in the figure (from −163 to +70 milliseconds, a total of 233 milliseconds; time scale at *top*). Abbreviations as in Fig. 35.14.

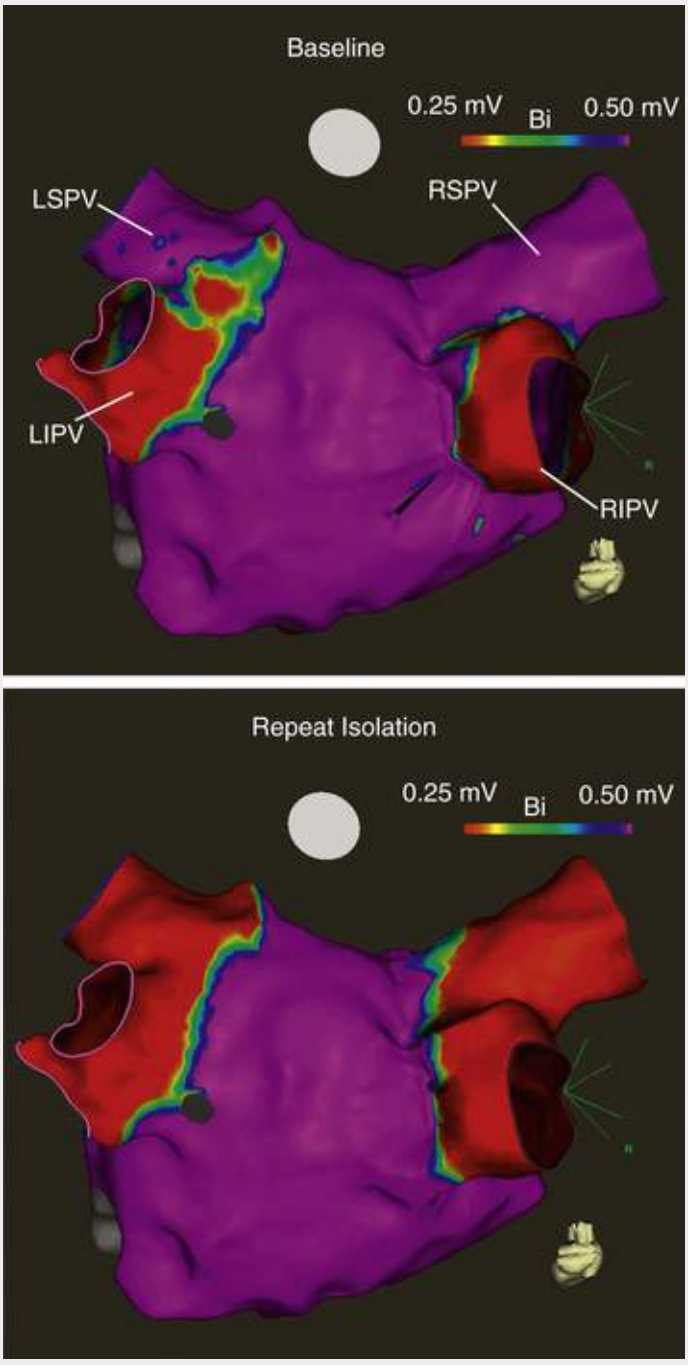

FIGURE 35.16 Electroanatomic left atrial voltage maps during sinus rhythm in a patient with recurrent atrial fibrillation after prior pulmonary vein (PV) isolation. **Top,** Posterior view of the left atrium at baseline, showing low voltage (*red,* tantamount to electrical isolation) in the left (*LIPV*) and right (*RIPV*) inferior PVs, but high residual voltage (*purple*) in the left (*LSPV*) and right (*RSPV*) superior PVs. **Bottom,** After repeat ablation around the PVs, the superior veins now have no residual voltage (*red*); all four PVs are now isolated. The patient has had no recurrence of symptoms. A voltage scale is shown at *upper right* of each panel.

Pace mapping is a technique in which pacing is performed at putative sites from which arrhythmias arise (a focus) or exit (reentrant circuit). The greater the degree of "match" in QRS complexes (for VT) or intracardiac activation sequences (for atrial tachycardias), the more likely that the paced site may be an appropriate site for ablation. Software has been developed to calculate the fidelity of match of the paced complexes to the target arrhythmia; ideally, this should approach 100% (**see Chapter 36**, **Figs. 36.16 and 36.18**). Other algorithms have been developed to analyze propagation patterns during complex arrhythmias such as AF by recording signals from multielectrode "basket" catheters in the atrium (**Fig. 35.17**). This has resolved many cases of an apparently chaotic rhythm to one in which erratic patterns of propagation emanate from a stable rapid source (either rotor or focus). Ablation at these source sites can

eliminate AF in some cases.[17] Work is ongoing in this area. Lastly, although computerized mapping systems acquire activation time and voltage at given sites in the heart, these features have been displayed separately. “Ripple mapping” is a new technique that integrates time and voltage information on the same display. Experience with this technique is limited, but the early results are promising.[18]

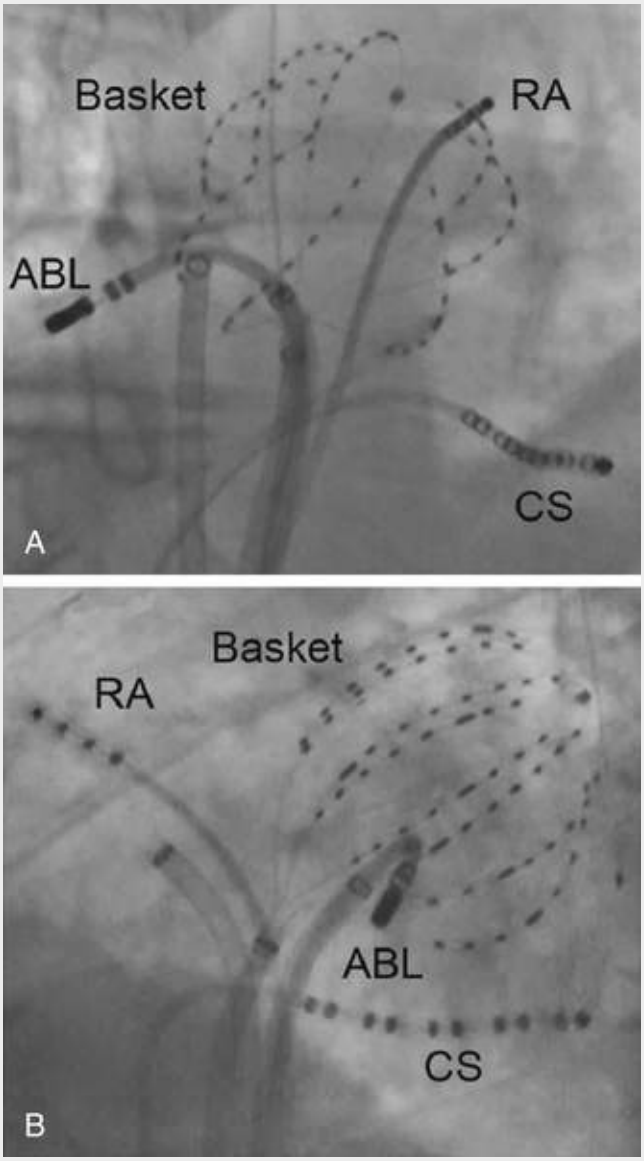

FIGURE 35.17 Basket catheter for mapping AF. Right **(A)** and left **(B)** anterior oblique fluoroscopic views of an eight-spline, eight electrodes per spline (64 total electrodes) “basket” catheter in the left atrium; other catheters are right atrial (*RA*), coronary sinus (*CS*), and an ablation catheter (*ABL*) in the right inferior pulmonary vein.

Current mapping systems have the ability to integrate previous imaging studies (computed tomography, magnetic resonance imaging) into the procedure for additional anatomic reference and to derive anatomic information by moving a catheter throughout a cardiac chamber to develop a contour of its inner surface, on which activation or voltage data can be plotted.

Guidelines

Ambulatory Electrocardiographic and Electrophysiologic Testing

John M. Miller, Gordon F. Tomaselli, and Douglas P. Zipes

Guidelines for the appropriate use of ambulatory electrocardiography (ECG) were first published by the American College of Cardiology and American Heart Association (ACC/AHA) in 1989[1] and updated in 1999.[2] In conjunction with other professional societies, the ACC/AHA issued a statement of requirements for clinical competence in ambulatory ECG in 2001.[3] Guidelines for performance of electrophysiologic testing were first published in 1985[4] and updated in 1989 and 1995.[5] A clinical competence statement was issued by the ACC/AHA for electrophysiologic studies and catheter ablation in 2000[6] and updated in 2006[7]; this was updated by a statement on training in electrophysiology, cardiac pacing, and arrhythmia management in 2006[8] and again in 2008[9] and 2015.[10] The AHA and the Heart Rhythm Society made recommendations on safety-related topics, such as restrictions on driving, for patients with arrhythmia in 1996[11] and updated them in 2007.[12] Since then, efforts to update the guidelines have focused on appropriate indications for the use of pacemakers and implantable cardioverter-defibrillators (ICDs) because of rapid advances in knowledge about the ability of ICDs to improve the survival of patients with arrhythmia with or without electrophysiologic testing. These guidelines were issued in 2002[13] and updated in 2008 and 2013[14] (see Guidelines in **Chapter 41**).

The standard ACC/AHA classification system is used for the following indications:

Class I: conditions for which there is evidence and/or general agreement that the test is useful and effective
Class II: conditions for which there is conflicting evidence and/or a divergence of opinion about the usefulness or efficacy of performing the test.
Class IIa: weight of evidence or opinion in favor of usefulness or efficacy.
Class IIb: usefulness or efficacy less well established by evidence or opinion.
Class III: conditions for which there is evidence and/or general agreement that the test is not useful or effective and in some cases may be harmful.

Three levels are used to rate the evidence on which recommendations have been based:

Level A recommendations are derived from data from multiple randomized clinical trials.
Level B recommendations are derived from a single randomized trial or nonrandomized studies.
Level C recommendations are based on the consensus opinion of experts.

Ambulatory Electrocardiography

The evolution of guidelines for the use of ambulatory electrocardiography (ECG) from 1989 to 1999 and updated in 2015 reflected important progress in several areas, including the following:

- Understanding of the limited usefulness of suppression of ventricular ectopy with drug therapy
- Solid-state digital technology, which facilitates transtelephonic

transmission of electrocardiographic data
- Technical advances in long-term event recorders
- Improved signal quality and interpretation
- Improved computer arrhythmia interpretation
- Increasingly sophisticated monitoring capacity of pacemakers and ICDs

As a result of progress in these areas and increased knowledge about arrhythmias, ambulatory ECG monitoring is now considered to be of uncertain appropriateness for many indications for which it was once an accepted strategy.

Diagnosis

In assessing symptoms that may be caused by arrhythmias, ambulatory ECG (Holter) monitoring is clearly established for the evaluation of syncope (**Table 35G.1**; **see Chapter 43**). A 2006 AHA/ACC Foundation scientific statement on the evaluation of syncope stipulates that the type and duration of ambulatory ECG monitoring are dictated by the frequency of symptoms.[15] Holter monitors (24 to 48 hours) are appropriate for episodes that occur at least daily and event recorders (30 to 60 days) for episodes that occur at least monthly. Implantable loop recorders inserted subcutaneously can record bipolar ECG signals for up to 24 months. In patients with unexplained syncope, use of an implantable loop recorder for 1 year is more likely to identify the mechanism of syncope than is a conventional approach that uses Holter or event monitors and electrophysiologic testing and is cost-effective.

TABLE 35G.1

ACC/AHA 1999 Guidelines on Ambulatory Electrocardiography for Assessment of Symptoms and Arrhythmias

INDICATION	CLASS I (INDICATED)	CLASS IIa (GOOD SUPPORTIVE EVIDENCE)	CLASS IIb (WEAK SUPPORTIVE EVIDENCE)	CLASS III (NOT INDICATED)
Assessment of symptoms possibly related to rhythm disturbances	Patients with unexplained syncope, near-syncope, or episodic dizziness in whom the cause is not obvious Patients with unexplained recurrent palpitation		Patients with episodic shortness of breath, chest pain, or fatigue that is not otherwise explained Patients with neurologic events when transient atrial fibrillation or flutter is suspected Patients with symptoms such as syncope, near-syncope, episodic dizziness, or palpitation in whom a probable cause other than an arrhythmia has been identified but in whom symptoms persist despite treatment of this other cause	Patients with symptoms such as syncope, near-syncope, episodic dizziness, or palpitation in whom other causes have been identified by history, physical examination, or laboratory tests Patients with cerebrovascular accidents but without other evidence of arrhythmia
Arrhythmia detection to assess risk for future cardiac events in patients without symptoms from arrhythmia			Post-MI patients with LV dysfunction (ejection fraction <40%) Patients with CHF Patients with idiopathic hypertrophic cardiomyopathy	Patients who have sustained myocardial contusion Systemic hypertensive patients with LV hypertrophy Post-MI patients with normal LV function Preoperative arrhythmia evaluation of patients for noncardiac surgery Patients with sleep apnea Patients with valvular heart disease
Measurement of HRV to assess risk for future cardiac events in patients without symptoms from arrhythmia			Post-MI patients with LV dysfunction Patients with CHF Patients with idiopathic hypertrophic cardiomyopathy	Post-MI patients with normal LV function Diabetic patients to evaluate for diabetic neuropathy Patients with rhythm disturbances that preclude HRV analysis (e.g., atrial fibrillation)
Assessment of antiarrhythmic therapy	To assess antiarrhythmic drug response in individuals in whom the baseline frequency of arrhythmia has been characterized as reproducible and of sufficient frequency to permit analysis	To detect proarrhythmic responses to antiarrhythmic therapy in patients at high risk	To assess rate control during atrial fibrillation To document recurrent or asymptomatic nonsustained arrhythmias during therapy in the outpatient setting	

CHF, Congestive heart failure; *HRV,* heart rhythm variability; *LV,* left ventricular; *MI,* myocardial infarction.

Ambulatory ECG is also supported for the evaluation of recurrent palpitations, particularly if the frequency of these symptoms makes it reasonably likely that they can be correlated with the tracings obtained during a 24-hour monitoring period. The guidelines note that data on the use of ambulatory ECG for near-syncope or dizziness are insufficient to describe the diagnostic performance of this technology for patients with such symptoms.

The ACC/AHA guidelines explicitly discourage ambulatory ECG for patients with syncope or palpitations if other causes have been identified during the clinical evaluation and for patients with cerebrovascular accidents (strokes) and no other evidence of arrhythmia. The guidelines seek to reduce performance of ambulatory ECG “for completeness” in such cases. Little support is provided for use of ambulatory ECG in cases in which the cause of the patient's symptoms is unclear but in which the likelihood of detecting an unsuspected arrhythmia is low (class IIb indications).

Assessment of Risk

The ACC/AHA guidelines discouraged the use of ambulatory ECG for either arrhythmia detection or analysis of heart rhythm variability for the purpose of risk assessment in patients without symptoms of arrhythmia, even if they had cardiovascular conditions such as myocardial contusions, left ventricular hypertrophy, or valvular heart disease (**see Table 35G.1**). Routine use for patients in whom arrhythmia is

a common cause of death (left ventricular dysfunction, hypertrophic cardiomyopathy) was considered a class IIb indication. These recommendations preceded data demonstrating the beneficial impact of ICDs for patients with left ventricular dysfunction after acute myocardial infarction even without symptoms of arrhythmia. These more recent findings are leading to an expanded role for ambulatory ECG in determining which asymptomatic patients most need these expensive devices.

Efficacy of Antiarrhythmic Therapy

In the absence of data demonstrating that oral antiarrhythmic therapy can improve survival through control of ventricular arrhythmias, ambulatory ECG has a diminished role as a test for evaluation of the efficacy of treatment (**see Table 35G.1**). Oral antiarrhythmic agents are important for control of supraventricular arrhythmias, but most patients with such arrhythmias do not have episodes every day. Event recorders can be useful for documenting the relationship between symptoms and recurrent arrhythmia and the interval between episodes, which can help guide therapy.

The guidelines provide some support for the use of ambulatory ECG for detection of proarrhythmia during initiation of drug therapy in patients at high risk (class IIa), but such patients tend to have these medications initiated as inpatients, or have ICDs in place.

Assessment of Pacemaker/ICD Function

Ambulatory ECG was considered to be appropriate for evaluation of the function of pacemakers and ICDs (**see Chapter 41**), but the role of ambulatory ECG is being reduced by increasing the diagnostic and monitoring functions being built into these devices, especially with the use of remote monitoring. Ambulatory ECG can provide useful information by correlating symptoms with device activity and by detecting abnormalities in sensing and capture during chronic follow-up (**Table 35G.2**). However, the ACC/AHA guidelines emphasize that ambulatory ECG should not be used when data available from device interrogation are sufficient to guide clinical management.

TABLE 35G.2

ACC/AHA 1999 Guidelines on Ambulatory Electrocardiography for Assessment of Pacemaker and Implantable Cardioverter-Defibrillator (ICD) Function

CLASS	INDICATION
Class I (indicated)	Evaluation of frequent symptoms of palpitations, syncope, or near-syncope to assess device function, to exclude myopotential inhibition and pacemaker-mediated tachycardia, and to assist in the programming of enhanced features, such as rate responsivity and automatic mode switching Evaluation of suspected component failure or malfunction when device interrogation is not definitive in establishing a diagnosis To assess response to adjunctive pharmacologic therapy in patients receiving frequent ICD therapy
Class IIa (good supportive evidence)	
Class IIb (weak supportive evidence)	Evaluation of immediate postoperative pacemaker function after pacemaker or ICD implantation as an alternative or adjunct to continuous telemetric monitoring Evaluation of the rate of supraventricular arrhythmias in patients with implanted defibrillators
Class III (not indicated)	Assessment of ICD or pacemaker malfunction when device interrogation, electrocardiogram, or other available data (e.g., chest radiograph) are sufficient to establish an underlying cause or diagnosis Routine follow-up in asymptomatic patients

Monitoring for Myocardial Ischemia

The 1999 ACC/AHA guidelines do not provide strong support of any indications for routine clinical use of ambulatory ECG monitoring for myocardial ischemia (**Table 35G.3**). The only indication for which the task force thought that there was good supportive evidence was suspected variant angina. This technology was not considered a first-choice alternative to exercise testing for patients who are unable to exercise.

TABLE 35G.3

ACC/AHA 1999 Guidelines on Monitoring for Ischemia

CLASS	INDICATION
Class I (indicated)	
Class IIa (good supportive evidence)	Patients with suspected variant angina
Class IIb (weak supportive evidence)	Evaluation of patients with chest pain who cannot exercise Preoperative evaluation for vascular surgery in patients who cannot exercise Patients with known coronary artery disease and atypical chest pain syndrome
Class III (not indicated)	Initial evaluation of patients with chest pain who are able to exercise Routine screening of asymptomatic patients

Clinical Competence

The ACC/AHA statement on clinical competence recommended that trainees interpret at least 150 ambulatory electrocardiograms under supervision to acquire minimal competence in this technology.[3] A minimum of 25 test interpretations per year was recommended to maintain competence.

Electrophysiologic procedures for Diagnosis

The ACC/AHA guidelines for the use of intracardiac electrophysiologic procedures from 1985[4] and 1995[5] reflected the emerging role of catheter ablation as a therapeutic strategy but did not fully reflect the reduced importance of antiarrhythmic medications and the growing role of ICDs that had occurred. Nevertheless, most of the basic themes of these guidelines remain valid. An updated clinical competence statement for performing these procedures was issued in 2006.[7]

Evaluation of Sinus Node Function

Clinical evaluation of sinus node dysfunction is often difficult because of the episodic nature of symptomatic abnormalities and the wide variability in sinus node function in asymptomatic individuals. Invasive tests of sinus function can test the ability of the sinus node to recover from overdrive suppression and assess sinoatrial conduction by introducing atrial extrastimuli or by atrial pacing.

The ACC/AHA guidelines consider electrophysiologic studies (EPSs) of sinus node function most appropriate for patients in whom dysfunction is suspected but not proved after a noninvasive evaluation (**Table 35G.4**). In contrast, the guidelines consider such studies inappropriate when a documented bradyarrhythmia has been correlated with the patient's symptoms and if management is unlikely to be influenced by an EPS. Studies are also considered inappropriate in asymptomatic patients and those who have sinus pauses only during sleep. When bradyarrhythmias were recognized as the cause of the patient's symptoms, EPSs were considered to have possible but uncertain appropriateness (class II) if such data might refine treatment choices.

TABLE 35G.4

ACC/AHA Year Guidelines on Clinical Intracardiac Electrophysiologic Studies for Evaluation of Specific Electrocardiographic Abnormalities

INDICATION	CLASS I (APPROPRIATE)	CLASS II (EQUIVOCAL)	CLASS III (INAPPROPRIATE)
Evaluation of sinus node function	Symptomatic patients in whom sinus node dysfunction is suspected as the cause of symptoms, but a causal relationship between an arrhythmia and the symptoms has not been established after appropriate evaluation	Patients with documented sinus node dysfunction in whom evaluation of AV or ventriculoatrial conduction or susceptibility to arrhythmias may aid in selection of the most appropriate pacing modality	Symptomatic patients in whom an association between symptoms and a documented bradyarrhythmia has been established and the choice of therapy would not be affected by EPS results

		Patients with electrocardiographically documented sinus bradyarrhythmias to determine whether abnormalities are caused by intrinsic disease, autonomic nervous system dysfunction, or effects of drugs to help select therapeutic options Symptomatic patients with known sinus bradyarrhythmias to evaluate potential for other arrhythmias as the cause of symptoms	Asymptomatic patients with sinus bradyarrhythmias or sinus pauses observed only during sleep, including sleep apnea
Acquired AV block	Symptomatic patients in whom His-Purkinje block, suspected as a cause of symptoms, has not been established Patients with second- or third-degree AV block treated with a pacemaker who remain symptomatic and in whom another arrhythmia is suspected as a cause of the symptoms	Patients with second- or third-degree AV block in whom knowledge of the site of block or its mechanism or response to pharmacologic or other temporary intervention may help in directing therapy or assessing prognosis Patients with premature, concealed junctional depolarizations suspected as the cause of a second- or third-degree AV block pattern (e.g., pseudo–AV block)	Symptomatic patients in whom the symptoms and presence of AV block are correlated by ECG findings Asymptomatic patients with transient AV block associated with sinus slowing (e.g., nocturnal type I second-degree AV block)
Chronic intraventricular conduction delay	Symptomatic patients in whom the cause of symptoms is not known	Asymptomatic patients with bundle branch block in whom pharmacologic therapy that could increase conduction delay or produce heart block is contemplated	Asymptomatic patients with intraventricular conduction delay Symptomatic patients whose symptoms can be correlated with or excluded by ECG events
Narrow-QRS tachycardia (QRS complex <0.12 sec)	Patients with frequent or poorly tolerated episodes of tachycardia who do not adequately respond to drug therapy and for whom information about the site of origin, mechanism, and electrophysiologic properties of pathways of the tachycardia is essential for choosing appropriate therapy (e.g., drugs, catheter ablation, pacing, or surgery) Patients who prefer ablative therapy to pharmacologic treatment	Patients with frequent episodes of tachycardia requiring drug treatment for whom there is concern about proarrhythmia or effects of the antiarrhythmic drug on the sinus node or AV conduction	Patients with tachycardias easily controlled by vagal maneuvers and/or well-tolerated drug therapy who are not candidates for nonpharmacologic therapy
Wide-complex tachycardias	Patients with wide–QRS complex tachycardia in whom the correct diagnosis is unclear after analysis of available ECG tracings and for whom knowledge of the correct diagnosis is necessary for care	None	Patients with VT or supraventricular tachycardia with aberrant conduction or preexcitation syndromes diagnosed with certainty by ECG criteria and for whom invasive electrophysiologic data would not influence therapy; however, data obtained at baseline EPS in these patients might be appropriate as a guide for subsequent therapy
Prolonged–QT interval syndrome	None	Identification of proarrhythmic effect of a drug in patients experiencing sustained VT or cardiac arrest while receiving the drug Patients who have equivocal abnormalities in QT interval duration or T-U wave configuration, along with syncope or symptomatic arrhythmias, in whom the effects of catecholamine may unmask a distinct QT abnormality	Patients with clinically manifest congenital QT prolongation, with or without symptomatic arrhythmias Patients with acquired prolonged-QT syndrome with symptoms closely related to an identifiable cause or mechanism
Wolff-Parkinson-White syndrome	Patients being evaluated for catheter ablation or surgical ablation of an accessory pathway Patients with ventricular preexcitation who have survived cardiac arrest or who have unexplained syncope Symptomatic patients in whom determination of the mechanism of arrhythmia or knowledge of the electrophysiologic properties of the accessory pathway and normal conduction system would help in determining appropriate therapy	Asymptomatic patients with a family history of sudden cardiac death or with ventricular preexcitation but no spontaneous arrhythmia who engage in high-risk occupations or activities and in whom knowledge of the electrophysiologic properties of the accessory pathway or inducible tachycardia may help determine recommendations for further activities or therapy Patients with ventricular preexcitation who are undergoing cardiac surgery for other reasons	Asymptomatic patients with ventricular preexcitation, except those in class II
Premature ventricular complexes (PVCs), couplets, and nonsustained VT	None	Patients with other risk factors for future arrhythmic events, such as a low ejection fraction, positive signal-averaged electrocardiogram, and nonsustained VT on ambulatory ECG recordings in whom EPS will be used for further risk assessment and for guiding therapy in patients with inducible VT Patients with highly symptomatic, uniform-morphology PVCs, couplets, and nonsustained VT who are considered potential candidates for catheter ablation	Asymptomatic or mildly symptomatic patients with PVCs, couplets, and nonsustained VT without other risk factors for sustained arrhythmias

AV, Atrioventricular; *EPS,* electrophysiologic study; *VT,* ventricular tachycardia.

Acquired Atrioventricular Block

The ACC/AHA guidelines emphasize that EPSs are inappropriate (class III) when ECG findings correlate with symptoms and the EPS findings are unlikely to alter management. For example, documentation of His bundle conduction rarely improves the management of a patient whose other clinical data indicate that placement of a permanent pacemaker is warranted because of symptomatic advanced atrioventricular

(AV) block. Similarly, EPSs are not appropriate for asymptomatic patients with mild degrees of AV block who are not likely to warrant pacemaker implantation. According to these guidelines, EPSs of AV conduction should be performed when a relationship between symptoms and AV block is a reasonable possibility but has not been proved.

Chronic Intraventricular Delay

According to the 1999 ACC/AHA guidelines, the main role of electrophysiologic testing (EPT) in patients with prolonged H-V intervals is not to predict future complications but to determine whether the symptoms of arrhythmia are caused by conduction delay or block versus some other arrhythmia. The only class I (clearly appropriate) indication for EPT is symptomatic patients for whom the cause of symptoms is not known. The guidelines specifically discourage EPT of asymptomatic patients and provide only equivocal support for asymptomatic patients with bundle branch block in whom treatment with drugs that might increase conduction delay is being considered.

Narrow– and Wide–QRS Complex Tachycardia

The ACC/AHA guidelines define different roles for EPT in patients with narrow- and wide-complex tachycardias. In narrow-QRS tachycardia, the site of abnormal impulse formation or the reentry circuit can often be determined from information on the 12-lead electrocardiogram. Thus, EPT was considered more appropriate as a guide to therapy in this setting than as a tool for diagnosis. Class I indications for EPT include patients with recurrent tachycardia for whom data from testing may help clinicians choose among drug therapy, catheter ablation, pacing, and surgery. However, testing is not considered useful for patients whose tachycardias are controlled by vagal maneuvers or medications and who are not candidates for nonpharmacologic therapy.

In wide-complex tachycardias, the correct diagnosis is occasionally not possible from ECG tracings alone. However, EPT permits accurate diagnosis in virtually all patients. Because knowledge of the mechanism of the arrhythmia is essential for selection of optimal therapy, EPT was considered appropriate (class I) for the diagnosis of wide-complex tachycardias in these guidelines. However, when the diagnosis is clear from other data and EPT is not likely to influence therapy, the guidelines consider it inappropriate.

Prolonged QT Intervals

The ACC/AHA guidelines do not consider routine use of EPT appropriate for any indications in patients with prolonged QT intervals. Whether catecholamine infusion during testing is useful for revealing patients who are at high risk for complications or whether EPT can be used to evaluate proarrhythmic effects in this population is considered uncertain.

Wolff-Parkinson-White Syndrome

Electrophysiologic testing is useful for patients with WPW syndrome for both diagnosis and planning of therapy. The ACC/AHA guidelines consider EPT appropriate for patients who are candidates for catheter or surgical ablation, for those who have had cardiac arrests or unexplained syncope, or for patients whose management might be altered by knowledge of the electrophysiologic properties of the accessory pathway and normal conduction system. For asymptomatic patients, however, EPSs are deemed inappropriate except in special situations, such as patients with high-risk occupations or those with a family history of sudden cardiac death. More recently recognized entities, such as Brugada syndrome,

catecholaminergic polymorphic ventricular tachycardia, and right ventricular cardiomyopathy, were not considered.

Nonsustained Ventricular Tachycardia

For patients with ventricular premature complexes, couplets, and nonsustained ventricular tachycardia, the usefulness of EPT is compromised by the lack of therapeutic strategies that have been shown to improve outcomes. There are no clearly appropriate indications for EPSs in these patients, and the guidelines discourage testing in patients without other risk factors for sustained arrhythmias. Research published since these guidelines suggests that exceptions would include patients who fit the MADIT (Multicenter Automatic Defibrillator Implantation Trial) or MUSTT (Multicenter Unsustained Tachycardia Trial) criteria. For certain patients with other features suggesting an adverse prognosis, EPT is thought to have possible but unproven appropriateness (class II).

Unexplained Syncope

In patients with unexplained syncope and structural heart disease (**see Chapter 43**), recent ACC/AHA guidelines on the evaluation of syncope[12] recommend a low threshold for EPT (**Table 35G.5**). In patients without structural heart disease, the yield of electrophysiologic testing is low. Thus the guidelines recommend a higher threshold for use of EPSs in such patients and suggest that head-up tilt testing may be a more useful test. However, given the low risk associated with EPT and the high risk for potentially harmful recurrent syncope, EPT may be beneficial for patients with a malignant episode of syncope.[15]

TABLE 35G.5

ACC/AHA 1995 Guidelines on Clinical Intracardiac Electrophysiologic Studies for Evaluation of Clinical Syndromes

INDICATION	CLASS I (APPROPRIATE)	CLASS II (EQUIVOCAL)	CLASS III (INAPPROPRIATE)
Unexplained syncope	Patients with suspected structural heart disease and syncope that remain unexplained after appropriate evaluation	Patients with recurrent unexplained syncope but without structural heart disease and a negative head-up tilt test result	Patients with a known cause of syncope for whom treatment will not be guided by electrophysiologic testing
Survivors of cardiac arrest	Patients surviving cardiac arrest without evidence of acute Q wave MI Patients surviving cardiac arrest occurring more than 48 hours after acute phase of MI in the absence of recurrent ischemic events	Patients surviving cardiac arrest caused by bradyarrhythmia Patients surviving cardiac arrest thought to be associated with a congenital repolarization abnormality (long-QT syndrome) in whom the results of noninvasive diagnostic testing are equivocal	Patients surviving a cardiac arrest that occurred during acute phase (<48 hr) of MI Patients with cardiac arrest resulting from clearly definable specific causes, such as reversible ischemia, severe valvular aortic stenosis, or noninvasively defined congenital or acquired long-QT syndrome
Unexplained palpitations	Patients with palpitations who have their pulse rate documented by medical personnel as inappropriately rapid and in whom ECG recordings fail to document the cause of the palpitations Patients with palpitations preceding a syncopal episode	Patients with clinically significant palpitations, suspected to be of cardiac origin in whom the symptoms are sporadic and cannot be documented; studies performed to determine mechanisms of arrhythmias, direct or provide therapy, or assess prognosis	Patients with palpitations documented to result from extracardiac causes (e.g., hyperthyroidism)

MI, Myocardial infarction.

Survivors of Cardiac Arrest

The ACC/AHA guidelines consider EPT appropriate for patients who are survivors of cardiac arrest (**see Chapter 42**) other than in the earliest phase of acute myocardial infarction (**see Table 35G.5**). Since publication of these guidelines, acceptance of the usefulness of ICDs has become more widespread, and many of these patients receive such a device without EPT or undergo limited EPT at device implantation. The guidelines consider EPSs inappropriate when cardiac arrest has occurred within the first 48 hours of

myocardial infarction or when the cardiac arrest results from clearly definable and reversible specific causes.

Unexplained Palpitations

The procedure of choice to determine the cause of palpitations is ambulatory ECG according to the ACC/AHA guidelines. The guidelines suggest that EPT should be reserved for patients with palpitations that are associated with syncope or for those in whom electrocardiograms have failed to capture a cause of the palpitations but who have been noted to have a rapid pulse rate by medical personnel (**see Table 35G.5**). EPT is considered to be of equivocal value in patients with symptoms so sporadic that they cannot be documented while ambulatory ECG is performed.

Electrophysiologic Studies for Therapeutic Intervention

The 1995 ACC/AHA guidelines on the appropriateness of EPSs for guidance of drug therapy and implantable electrical devices do not reflect the decline in the role of oral antiarrhythmic therapy and the rise in the use of ICDs for the treatment of patients who have experienced cardiac arrest (**Table 35G.6**). However, the guideline recommendations for the role of catheter ablation remain valid. Characteristics that are common among appropriate indications include supraventricular arrhythmias, including atrial fibrillation, that are symptomatic; that cannot be controlled with medications because of limited effectiveness, side effects, or inconvenience; or that have caused sudden cardiac death.[16] Catheter ablation is also useful for the same reasons in some patients with ventricular tachycardia when it occurs in the absence of structural heart disease, and ablation is often useful as an adjunct to ICD implantation to limit episodes of ventricular tachycardia requiring ICD treatment.[17] Left ventricular dysfunction develops in some patients from frequent premature ventricular complexes, with reversal after ablation of the PVC.

TABLE 35G.6

ACC/AHA 1995 Guidelines on Clinical Intracardiac Electrophysiologic Studies for Therapeutic Intervention

INDICATION	CLASS I (APPROPRIATE)	CLASS II (EQUIVOCAL)	CLASS III (INAPPROPRIATE)
Guidance of drug therapy	Patients with sustained VT or cardiac arrest, especially those with prior MI Patients with AVNRT, AV reentrant tachycardia using an accessory pathway, or AF associated with an accessory pathway for whom chronic drug therapy is planned	Patients with sinus node reentrant tachycardia, atrial tachycardia, AF, or atrial flutter without ventricular preexcitation syndrome for whom chronic drug therapy is planned Patients with arrhythmias not inducible during controlled EPS for whom drug therapy is planned	Patients with isolated atrial or ventricular premature complexes Patients with ventricular fibrillation with a clearly identified reversible cause
Patients who are candidates for or who have implantable electrical devices	Patients with tachyarrhythmias before and during implantation and final (predischarge) programming of an electrical device to confirm its ability to perform as anticipated Patients with an implanted electrical antitachyarrhythmia device in whom changes in status or therapy may have influenced the continued safety and efficacy of the device Patients who have a pacemaker to treat a bradyarrhythmia and receive an ICD to test for device interactions	Patients with previously documented indications for pacemaker implantation to test for the most appropriate long-term pacing mode and sites to optimize symptomatic improvement and hemodynamics	Patients who are not candidates for device therapy
Indications for catheter ablation procedures	Patients with symptomatic atrial tachyarrhythmias who have inadequately controlled ventricular rates unless primary ablation of the atrial tachyarrhythmia is possible Patients with symptomatic atrial tachyarrhythmias such as those above but in whom drugs are not tolerated, or the patient does not wish to take them, even though the ventricular rate can be controlled Patients with symptomatic nonparoxysmal	Patients with a dual-chamber pacemaker and pacemaker-mediated tachycardia that cannot be treated effectively by drugs or by reprogramming the pacemaker	Patients with atrial tachyarrhythmias responsive to drug therapy acceptable to the patient

	junctional tachycardia that is drug resistant, or the patient is drug intolerant or does not wish to take it Patients resuscitated from sudden cardiac death caused by atrial flutter or AF with a rapid ventricular response in the absence of an accessory pathway		
Radiofrequency catheter ablation for AVNRT	Patients with symptomatic sustained AVNRT that is drug resistant, or the patient is drug intolerant or does not desire long-term drug therapy	Patients with sustained AVNRT identified during EPS or catheter ablation of another arrhythmia Finding of dual–AV nodal pathway physiology and atrial echoes but without AVNRT during EPS in patients clinically suspected of having AVNRT	Patients with AVNRT responsive to drug therapy that is well tolerated and preferred by the patient over ablation Finding of dual–AV nodal pathway physiology (with or without echo complexes) during EPS in patients in whom AVNRT is not suspected clinically
Ablation of atrial tachycardia, flutter, and fibrillation: atrium/atrial sites	Patients with atrial tachycardia that is drug resistant, or the patient is drug intolerant or does not desire long-term drug therapy Patients with atrial flutter that is drug resistant, or the patient is drug intolerant or does not desire long-term drug therapy	Atrial flutter or atrial tachycardia associated with paroxysmal AF when the tachycardia is drug resistant, or the patient is drug intolerant or does not desire long-term drug therapy Patients with AF and evidence of a localized site of origin when the tachycardia is drug resistant, or the patient is drug intolerant or does not desire long-term drug therapy	Patients with atrial arrhythmia responsive to drug therapy that is well tolerated and preferred by the patient over ablation Patients with multiform atrial tachycardia
Ablation of atrial tachycardia, flutter, and fibrillation: accessory pathways	Patients with symptomatic AV reentrant tachycardia that is drug resistant, or the patient is drug intolerant or does not desire long-term drug therapy Patients with AF (or other atrial tachyarrhythmia) and a rapid ventricular response through the accessory pathway when the tachycardia is drug resistant, or the patient is drug intolerant or does not desire long-term drug therapy	Patients with AV reentrant tachycardia or AF with rapid ventricular rates identified during EPS for another arrhythmia Asymptomatic patients with ventricular preexcitation whose livelihood or profession, important activities, insurability, or mental well-being or the public safety would be affected by spontaneous tachyarrhythmias or the presence of the ECG abnormality Patients with AF and a controlled ventricular response through the accessory pathway Patients with a family history of sudden cardiac death	Patients who have accessory pathway–related arrhythmias responsive to drug therapy that is well tolerated and preferred by the patient over ablation
Ablation of VT	Patients with symptomatic sustained monomorphic VT when the tachycardia is drug resistant, or the patient is drug intolerant or does not desire long-term drug therapy Patients with bundle branch reentrant VT Patients with sustained monomorphic VT and an ICD who are receiving multiple shocks not manageable by reprogramming or concomitant drug therapy	Nonsustained VT that is symptomatic when the tachycardia is drug resistant, or the patient is drug intolerant or does not desire long-term drug therapy	Patients with VT responsive to drug, ICD, or surgical therapy that is well tolerated and preferred by the patient over ablation Asymptomatic and clinically benign nonsustained VT

AF, Atrial fibrillation; *AVNRT,* atrioventricular nodal reentrant tachycardia; *EPS,* electrophysiologic study; *ICD,* implantable cardioverter-defibrillator; *MI,* myocardial infarction; *VT.* ventricular tachycardia.

Clinical Competence

The ACC/AHA statements on clinical competence[9,10] describes three levels of training: level 1 for every cardiology trainee, level 2 for those wanting to acquire advanced training in the management of arrhythmia, and level 3 for those intending to specialize in invasive diagnostic and therapeutic cardiac electrophysiology. The level 3 guidelines recommend a minimum of 1 year of specialized training in EPSs (as of 2017, 2 years are required), during which the physician should be the primary operator and analyze 100 to 150 initial diagnostic studies, at least 50 of which should involve patients with supraventricular arrhythmias. Because antiarrhythmic devices constitute a major part of current electrophysiology practice, the guidelines suggest that a trainee should be the primary operator during at least 25 electrophysiologic evaluations of implantable antiarrhythmic devices. For maintenance of competence, a minimum of 100 diagnostic EPSs per year is recommended. The statement also recommends that specialists in electrophysiology attend at least 30 hours of formal continuing medical education every 2 years to remain abreast of changes in knowledge and technology.

For physicians who perform catheter ablation, the Heart Rhythm Society Ad Hoc Committee on Catheter Ablation has recommended that training should include at least 75 catheter ablations, at least 10 of which are accessory pathway ablations and 30 to 50 are mentored ablations.[9,10] The ACC/AHA statement recommends that physicians who perform ablations carry out at least 20 to 50 ablations per year.

Individuals receiving training in pacemaker implantation must participate as the primary operator (under direct supervision) in at least 50 primary implantations of transvenous pacemakers and 20 pacemaker system revisions or replacements. At least half the implantations should involve dual-chamber pacemakers. The trainee must also participate in the follow-up of at least 100 pacemaker patient visits and acquire proficiency in advanced pacemaker electrocardiography, interrogation, and programming of complex pacemakers.[9,10]

Therapy for Cardiac Arrhythmias

John M. Miller, Gordon F. Tomaselli, Douglas P. Zipes

According to some evidence, more than 30% of people will have a problematic tachyarrhythmia, most often atrial fibrillation, at some point during a normal life span. Thus, most clinicians will need to manage their patients' rhythm problems, or those treatments may impact or may be impacted by treatment of the patient's other disorders. Treatment of patients with tachyarrhythmias has evolved dramatically over the last 40 years and has become more complex and specialized. A few, relatively ineffective antiarrhythmic drugs (AADs) were the only therapeutic option until the late 1960s, when surgical therapy to cure (not just suppress) tachyarrhythmias was developed. This mode in turn was replaced by catheter ablation for better control or even cure of many types of supraventricular tachycardias and ventricular tachycardias in the absence of structural heart disease starting in the 1980s. The implantable cardioverter-defibrillator (ICD) was introduced in the early 1980s and has become standard therapy for patients with serious ventricular arrhythmias in the presence of structural heart disease. Some patients require a combination of treatments, such as an ICD and AADs or surgery and an ICD; drug therapy can also affect ICD function, positively or negatively. Drug therapy for arrhythmias, at one time the only option, has largely been replaced as the mainstay of therapy by ablation or implanted devices. In most patients, however, tachyarrhythmias are initially treated with AADs, and thus these agents continue to have a significant role in management of patients with a variety of arrhythmias.

Pharmacologic Therapy

The principles of clinical pharmacokinetics and pharmacodynamics are discussed in **Chapter 8**.

General Considerations Regarding Antiarrhythmic Drugs

Most of the AADs available can be classified according to whether they exert blocking actions predominantly on sodium (Na^+), potassium (K^+), or calcium (Ca^{2+}) channels and whether they block receptors (**Table 36.1**). The commonly used classification (Vaughan Williams) is a useful framework for categorizing drug action but is limited because it is based on the electrophysiologic effects exerted by an arbitrary concentration of the drug, generally on a laboratory preparation of normal cardiac tissue. In practice, the actions of these drugs are complex and depend on tissue type, degree of acute or chronic damage, heart rate, membrane potential, ionic composition of the extracellular milieu, autonomic influences (**see Chapter 99**), genetics (**see Chapter 33**), age (**Chapter 88**), and other factors (**Table 36.1**). Many drugs exert more than one type of electrophysiologic effect or operate indirectly, such as by altering hemodynamics, myocardial metabolism, or autonomic neural transmission. Some drugs have active metabolites that exert effects different from those of the parent compound. Not all drugs in the same class have identical effects (e.g., amiodarone, sotalol, and ibutilide). Whereas all class III agents are dramatically different, some drugs in different classes have overlapping actions (e.g., class IA and class IC drugs). Thus, in vitro studies on healthy myocardium usually establish the idealized properties of AADs rather than their actual antiarrhythmic properties in vivo. Since many AADs affect ventricular repolarization and thus have the potential for producing lethal ventricular arrhythmias, development and approval of new agents is uncommon (none in the United States since dronedarone in 2009).[1]

TABLE 36.1

Actions of Drugs Used in Treatment of Arrhythmias

DRUG	CHANNELS						RECEPTORS				PUMPS	PREDOMINANT CLINICAL EFFECTS		
	Na*			Ca	K_r	K_s	α	β	M_2	P	Na-K ATPase	LV Function	Sinus Rate	Extracardiac

Relative potency of blockade or extracardiac side effect: ○ = low; = moderate; ● = high; □ = agonist; A = activated state blocker; I = inactivated state blocker.

— = minimal effect; ↑ = increase; ↓ = decrease; var = variable effects.

K_r, Rapid component of delayed rectifier K^+ current; K_s, slow component of delayed rectifier K^+ current; M_2, muscarinic receptor subtype 2; _P,_ A_1 purinergic receptor; _LV,_ left ventricular.

Modified from Schwartz PJ, Zaza A. Haemodynamic effects of a new multifactorial antihypertensive drug. Eur Heart J 1992;13:26.

Despite its limitations, the Vaughan Williams classification is widely known and provides a useful communication shorthand, but the reader is cautioned that drug actions are more complex than those depicted by the classification. A more realistic but not widely used framework regarding AADs is provided by the “Sicilian Gambit.” This approach to drug classification is an attempt to identify the mechanisms of a particular arrhythmia, to determine the vulnerable parameter of the arrhythmia most susceptible to modification, to define the target most likely to affect the vulnerable parameter, and then to select a drug that will modify the target[2] (**Table 36.2**; **also see Table 36.1**).

TABLE 36.2

Classification of Drug Actions on Arrhythmias Based on Modification of Vulnerable Parameter

MECHANISM	ARRHYTHMIA	VULNERABLE PARAMETER (EFFECT)	DRUGS (EFFECT)
Automaticity			
Enhanced normal	Inappropriate sinus tachycardia Some idiopathic ventricular tachycardias	Phase 4 depolarization (decrease)	β-Adrenergic blocking agents Na^+ channel blocking agents
Abnormal	Atrial tachycardia	Maximum diastolic potential (hyperpolarization)	M_2 agonist
		Phase 4 depolarization (decrease)	Ca^{2+} or Na^+ channel blocking agents M_2 agonist
	Accelerated idioventricular rhythms	Phase 4 depolarization (decrease)	Ca^{2+} or Na^+ channel blocking agents
Triggered Activity			
EAD	Torsades de pointes	Action potential duration (shorten)	β-adrenergic agonists; vagolytic agents (increase rate)
		EAD (suppress)	Ca^{2+} channel blocking agents; Mg^{2+}; β-adrenergic blocking agents; ranolazine
DAD	Digitalis-induced arrhythmias	Calcium overload (unload)	Ca^{2+} channel blocking agents
		DAD (suppress)	Na^+ channel blocking agents
	RV outflow tract ventricular tachycardia	Calcium overload (unload)	β-adrenergic blocking agents
		DAD (suppress)	Ca^{2+} channel blocking agents; adenosine
Reentry—Na^+ Channel Dependent			
Long excitable gap	Typical atrial flutter	Conduction and excitability (depress)	Type IA, IC Na^+ channel blocking agents
	Circus movement tachycardia in WPW	Conduction and excitability (depress)	Type IA, IC Na^+ channel blocking agents
	Sustained uniform ventricular tachycardia	Conduction and excitability (depress)	Na^+ channel blocking agents
Short excitable gap	Atypical atrial flutter	Refractory period (prolong)	K^+ channel blocking agents
	Atrial fibrillation	Refractory period (prolong)	K^+ channel blocking agents
	Circus movement tachycardia in WPW	Refractory period (prolong)	Amiodarone, sotalol
	Polymorphic and uniform ventricular tachycardia	Refractory period (prolong)	Type IA Na^+ channel blocking agents
	Bundle branch reentry	Refractory period (prolong)	Type IA Na^+ channel blocking agents; amiodarone
	Ventricular fibrillation	Refractory period (prolong)	
Reentry—Ca^{2+} Channel Dependent			
	AV nodal reentrant tachycardia	Conduction and excitability (depress)	Ca^{2+} channel blocking agents
	Circus movement tachycardia in WPW	Conduction and excitability (depress)	Ca^{2+} channel blocking agents
	Verapamil-sensitive ventricular tachycardia	Conduction and excitability (depress)	Ca^{2+} channel blocking agents

AV, Atrioventricular; *DAD,* delayed afterdepolarization; *EAD,* early afterdepolarization; *RV,* right ventricular; *WPW,* Wolff-Parkinson-White syndrome.

Drug Classification

According to the Vaughan Williams classification, class I drugs predominantly block the fast sodium channel (I_{Na}). These in turn are divided into three subgroups, classes IA, IB, and IC (**Table 36.3**). Some also block potassium channels at pharmacologically relevant concentrations.

TABLE 36.3

In vitro Electrophysiologic Characteristics of Antiarrhythmic Drugs

DRUG	APD	dV/dt	MDP	ERP	CV	PF PHASE 4	SN Auto	Contr	SI Curr	AUTONOMIC NERVOUS SYSTEM

*With a background of sympathetic activity.

↑ = increase; ↓ = decrease; 0 = no change; 0 ↑ or 0 ↓ = slight or inconsistent increase or decrease.

APD, Action potential duration; *dV/dt,* rate of rise of action potential; *MDP,* maximum diastolic potential; *ERP,* effective refractory period (longest S_1-S_2 interval at which S_2 fails to produce a response); *CV,* conduction velocity; *PF,* Purkinje fiber; *SN Auto,* sinus nodal automaticity; *Contr,* contractility; *SI Curr,* slow inward current.

Class IA

This class includes drugs that reduce Vmax (rate of rise in action potential upstroke [phase 0]) and prolong the action potential duration (APD; **see Chapter 34**)—quinidine, procainamide, and disopyramide. The kinetics of onset and offset of class IA drugs in blocking the Na^+ channel is of intermediate rapidity (<5 seconds) when compared with class IB and class IC agents.

Class IB

This class of drugs does not reduce Vmax and shortens the APD—mexiletine, phenytoin, and lidocaine. The kinetics of onset and offset of these drugs in blocking the sodium channel is rapid (<500 milliseconds).

Class IC

This class of drugs, including flecainide and propafenone, can reduce Vmax, slow conduction velocity, and prolong refractoriness minimally. These drugs have slow onset and offset kinetics (10 to 20 seconds).

Class II

These drugs block beta-adrenergic receptors and include propranolol, metoprolol, nadolol, carvedilol, nebivolol, and timolol.

Class III

This class of drugs predominantly blocks potassium channels (e.g., I_{Kr}) and prolongs repolarization. Included are sotalol, amiodarone, dronedarone, and ibutilide.

Class IV

This class of drugs predominantly blocks the slow calcium channel ($I_{Ca.L}$)—verapamil, diltiazem, nifedipine, and others (felodipine blocks $I_{Ca.T}$).

Antiarrhythmic agents appear to cross the cell membrane and interact with receptors in the membrane channels when the channels are in the resting, activated, or inactivated state (**see Table 36.1** and **Chapter 34**), and each of these interactions is characterized by different association and dissociation rate constants of a drug on its receptor. Such interactions depend on voltage and time. Transitions among resting, activated, and inactivated states are time and voltage dependent. When the drug is bound (associated) to a receptor site at or close to the channel pore (the drug may not actually "plug" the channel), the channel cannot conduct, even in the activated state.

Use Dependence.

Some drugs exert greater inhibitory effects on the upstroke of the action potential at more rapid rates of stimulation and after longer periods of stimulation, a characteristic called *use dependence*. Drugs with this property depress Vmax to a greater extent after the channel has been "used" (i.e., after action potential depolarization rather than after a rest period). Agents with class IB action exhibit rapid binding and unbinding from their receptor site on the channel protein, or exhibit use-dependent block of the fast channel at fast rates. Class IC drugs have slow kinetics, and class IA drugs are intermediate. With increased time spent in diastole (slower rate), a greater proportion of receptors become drug free, and the drug exerts less effect. Unhealthy cells with reduced (i.e., abnormal) membrane potentials recover more slowly from drug actions than do healthier cells with more negative (i.e., normal) membrane potentials. This is referred to as *voltage dependence of block*.

Reverse Use Dependence.

Some drugs exert greater effects at slow rates than at fast rates, a property known as *reverse use dependence*. This is particularly true for drugs that lengthen repolarization; in the ventricle the QT interval becomes more prolonged at slow rather than at fast rates. This effect is not an ideal antiarrhythmic property, because prolongation of refractoriness should be increased at fast rates to interrupt or prevent a tachycardia and should be minimal at slow rates to avoid precipitation of torsades de pointes (TdP).

Mechanisms of Arrhythmia Suppression.

Given that enhanced automaticity, triggered activity, or reentry can cause cardiac arrhythmias (**see Chapter 34**), mechanisms by which AADs suppress arrhythmias can be postulated (**see Table 36.2**). AADs can slow the spontaneous discharge frequency of an automatic pacemaker by depressing the slope of diastolic depolarization, shifting the threshold voltage toward zero, or hyperpolarizing the resting membrane potential. In general, most AADs in therapeutic doses depress the automatic firing rate of spontaneously discharging ectopic sites while minimally affecting the discharge rate of the normal sinus node. Other agents act directly on the sinus node to slow heart rate, whereas drugs that exert vagolytic effects, such as disopyramide and quinidine, can increase the sinus discharge rate. Drugs can also suppress early or delayed afterdepolarizations and eliminate triggered arrhythmias based on these mechanisms.

Reentry depends critically on the interrelationships between refractoriness and conduction velocity, the presence of unidirectional block in one of the pathways, and other factors that influence refractoriness

and conduction, such as excitability (**see Chapter 34**). An antiarrhythmic agent can stop ongoing reentry that is already present or can prevent it from starting if the drug depresses or, alternately, improves conduction. For example, improving conduction can (1) eliminate unidirectional block so that reentry cannot begin or (2) facilitate conduction in the reentrant loop so that the returning wavefront reenters too quickly, encounters cells that are still refractory, and is extinguished. A drug that depresses conduction can transform unidirectional block into bidirectional block and thus terminate reentry or prevent it from starting by creating an area of complete block in the reentrant pathway. Conversely, a drug that slows conduction without producing block or significantly lengthening refractoriness can actually promote reentry. Lastly, most AADs share the ability to prolong refractoriness relative to their effects on APD; that is, the ratio of the effective refractory period (ERP) to APD exceeds 1.0. If a drug prolongs the refractoriness of fibers in the reentrant pathway, the pathway may not recover excitability in time to be depolarized by the reentering impulse, and reentrant propagation ceases. The different types of reentry influence the effectiveness of a drug.

In considering the properties of a drug, it is important to define carefully the situation or model from which conclusions are drawn. Electrophysiologic, hemodynamic, autonomic, pharmacokinetic, and adverse effects can all differ in normal individuals compared with patients, in normal versus abnormal tissue, in cardiac muscle compared with specialized conduction fibers, and in atrial versus ventricular muscle (**Table 36.4**).

TABLE 36.4

Dosage and Other Information for Clinical Use of Common Antiarrhythmic Agents

DRUG	USUAL DOSAGE RANGES				TIME TO PEAK PLASMA CONCENTRATION (ORAL) (HR)	EFFECTIVE SERUM OR PLASMA CONCENTRATION (µg/mL)	HALF-LIFE (hr)	BIOAVAILABILITY (%)	MA RO ELI
	INTRAVENOUS (mg)		ORAL (mg)						
	Loading	Maintenance	Loading	Maintenance					
Quinidine	6-10 mg/kg at 0.3-0.5 mg/kg/min	—	800-1000	300-600 q6h	1.5-3.0	3-6	5-9	60 to 80	Liver

*Intravenous use investigational or unavailable in United States.

N/A, Not applicable; *q4-6h,* every 4 to 6 hours; *qd,* every day; *bid,* twice daily.

Results presented may vary according to doses, disease state, and IV or oral administration.

Pregnancy Class: *A,* controlled studies show no fetal risk; *B,* no controlled studies, but no evidence of fetal risk; fetal harm unlikely; *C,* fetal risk cannot be excluded; drug should be used only if potential benefits outweigh potential risk; *D,* definite fetal risk; drug should be avoided unless in a life-threatening situation or safer alternatives do not exist; *X,* contraindicated in pregnancy. Categorization of safety during pregnancy and lactation is currently undergoing revision.

Drug Metabolites.

Drug metabolites can add to or alter the effects of the parent compound by exerting similar actions, competing with the parent compound, or mediating drug toxicity. Quinidine has at least four active metabolites, but none with a potency exceeding that of the parent drug, and none implicated in causing TdP. About 50% of procainamide is metabolized to *N*-acetylprocainamide (NAPA), which prolongs repolarization and is a less effective AAD but competes with procainamide for renal excretion and can increase the parent drug's elimination half-life. A lidocaine metabolite can compete with the parent drug

for sodium channels and partially antagonize its blocking effect.

Pharmacogenetics.

Genetically determined metabolic pathways account for many of the differences in patients' responses to some drugs[3] (**see Chapter 8**). The genetically determined activity of hepatic *N*-acetyltransferase regulates the development of antinuclear antibodies (ANAs) and lupus syndrome in response to procainamide. Slow acetylator phenotypes appear to be more prone than rapid acetylators to the development of lupus. The enzyme cytochrome P-450 (CYP450) is needed to metabolize propafenone, to hydroxylate several beta blockers, and to biotransform flecainide. Lack of this enzyme (in approximately 7% of patients) reduces metabolism of the parent compound and thereby leads to increased plasma concentrations of the parent drug and reduced concentrations of metabolites. Propafenone is metabolized by CYP450 to a compound with slightly less antiarrhythmic and beta-adrenergic blocking effects, as well as fewer central nervous system (CNS) side effects. Thus, poor metabolizers may experience more heart rate slowing and neurotoxicity than extensive metabolizers do.

Drugs such as rifampin, phenobarbital, and phenytoin induce the synthesis of larger amounts of CYP450, which leads to lower concentrations of the parent drugs because of extensive metabolism, whereas erythromycin, clarithromycin, fluoxetine, and grapefruit juice inhibit enzyme activity, which leads to accumulation of the parent compound. Therefore, clinicians caring for patients who take AADs should be sensitive to the effects of noncardiac medications and supplements on AAD metabolism and elimination and to drug-drug interactions. Over-the-counter (OTC) drugs such as proton pump inhibitors can promote hypokalemia and hypomagnesemia and interact with a simple antibiotic such as ceftriaxone to cause TdP.[4] Many astute clinicians use, and refer their patients to, websites such as Crediblemeds.org, where updated information on drug interactions of this type is available.

Clinical Use

In treating cardiac rhythm disorders, most drugs are given on a daily basis (in one to three doses) to prevent episodes from occurring or, in some cases of atrial fibrillation (AF), to control the ventricular rate. Efficacy can be judged in various ways, depending on the clinical circumstances. Symptom reduction (in the case of benign arrhythmias, such as most premature ventricular complexes) and electrocardiographic monitoring (long-term or event; **see Chapter 35**) are useful; electrophysiologic study (EPS) has been used in the past, with suppression of electrical induction of arrhythmia being the goal, but is rarely used currently. Interrogation of implanted device memory can also provide an indicator of the success of drug therapy.

In some patients, tachycardia episodes are infrequent enough (months between occurrences) and symptoms mild enough that reactive drug administration is more reasonable than chronic daily dosing. The patient takes a medication only after an episode has started, in the hope that the tachycardia can be terminated and a visit to a physician's office or emergency department avoided. This “pill in the pocket” strategy has worked well for some patients with AF, who have been given one of various medications orally in a monitored setting to ensure safety as well as efficacy before allowing self-medication at home or elsewhere.

Adverse Effects

Antiarrhythmic drugs produce one group of adverse effects related to excessive dosage and plasma concentrations that result in both noncardiac (e.g., neurologic defects) and cardiac (e.g., heart failure, some arrhythmias) toxicity. Another group of side effects unrelated to plasma concentrations is termed

idiosyncratic; examples include amiodarone-induced pulmonary fibrosis and some arrhythmias, such as quinidine-induced TdP, which can occur in individuals with a forme fruste of long-QT syndrome (i.e., marked prolongation of normal QT interval in the presence of certain medications; **see Chapters 8 and 33**). Genetic variants can underlie susceptibility to idiosyncratic reactions.

The U.S. Food and Drug Administration (FDA) has recently determined that the risk of adverse events during pregnancy and lactation (previously categorized as A, B, C, D, and X; **see Table 36.4**, footnote) should be modified (the Pregnancy and Lactation Labeling rule of 2014). This process is underway but until completed, adverse event risk in this setting is characterized using the previous classification.[5]

Proarrhythmia

Drug-induced or drug-exacerbated cardiac arrhythmias (proarrhythmia) constitute a major clinical problem.[6] Proarrhythmia can manifest as an increase in frequency of a preexisting arrhythmia, sustaining of a previously nonsustained arrhythmia (even making it incessant), or development of arrhythmias that the patient has not previously experienced. Electrophysiologic mechanisms are probably related to prolongation of repolarization or an increase in its transmural dispersion, development of early afterdepolarizations (EADs) with resultant TdP, and alterations in reentry pathways to initiate or to sustain tachyarrhythmias. Proarrhythmic events can occur in as many as 5% to 10% of patients receiving antiarrhythmic agents; heart failure increases this risk. Reduced left ventricular function, treatment with digitalis and diuretics, and a longer pretreatment QT interval characterize patients who experience AAD-induced ventricular fibrillation (VF). The more commonly known proarrhythmic events occur within several days of beginning drug therapy or changing dosage and are represented by such developments as incessant ventricular tachycardia (VT) and long-QT–related TdP. In the Cardiac Arrhythmia Suppression Trial (CAST), however, researchers found that encainide and flecainide reduced spontaneous ventricular arrhythmias but were associated with a total mortality of 7.7%, versus 3.0% in the placebo group. Deaths were equally distributed throughout the treatment period, indicating that another type of proarrhythmic response can occur sometime after the beginning of drug therapy. Such late proarrhythmic effects may be related to drug-induced exacerbation of the regional myocardial conduction delay caused by ischemia and to heterogeneous drug concentrations that can promote reentry. In the future, a candidate antiarrhythmic compound's potential for proarrhythmia may be modeled computationally and tested in stem cells.[7]

The availability of catheter ablation (see later) and implantable devices (pacemakers and ICDs; **see Chapter 41**) to treat a wide variety of arrhythmias has largely relegated drug therapy to a secondary role in the treatment of serious arrhythmias. Drugs are still useful to prevent or to decrease the frequency of recurrences in patients who have relatively infrequent episodes of benign tachycardias, as well as in those who have had incomplete success with catheter ablation procedures and in patients with an ICD, to decrease the frequency of shocks because of supraventricular or ventricular arrhythmias.

Antiarrhythmic Agents

Class IA Agents

Quinidine

Quinidine and quinine are isomeric alkaloids isolated from cinchona bark. Although quinidine shares the antimalarial, antipyretic, and vagolytic actions of quinine, only quinidine has direct cellular electrophysiologic effects. It blocks several channels, including the rapid inward sodium channel, I_{Kr}, I_{to}, and to a lesser extent the slow inward calcium channel, I_{Ks}, and the adenosine triphosphate (ATP)–sensitive potassium current (K_{ATP}). The ultimate biologic effect of the drug in a given patient depends on heart rate, drug concentration, and which channels are more prominently affected. Because of decreased demand for quinidine, manufacturing had ceased for a time, with little remaining supply in many countries; with recent renewed demand for its use in patients with Brugada syndrome, for example, quinidine is more readily available.

Electrophysiologic Actions.

Quinidine exerts little effect on automaticity of the normal sinus node but suppresses automaticity in normal Purkinje fibers (**Table 36.5**; **see also Tables 36.1, 36.2, and 36.3**). In patients with sinus node dysfunction, quinidine can further depress sinus node automaticity. Quinidine lengthens the QT interval in part via formation of EADs in experimental preparations and in humans, which appears to be responsible for TdP. Because of its significant anticholinergic effect and the reflex sympathetic stimulation resulting from alpha-adrenergic blockade, which causes peripheral vasodilation, quinidine can cause a reflex increase the sinus node discharge rate and improve atrioventricular (AV) nodal conduction. Quinidine prolongs repolarization, an effect that is more prominent at slow heart rates (reverse use dependence) because of block of I_{Kr} (as well as enhancing the late inward Na^+ current). Faster rates result in more block of sodium channels and less unblocking because a smaller percentage of time is spent in the rested state (use dependence). Isoproterenol can modulate the effects of quinidine on reentrant circuits in humans. Quinidine at higher doses inhibits the late inward Na^+ current. As noted, quinidine blocks the transient outward current I_{to}, which probably explains its efficacy in suppressing ventricular arrhythmias in Brugada syndrome (**see Chapter 33**).

Table 36.5

In vivo Electrophysiologic Characteristics of Antiarrhythmic Drugs

Results presented may vary according to tissue type, and drug concentration and autonomic tone.

↑ = increase; ↓ = decrease; 0 = no change; 0 ↑ or 0 ↓ = slight or inconsistent increase or decrease.

A, Atrium; *AVN,* atrioventricular node; *HPS,* His-Purkinje system; *V,* ventricle; *AH,* atrio-His interval (an index of AV nodal conduction); *HV,* His-ventricular interval (an index of His-Purkinje conduction); *ERP,* effective refractory period (longest S_1-S_2 interval at which S_2 fails to produce a response).

Hemodynamic Effects.

Quinidine induces vasodilation by blocking alpha-adrenergic receptors and can cause significant hypotension. It does not result in significant direct myocardial depression.

Pharmacokinetics.

Plasma quinidine concentrations peak at approximately 1.5 to 3 hours after an oral dose of a quinidine gluconate preparation (**see Table 36.4**). Quinidine can be given intravenously if it is infused slowly, but intramuscular dosing should be avoided. Approximately 80% of plasma quinidine is protein bound, especially to $alpha_1$-acid glycoprotein. Both the liver and the kidneys remove quinidine; dose adjustments may be made to achieve appropriate serum concentrations. Its elimination half-life is 8 to 9 hours after oral administration. Quinidine's effect on repolarization and its overall efficacy vary directly with left ventricular function; at the same serum concentration, the QT interval is longer in women than in men.

Dosage and Administration.

The usual oral dose of quinidine sulfate for an adult is 300 to 600 mg four times daily, which results in a steady-state level within about 24 hours (**see Table 36.4**). A loading dose of 600 to 800 mg produces an earlier effective concentration. Oral doses of the gluconate are about 30% higher than those of the sulfate form. Important interactions with other drugs occur.

Indications.

Quinidine is a versatile AAD that was used previously to treat premature supraventricular and ventricular complexes and sustained tachyarrhythmias. However, because of its side effect profile and potential for causing TdP, as well as its limited usefulness in preventing VT and VF in most applications, its use has

decreased greatly. In recent years, however, interest has increased in quinidine for treating primary VF, ventricular arrhythmias in patients with Brugada syndrome[8] (**see Chapter 33**), and short-QT syndrome. Because it crosses the placenta, quinidine can be used to treat arrhythmias in the fetus.

Adverse Effects.

The most common adverse effects of chronic oral quinidine therapy are gastrointestinal (GI) and include nausea, vomiting, diarrhea, abdominal pain, and anorexia (milder with the gluconate form). CNS toxicity includes tinnitus, hearing loss, visual disturbances, confusion, delirium, and psychosis (cinchonism). Allergic reactions include rash, fever, immune-mediated thrombocytopenia, hemolytic anemia, and rarely, anaphylaxis. Side effects may preclude long-term administration of quinidine in 30% to 40% of patients.

Quinidine can slow cardiac conduction, sometimes to the point of block, which is manifested as prolongation of the QRS duration or as sinoatrial (SA) or AV nodal conduction disturbances. Quinidine can produce syncope in 0.5% to 2.0% of patients, most often the result of a self-terminating episode of TdP. Quinidine prolongs the QT interval in most patients, regardless of whether ventricular arrhythmias occur, but significant QT prolongation (QT interval of 500 to 600 milliseconds) is often a characteristic of patients with quinidine-related syncope, who may have a genetic predisposition underlying such a response (**see Chapter 8**). Many of these patients are also receiving digitalis or diuretics or have hypokalemia; women are more susceptible than men. Importantly, syncope is unrelated to plasma concentrations of quinidine or the duration of therapy, although most episodes occur within the first 2 to 4 days of therapy, often after conversion of AF to sinus rhythm. This proarrhythmic effect during initiation of treatment is reproducible and because of this, the drug should not be taken on an intermittent basis. Therapy of proarrhythmia requires immediate discontinuation of use of the drug; magnesium given intravenously (2 g over 1 to 2 minutes, followed by an infusion of 3 to 20 mg/min) is the initial drug treatment of choice. Atrial or ventricular pacing can be used to suppress the ventricular tachyarrhythmia, perhaps by suppressing EADs. When pacing is not available, isoproterenol can be given with caution. The arrhythmia gradually dissipates as quinidine is cleared and the QT interval returns to baseline. Affected patients should not use quinidine thereafter and also should avoid other drugs with similar effects on the QT interval (see Crediblemeds.org).

Drugs that induce hepatic enzyme production, such as phenobarbital and phenytoin, can shorten the duration of action of quinidine by increasing its rate of elimination. Quinidine can increase plasma concentrations of flecainide by inhibiting the CYP450 enzyme system. Quinidine can elevate serum digoxin concentrations by decreasing its clearance and volume of distribution and the affinity of tissue receptors.

Procainamide

Electrophysiologic Actions.

The cardiac actions of procainamide on automaticity, conduction, excitability, and membrane responsiveness resemble those of quinidine (**see Tables 36.1, 36.2, 36.3, and 36.5**). Procainamide predominantly blocks the inactivated state of I_{Na}. It also blocks I_{Kr} and $I_{K.ATP}$. Like quinidine, procainamide usually prolongs the ERP more than it prolongs the APD and thus may prevent reentry. Procainamide exerts the least anticholinergic effects among type IA drugs. It does not affect normal sinus node automaticity. In vitro, procainamide decreases abnormal automaticity, with less effect on triggered

activity or catecholamine-enhanced normal automaticity. Unlike the parent drug, NAPA, its major metabolite, is a K^+ channel blocker (I_{Kr}) and exerts class III action, prolonging the APD of ventricular muscle and Purkinje fibers in a dose-dependent manner. High levels of NAPA, such as in patients with renal disease, can produce EADs, triggered activity, and TdP. Because of decreased demand, availability of intravenous (but not oral) procainamide is limited in some areas.

Hemodynamic Effects.

Procainamide can depress myocardial contractility in high concentrations. It does not produce alpha blockade but can result in peripheral vasodilation, possibly through antisympathetic effects on the brain or spinal cord, which can impair cardiovascular reflexes (e.g., provoking orthostatic symptoms).

Pharmacokinetics.

Oral administration produces a peak plasma concentration in approximately 1 hour. Approximately 80% of oral procainamide is bioavailable; the overall elimination half-life of procainamide is 3 to 5 hours, with 50% to 60% of the drug eliminated by the kidneys and 10% to 30% metabolized by the liver (**see Table 36.4**). The drug is acetylated to NAPA, which is excreted almost exclusively by the kidneys. As renal function decreases and in patients with heart failure, NAPA levels increase and, because of the risk for serious cardiotoxicity, need to be carefully monitored in these situations. NAPA has an elimination half-life of 7 to 8 hours, but the half-life exceeds 10 hours if high doses of procainamide are used. Increased age, congestive heart failure, and reduced creatinine clearance lower the clearance of procainamide and necessitate a reduced dosage.

Dosage and Administration.

Procainamide can be given by the oral, intravenous (IV), or intramuscular (IM) route to achieve plasma concentrations in the range of 4 to 10 mg/mL and produce an antiarrhythmic effect (**see Table 36.4**). Several IV regimens have been used to administer procainamide, but usually doses of 10 to 15 mg/kg are used a rate of up to 50 mg/min until the arrhythmia has been controlled, hypotension results, or the QRS complex is prolonged more than 50%. With this method, the plasma concentration falls rapidly during the first 15 minutes after the loading dose, with parallel effects on refractoriness and conduction. A constant-rate IV infusion of procainamide can be given at a dosage of 2 to 6 mg/min, depending on the patient's response.

Oral administration of procainamide requires a 3- to 4-hour dosing interval at a total daily dose of 2 to 6 g, with a steady-state concentration being reached within 1 day. When a loading dose is used, it should be twice the maintenance dose. Frequent dosing is required because of its short elimination half-life in normal persons. For the extended-release forms of procainamide, dosing is at 6- to 12-hour intervals. Procainamide by IM injection is almost 100% bioavailable.

Indications.

Procainamide is used to treat both supraventricular and ventricular arrhythmias in a manner comparable to that of quinidine. Although both drugs have similar electrophysiologic actions, either drug can effectively suppress a supraventricular or ventricular arrhythmia that is resistant to the other drug. Procainamide can be used to convert recent-onset AF to sinus rhythm. As with quinidine, prior treatment with beta or calcium channel blockers is recommended to prevent acceleration of the ventricular response during atrial flutter or fibrillation after procainamide therapy. Procainamide can block conduction in the accessory pathway of patients with Wolff-Parkinson-White (WPW) syndrome and can be used in patients with AF and a rapid ventricular response related to conduction over the accessory pathway. It can

produce His-Purkinje block and is sometimes administered during an EPS to stress the His-Purkinje system and evaluate the need for a pacemaker (**see Fig. 35.9**). However, it should be used with caution in patients with evidence of His-Purkinje disease (bundle branch block) in whom a ventricular pacemaker is not readily available.

Procainamide is more effective than lidocaine in acutely terminating sustained VT. Most consistently, procainamide slows the VT rate, a change correlated with the increase in QRS duration. The drug also has diagnostic application when given intravenously (10 mg/kg over 5 to 10 minutes). In patients with suspected Brugada syndrome who have a normal resting electrocardiogram (ECG), drug infusion can result in the characteristic "Brugada sign," whereas in patients with WPW syndrome, the drug can cause sudden loss of preexcitation, a finding indicative of an accessory pathway with a long refractory period and suggesting low risk for a dangerously rapid ventricular rate during AF. Evidence for the latter point, however, is mixed.

Adverse Effects.

Noncardiac adverse effects from administration of procainamide include rash, myalgia, digital vasculitis, and Raynaud phenomenon. Fever and agranulocytosis may be the result of hypersensitivity reactions, and the white blood cell and differential counts should be assessed at regular intervals. GI side effects are less frequent than with quinidine, and adverse CNS side effects are less frequent than with lidocaine. Toxic concentrations of procainamide can diminish myocardial performance and promote hypotension. Various conduction disturbances or ventricular tachyarrhythmias can occur, similar to those produced by quinidine. NAPA can cause QT prolongation and TdP. In the absence of sinus node disease, procainamide does not adversely affect sinus node function. In patients with sinus node dysfunction, however, procainamide can prolong sinus node recovery time and worsen symptoms in some patients with bradycardia-tachycardia syndrome.

Arthralgia, fever, pleuropericarditis, hepatomegaly, and hemorrhagic pericardial effusion with tamponade have been described in a systemic lupus erythematosus (SLE)-like syndrome related to procainamide administration. The syndrome occurs more frequently and earlier in patients who are slow acetylators of procainamide and is genetically influenced (**see Chapter 8**). Acetylation of procainamide to form NAPA appears to block the SLE-inducing effect. In 60% to 70% of patients receiving long-term procainamide therapy, ANAs develop, with clinical symptoms occurring in 20% to 30%, but this is reversible when procainamide is stopped. Positive serologic test results are not necessarily a reason to discontinue drug therapy; however, the development of symptoms with a positive anti-DNA antibody generally indicates that drug therapy should be discontinued. Corticosteroid administration in these patients may eliminate the symptoms. In this syndrome, in contrast to naturally occurring SLE, the brain and kidneys are typically spared, and there is no predilection for women.

Disopyramide

Disopyramide has been approved in the United States for oral administration to treat patients with ventricular and supraventricular arrhythmias.

Electrophysiologic Actions.

Disopyramide produces electrophysiologic effects similar to those of quinidine and procainamide, causing use-dependent block of I_{Na} and non–use-dependent block of I_{Kr} (**see Tables 36.1, 36.2, 36.3, and**

36.5). Disopyramide also inhibits $I_{K.ATP}$; it does not affect calcium-dependent action potentials, except possibly at very high concentrations.

Disopyramide is a muscarinic blocker and can increase the sinus node discharge rate and shorten AV nodal conduction time and refractoriness when the nodes are under cholinergic (vagal) influence. However, disopyramide can also slow the sinus node discharge rate by a direct action when given in high concentration and can significantly depress sinus node activity in patients with sinus node dysfunction. It exerts greater anticholinergic effects than quinidine and does not appear to affect alpha or beta adrenoceptors. The drug prolongs atrial and ventricular refractory periods, but its effect on AV nodal conduction and refractoriness is not consistent. Disopyramide prolongs His-Purkinje conduction time, but infra-His block rarely occurs. It can be administered safely to patients who have first-degree AV delay and narrow QRS complexes.

Hemodynamic Effects.

Disopyramide suppresses ventricular systolic performance and is a mild arterial vasodilator. The drug should generally be avoided in patients with reduced left ventricular systolic function because they tolerate its negative inotropic effects poorly.

Pharmacokinetics.

Oral disopyramide is 80% to 90% absorbed, with a mean elimination half-life of 8 to 9 hours in healthy volunteers but almost 10 hours in patients with heart failure (**see Table 36.4**). Renal insufficiency prolongs its elimination time. Thus, in patients with renal, hepatic, or cardiac insufficiency, loading and maintenance doses need to be reduced. Peak blood levels after oral administration occur in 1 to 2 hours. Approximately 50% of an oral dose is excreted unchanged in urine, with 30% occurring as the mono-*N*-dealkylated metabolite. The metabolites appear to exert less effect than the parent compound. Erythromycin inhibits its metabolism.

Dosage and Administration.

Doses are generally 100 to 200 mg orally every 6 hours, with a range of 400 to 1200 mg/day (**see Table 36.4**). A controlled-release preparation can be given as 200 to 300 mg every 12 hours.

Indications.

Disopyramide appears to be comparable to quinidine and procainamide in reducing the frequency of premature ventricular complexes (PVCs) and effectively preventing recurrence of VT in selected patients. Disopyramide has been combined with other drugs, such as mexiletine, to treat patients who do not respond or respond only partially to one drug.

Although rarely used for this, disopyramide helps prevent recurrence of AF after successful cardioversion as effectively as quinidine and may terminate atrial flutter. In treating patients with AF, particularly atrial flutter, the ventricular rate must be controlled before disopyramide is administered, or the combination of a decrease in atrial rate with vagolytic effects on the AV node can result in 1 : 1 AV conduction during atrial flutter (**see Chapter 38**). Disopyramide may be useful in preventing episodes of neurally mediated syncope. It has been used in patients with hypertrophic cardiomyopathy for both AF therapy and its negative inotropic effect.

Adverse Effects.

Three types of adverse effects follow disopyramide administration. The most common effects are related to the drug's potent parasympatholytic properties and include urinary hesitancy or retention, constipation,

blurred vision, closed-angle glaucoma, and dry mouth. Symptoms are less with the sustained-release form. Second, disopyramide can produce ventricular tachyarrhythmias frequently associated with QT prolongation and TdP. Cross-sensitization to both quinidine and disopyramide occurs in some patients, and TdP can develop while receiving either drug. When drug-induced torsades de pointes (DI-TdP) occurs, agents that prolong the QT interval should be used cautiously or not at all. Lastly, disopyramide can reduce contractility of the normal ventricle, but the depression of ventricular function is much more pronounced in patients with preexisting ventricular failure. Rarely, cardiovascular collapse can result.

Ajmaline

Ajmaline, a rauwolfia derivative, has been used extensively to treat patients with ventricular and supraventricular arrhythmias in Europe and Asia but is not available in the United States.

Electrophysiologic Actions.
As with other class IA drugs, ajmaline produces use-dependent block of I_{Na}; it also weakly blocks I_{Kr}. The drug has mild anticholinergic activity (**see Tables 36.1, 36.2, 36.3, and 36.5**).

Hemodynamic Effects.
Ajmaline mildly suppresses ventricular systolic performance but does not affect peripheral resistance. It also inhibits platelet activity more potently than aspirin does.

Pharmacokinetics, Dosage, and Administration.
Ajmaline is well absorbed with a mean elimination half-life of 13 minutes in most patients, thus making it poorly suited to long-term oral use. The dose for termination of acute arrhythmia is generally 50 mg intravenously infused over 1 to 2 minutes (**see Table 36.4**).

Indications.
Although it is useful for terminating supraventricular tachycardias (SVTs) by IV infusion, other medications have largely supplanted ajmaline for this purpose and its use has evolved to that of a diagnostic tool. When administered intravenously at doses of 50 mg over a 3-minute period, or 10 mg/min, to a total dose of 1 mg/kg, ajmaline can have the following effects: (1) delta wave disappearance in patients with WPW syndrome (indicating an accessory pathway anterograde ERP longer than 250 milliseconds); (2) ST-T abnormalities and interventricular conduction blocks in patients with occult Chagasic cardiomyopathy; (3) heart block in patients with bundle branch block and syncope, but in whom no rhythm disturbance had been discovered; and (4) right precordial ST elevation in patients with suspected Brugada syndrome in whom findings on the resting ECG are normal. It is in this last setting that ajmaline is used most frequently.

Adverse Effects.
Ajmaline can produce mild anticholinergic side effects, as well as mild depression of left ventricular systolic function, and can worsen AV conduction in patients with His-Purkinje disease. Rare occurrences of TdP have been reported. Ajmaline can increase the defibrillation threshold.

Class IB Agents

Lidocaine

Electrophysiologic Actions.

Lidocaine blocks I_{Na}, predominantly in the open or inactivated state. It has rapid onset and offset kinetics and does not affect normal sinus node automaticity in usual doses but does depress other normal and abnormal forms of automaticity, as well as early and late afterdepolarizations in Purkinje fibers in vitro (**see Tables 36.1, 36.2, 36.3, and 36.5**). Lidocaine has only a modest depressant effect on Vmax; however, faster rates of stimulation, acidosis, increased extracellular K^+ concentration, and reduced membrane potential (changes that can result from ischemia) increase the ability of lidocaine to block I_{Na}. Lidocaine can convert areas of unidirectional block into bidirectional block during ischemia and inhibit the development of VF by preventing fragmentation of organized large wavefronts into heterogeneous wavelets.

Except in very high concentrations, lidocaine does not affect slow-channel–dependent action potentials despite its moderate suppression of the slow inward current. Lidocaine has minimal effect on atrial fibers and does not affect conduction in accessory pathways. Depressed automaticity or conduction can develop in patients with preexisting sinus node dysfunction, abnormal His-Purkinje conduction, or junctional or ventricular escape rhythms. Part of lidocaine's effects may involve inhibition of cardiac sympathetic nerve activity.

Hemodynamic Effects.

Clinically significant adverse hemodynamic effects are rarely noted with lidocaine at the usual drug concentrations unless left ventricular function is severely impaired.

Pharmacokinetics.

Lidocaine is used only parenterally because oral administration results in extensive first-pass hepatic metabolism and unpredictably low plasma levels, as well as excessive metabolites that can produce toxicity (**see Table 36.4**). Hepatic metabolism of lidocaine depends on hepatic blood flow; severe hepatic disease or reduced hepatic blood flow, as in heart failure or shock, can greatly decrease the rate of lidocaine metabolism. Beta-adrenoceptor blockers can decrease hepatic blood flow and increase the serum concentration of lidocaine. Prolonged infusion can reduce lidocaine clearance. Its elimination half-life averages 1 to 2 hours in normal individuals, longer than 4 hours in patients after uncomplicated myocardial infarction (MI), longer than 10 hours in patients after MI complicated by heart failure, and even longer in the presence of cardiogenic shock. Maintenance doses should be reduced by one third to one half in patients with low cardiac output.

Dosage and Administration.

Although lidocaine can be given intramuscularly, the IV route is most often used, with an initial bolus of 1 to 2 mg/kg body weight at a rate of 20 to 50 mg/min and a second injection of half the initial dose 20 to 40 minutes later to maintain the therapeutic concentration (**see Table 36.4**).

If the initial bolus of lidocaine is ineffective, up to two more boluses of 1 mg/kg may be administered at 5-minute intervals. Patients who require more than one bolus to achieve a therapeutic effect generally need a higher maintenance dose to sustain these higher concentrations, with infusion rates in the range of 1 to 4 mg/min to produce steady-state plasma levels of 1 to 5 mg/mL in patients with uncomplicated MI. These rates must be reduced during heart failure or shock because of the concomitant reduced hepatic blood flow. Higher doses and concentrations are unlikely to provide additional benefit but do increase the risk for toxicity.

Indications.

Lidocaine has moderate efficacy against ventricular arrhythmias of diverse causes; it is generally ineffective against supraventricular arrhythmias and rarely terminates monomorphic VT. Although once used in an attempt to prevent VF in the first 2 days after acute MI, its efficacy was marginal, and because it can produce side effects and a possible increase in the risk for the development of asystole, such use is not recommended. Lidocaine has been effective in patients after coronary revascularization and in those resuscitated from out-of-hospital VF, although amiodarone has been shown to yield higher rates of survival, at least to hospital admission.

Adverse Effects.

The most frequently reported adverse effects of lidocaine are dose-related manifestations of CNS toxicity: dizziness, paresthesias, confusion, delirium, stupor, coma, and seizures. Occasional sinus node depression and His-Purkinje block have been reported. Rarely, lidocaine can cause malignant hyperthermia.

Mexiletine

Mexiletine, a local anesthetic congener of lidocaine with anticonvulsant properties, is used for the oral treatment of patients with symptomatic ventricular arrhythmias.

Electrophysiologic Actions.

Mexiletine is similar to lidocaine in many of its electrophysiologic actions. In vitro, mexiletine shortens the APD and ERP of Purkinje fibers and, to a lesser extent, ventricular muscle. It depresses the Vmax of phase 0 by blocking I_{Na}, especially at faster rates, and depresses the automaticity of Purkinje fibers but not of the normal sinus node. Its onset and offset kinetics are rapid. Hypoxia or ischemia can increase its effects (**see Tables 36.1, 36.2, 36.3, and 36.5**).

Mexiletine can result in severe bradycardia and abnormal sinus node recovery time in patients with sinus node disease, but not in those with a normal sinus node. It does not affect AV nodal conduction and can depress His-Purkinje conduction, but not greatly, unless conduction was abnormal initially. Mexiletine does not appear to affect human atrial muscle. It does not affect the QT interval. It has been used in treating a variety of other disorders, including erythromelalgia (red, painful extremities) in children and myotonia.

Hemodynamic Effects.

Mexiletine exerts no major hemodynamic effects on ventricular contractile performance or peripheral resistance.

Pharmacokinetics.

Mexiletine is rapidly and almost completely absorbed after oral ingestion by volunteers, with peak plasma concentrations being attained in 2 to 4 hours (**see Table 36.4**). Its elimination half-life is approximately 10 hours in healthy individuals but 17 hours in post-MI patients. Therapeutic plasma levels of 0.5 to 2 mg/mL are maintained by oral doses of 200 to 300 mg every 6 to 8 hours. Absorption with less than a 10% first-pass hepatic effect occurs in the upper part of the small intestine and is delayed and incomplete in patients receiving narcotics or antacids. Approximately 70% of the drug is protein bound; the apparent volume of distribution is large because of extensive tissue uptake. Normally,

mexiletine is eliminated metabolically by the liver, with less than 10% being excreted unchanged in urine. Doses should be reduced in patients with cirrhosis or left ventricular failure. Renal clearance of mexiletine decreases as urinary pH increases. Its known metabolites exert no electrophysiologic effects. Metabolism can be increased by phenytoin, phenobarbital, and rifampin and can be reduced by cimetidine.

Dosage and Administration.

The recommended starting dose is 200 mg orally every 8 hours when rapid arrhythmia control is not essential (**see Table 36.4**). Doses may be increased or decreased by 50 to 100 mg every 2 to 3 days and are better tolerated when given with food. The total daily dose should generally not exceed 1200 mg. In some patients, administration every 12 hours can be effective.

Indications.

Mexiletine is a moderately effective antiarrhythmic agent for the treatment of acute and chronic ventricular tachyarrhythmias, but not SVTs. Success rates vary from 6% to 60% and can be increased in some patients if mexiletine is combined with other drugs such as procainamide, beta blockers, quinidine, disopyramide, propafenone, or amiodarone. Most studies show no clear superiority of mexiletine over other class I agents. Mexiletine may be very useful in children with congenital heart disease and serious ventricular arrhythmias. In treating patients with a long QT interval, mexiletine may be safer than drugs that increase the QT interval further, such as quinidine. Limited experience in treating subsets of patients with long-QT syndrome (LQT3, which is related to the *SCN5A* gene for the cardiac sodium channel) suggests a beneficial role (**see Chapter 33**).

Adverse Effects.

Up to 40% of patients may require a change in dose or discontinuation of mexiletine therapy as a result of adverse effects, including tremor, dysarthria, dizziness, paresthesia, diplopia, nystagmus, confusion, nausea, vomiting, and dyspepsia. Cardiovascular side effects are rare but include hypotension, bradycardia, and exacerbation of arrhythmia. The adverse effects of mexiletine appear to be dose related, and toxic effects occur at plasma concentrations only slightly higher than therapeutic levels. Therefore, its effective use requires careful titration of dose and monitoring for adverse effects and possibly plasma concentration. Lidocaine use as an AAD should be avoided or the dose reduced in patients receiving mexiletine.

Phenytoin

Phenytoin was used originally to treat seizure disorders. Its value as an AAD is limited to rare cases of digitalis-toxic atrial and ventricular tachyarrhythmias (for which more rapid and effective control can be achieved with digitalis-specific antibodies) and occasional cases of ventricular arrhythmias when used in combination with other agents (**see Tables 36.1 to 36.5**).

Class IC Agents

Flecainide

Flecainide is approved by the FDA to treat patients with life-threatening ventricular arrhythmias, as well as various supraventricular arrhythmias.

Electrophysiologic Actions.

Flecainide exhibits marked use-dependent depressant effects on the rapid sodium channel by decreasing Vmax and has slow onset and offset kinetics (**see Tables 36.1, 36.2, 36.3, and 36.5**). Drug dissociation from the sodium channel is slow, with time constants of 10 to 30 seconds (versus 4 to 8 seconds for quinidine and <1 second for lidocaine). Thus, marked drug effects can occur at physiologic heart rates. Flecainide shortens the duration of the Purkinje fiber action potential but prolongs it in ventricular muscle, actions that, depending on the circumstances, could enhance or reduce electrical heterogeneity and create or suppress arrhythmias. Flecainide profoundly slows conduction in all cardiac fibers and, in high concentrations, inhibits the slow Ca^{2+} channel (**see Chapter 34**). Conduction time in the atria, ventricles, AV node, and His-Purkinje system is prolonged. Minimal increases in atrial or ventricular refractoriness or in the QT interval result. Anterograde and retrograde refractoriness in accessory pathways can increase significantly in a use-dependent manner. Sinus node function remains unchanged in normal individuals but may be depressed in patients with sinus node dysfunction. Flecainide can facilitate or inhibit reentry and may transform atrial fibrillation to flutter. Pacing and defibrillation thresholds are characteristically slightly to significantly increased.

Hemodynamic Effects.

Flecainide depresses cardiac performance, particularly in patients with compromised ventricular systolic function, and should be used cautiously or not at all in those with moderate or severe ventricular systolic dysfunction.

Pharmacokinetics.

Flecainide is at least 90% absorbed, with peak plasma concentrations achieved in 3 to 4 hours. Its elimination half-life in patients with ventricular arrhythmias is 20 hours, with 85% of the drug excreted unchanged or as an inactive metabolite in urine (**see Table 36.4**). Its two major metabolites have less potency than the parent drug. Elimination is slower in patients with renal disease and heart failure, and doses should be reduced in these situations. Therapeutic plasma concentrations range from 0.2 to 1.0 mg/mL. Approximately 40% of the drug is protein bound. Increases in serum concentrations of digoxin (15% to 25%) and propranolol (30%) result during co-administration with flecainide. Propranolol, quinidine, and amiodarone may increase flecainide serum concentrations. Five to 7 days of dosing may be required to reach a steady-state concentration in some patients.

Dosage and Administration.

The starting dose is 100 mg every 12 hours, increased in increments of 50 mg twice daily, no sooner than every 3 to 4 days, until efficacy is achieved or an adverse effect is noted, or to a maximum of 400 mg/day (**see Table 36.4**). Cardiac rhythm and QRS duration should be monitored after changes in dose.

Indications.

Flecainide is indicated for the treatment of life-threatening ventricular tachyarrhythmias, SVTs, and paroxysmal atrial fibrillation. Encouraging experimental and early clinical data support its use for catecholaminergic polymorphic VT (**see Chapter 33**). Some experts have suggested that therapy should begin in the hospital while the ECG is being monitored because of the possibility of proarrhythmic events (see later). The dosage is adjusted to achieve the desired effect, but the serum concentration should not exceed 1.0 mg/mL. Flecainide is particularly effective in almost totally suppressing PVCs and short runs of nonsustained VT. As with other class I AADs, no data from controlled studies indicate that the drug

favorably affects survival or sudden cardiac death, and data from CAST indicate increased mortality in patients with coronary artery disease. Flecainide produces a use-dependent prolongation of VT cycle length, which can improve hemodynamic tolerance. Flecainide is also useful for various SVTs, such as atrial tachycardia (AT), atrial flutter, and AF (including oral loading to terminate episodes acutely). When it is administered chronically, isoproterenol can reverse some of these effects. It is important to slow the ventricular rate before treatment of AF with flecainide to avoid the 1 : 1 AV conduction of slowed atrial flutter that may result from the effect of flecainide on fibrillation. Flecainide has been used to treat fetal arrhythmias and arrhythmias in children. Flecainide administration can produce ST elevation in lead V_1, characteristic of Brugada syndrome, in susceptible patients (**see Chapter 33**) and has been used as a diagnostic tool in persons suspected of having this disorder.

Adverse Effects.

Proarrhythmic effects are some of the most important adverse effects of flecainide. Its marked slowing of conduction precludes its use in patients with second-degree AV block without a pacemaker and warrants cautious administration in patients with intraventricular conduction disorders. Worsening of existing ventricular arrhythmias or the onset of new ventricular arrhythmias can occur in 5% to 30% of patients, especially in those with preexisting sustained VT, cardiac decompensation, and higher doses of the drug. Failure of the flecainide-related arrhythmia to respond to therapy, including electrical cardioversion-defibrillation, may result in mortality as high as 10% in patients in whom proarrhythmic events develop. Negative inotropic effects can precipitate or worsen heart failure episodes. Patients with sinus node dysfunction may experience sinus arrest, and an increase in the pacing and defibrillation thresholds may develop in those with pacemakers and ICDs, respectively. In CAST, patients treated with flecainide had higher mortality or nonfatal cardiac arrest compared to the placebo group, possibly related to an interaction between the drug and myocardial ischemia. Exercise can amplify the conduction slowing in the ventricle produced by flecainide and in some cases can precipitate a proarrhythmic response. Therefore, exercise testing has been recommended to screen for proarrhythmia (as well as occult ischemia) before and periodically during treatment. CNS complaints, including confusion and irritability, represent the most frequent noncardiac adverse effects. The safety of flecainide during pregnancy has not been determined, although as noted previously, it is occasionally used to treat fetal arrhythmias. It is concentrated in breast milk to a level 2.5- to 4-fold higher than in plasma.

Propafenone

Propafenone has been approved by the FDA for the treatment of patients with life-threatening ventricular tachyarrhythmias, as well as AF.

Electrophysiologic Actions.

Propafenone blocks the fast sodium current in a use-dependent manner in Purkinje fibers and to a lesser degree in ventricular muscle (**see Tables 36.1, 36.2, 36.3, and 36.5**). Its use-dependent effects contribute to its ability to terminate AF. Its dissociation constant from the receptor is slow, similar to that of flecainide. Effects are greater in ischemic than in normal tissue and with reduced membrane potentials. Propafenone decreases excitability and suppresses spontaneous automaticity and triggered activity. The drug is a weak blocker of I_{Kr} and beta-adrenergic receptors. Although ventricular refractoriness increases, slowing of conduction is the major effect. Propafenone has several active metabolites that

exert electrophysiologic effects. It depresses sinus node automaticity, and the A-H, H-V, PR, and QRS intervals increase, as do the refractory periods of all tissues. The QT interval increases only as a function of increased QRS duration.

Hemodynamic Effects.

Propafenone and 5-hydroxypropafenone exhibit negative inotropic properties at high concentrations. In patients with left ventricular ejection fraction (EF) exceeding 40%, the negative inotropic effects are well tolerated, but patients with preexisting left ventricular dysfunction and congestive heart failure may have symptomatic worsening of their hemodynamic status.

Pharmacokinetics.

With more than 95% of the drug absorbed, the maximum plasma concentration of propafenone is achieved in 1 to 3 hours (**see Table 36.4**). Systemic bioavailability is dose dependent and ranges from 3% to 40% because of variable presystemic clearance. Bioavailability increases as the dose increases, and the plasma concentration is therefore not linearly related to dose. A threefold increase in dosage (300 to 900 mg/day) results in a 10-fold increase in plasma concentration, presumably because of saturation of hepatic metabolic mechanisms. Propafenone is 97% bound to $alpha_1$-acid glycoprotein, with an elimination half-life of 5 to 8 hours. Maximum therapeutic effects occur at serum concentrations of 0.2 to 1.5 mg/mL. The marked interpatient variability in pharmacokinetics and pharmacodynamics may be the result of genetically determined differences in metabolism (**see Chapter 8**). Approximately 7% of the population are poor metabolizers and have an elimination half-life of 15 to 20 hours for the parent compound. The (+)-enantiomer provides nonspecific beta-adrenergic receptor blockade with 2.5% to 5% of the potency of propranolol, but because plasma propafenone concentrations may be 50 or more times higher than propranolol levels, these beta-blocking properties may be relevant. Poor metabolizers have a greater beta receptor–blocking effect than extensive metabolizers.

Dosage and Administration.

Most patients respond to oral propafenone doses of 150 to 300 mg every 8 hours, not to exceed 1200 mg/day (**see Table 36.4**). Doses are similar for patients of both metabolizing phenotypes. A sustained-release form is available for the treatment of atrial fibrillation; dosing is 225 to 425 mg twice daily. Concomitant food administration increases its bioavailability, as does hepatic dysfunction. No good correlation between the plasma propafenone concentration and suppression of arrhythmia has been shown. Doses should not be increased more often than every 3 to 4 days. Propafenone increases plasma concentrations of warfarin, digoxin, and metoprolol.

Indications.

Propafenone is indicated for the treatment of paroxysmal SVT, AF, and life-threatening ventricular tachyarrhythmias, and effectively suppresses spontaneous PVCs and nonsustained and sustained VT. Acute termination of AF episodes occurred with a single 600-mg oral dose of propafenone in 76% of patients given the drug (twice the rate of those given placebo). It has been used effectively in the pediatric age group. Propafenone increases the pacing threshold but minimally affects the defibrillation threshold. The sinus rate during exercise is reduced.

Adverse Effects.

Minor noncardiac effects occur in approximately 15% of patients, with dizziness, disturbances in taste, and blurred vision being the most common and GI side effects next. Exacerbation of bronchospastic lung

disease can occur because of mild beta-blocking effects. Cardiovascular side effects develop in 10% to 15% of patients, including AV block, sinus node depression, and worsening of heart failure. Proarrhythmic responses, which occur more often in patients with a history of sustained VT and decreased EF, appear less often than with flecainide (approximately 5%). Applicability of data from CAST about flecainide to propafenone is not clear, but limiting the use of propafenone in a manner similar to that of other class IC drugs seems prudent; however, its beta-blocking actions may make it different. The safety of propafenone administration during pregnancy has not been established (class C).

Class II Agents

Beta Adrenoceptor–Blocking Agents

Although many beta adrenoceptor–blocking drugs have been approved for use in the United States, metoprolol, carvedilol, atenolol, propranolol, and esmolol have been most widely used to treat supraventricular and ventricular arrhythmias. Acebutolol, nadolol, timolol, betaxolol, pindolol, and bisoprolol have been used less extensively for the treatment of arrhythmias. Metoprolol, atenolol, carvedilol, timolol, and propranolol decrease overall mortality and sudden death after MI (**see Chapter 42**). It is generally thought that beta blockers possess class effects, and that when titrated to the proper dose, all can be used effectively to treat cardiac arrhythmias, hypertension, or other disorders. However, differences in pharmacokinetic or pharmacodynamic properties that confer safety, reduce adverse effects, or affect dosing intervals or drug interactions influence the choice of agent. For example, nadolol may be particularly effective in patients with long-QT syndrome (**see Chapter 33**). Also, some beta blockers, such as sotalol, pindolol, and carvedilol, exert unique actions in addition to beta receptor blockade.

Beta receptors can be separated into those that affect predominantly the heart ($beta_1$) and those that affect predominantly blood vessels and the bronchi ($beta_2$). In low doses, selective beta blockers can block $beta_1$ receptors more than they block $beta_2$ receptors and might be preferable for the treatment of patients with pulmonary or peripheral vascular disease. In high doses, the "selective" $beta_1$ blockers also block $beta_2$ receptors. Carvedilol also exerts alpha-blocking effects and is used primarily in patients with heart failure (**see Chapters 24 and 25**). It is a relatively poor agent for rate control in AF because of the alpha-blocking–induced hypotension that accompanies doses large enough to block the AV node adequately.

Some beta blockers exert intrinsic sympathomimetic activity; that is, they slightly activate the beta receptor. These drugs appear to be as efficacious as beta blockers without intrinsic sympathomimetic actions and may cause less slowing of the heart rate at rest and less prolongation of AV nodal conduction time. They have been shown to induce less depression of left ventricular function than do beta blockers without intrinsic sympathomimetic activity. Beta blockers without intrinsic sympathomimetic activity have been shown to reduce mortality in patients after MI, with nonselective agents possibly conferring slightly greater benefit (**see Chapters 58 and 59**).

The following discussion focuses on the use of propranolol as a prototypic antiarrhythmic agent but is generally applicable to other beta blockers.

Electrophysiologic Actions.
Beta blockers exert an electrophysiologic action by competitively inhibiting binding of catecholamines at

beta adrenoceptor sites, or by their quinidine-like or direct membrane-stabilizing action (**see Tables 36.1, 36.2, 36.3, and 36.5**). The latter is a local anesthetic effect that depresses I_{Na} and membrane responsiveness in cardiac Purkinje fibers, occurs at concentrations generally 10 times those necessary to produce beta blockade, and most likely plays an insignificant antiarrhythmic role. Thus, beta blockers exert their major effects in cells most actively stimulated by adrenergic actions. At a beta-blocking concentration, propranolol slows spontaneous automaticity in the sinus node or in Purkinje fibers that are being stimulated by adrenergic tone and produces an I_f block (**see Chapter 34**). Beta blockers also block the $I_{Ca.L}$ stimulated by beta agonists. In the absence of adrenergic stimulation, only high concentrations of propranolol slow normal automaticity in Purkinje fibers, probably by a direct membrane action.

Concentrations that cause beta receptor blockade but no local anesthetic effects do not alter the normal resting membrane potential, maximum diastolic potential amplitude, Vmax, repolarization, or refractoriness of atrial, Purkinje, or ventricular muscle cells in the absence of catecholamine stimulation. However, in the presence of isoproterenol, a relatively pure beta receptor stimulator, beta blockers reverse isoproterenol's accelerating effects on repolarization. Propranolol reduces the amplitude of digitalis-induced delayed afterdepolarizations (DADs) and suppresses triggered activity in Purkinje fibers.

Concentrations exceeding 3 mg/mL are required to depress Vmax, action potential amplitude, membrane responsiveness, and conduction in normal atrial, ventricular, and Purkinje fibers without altering resting membrane potential. These effects probably result from depression of I_{Na}. Long-term administration of propranolol may lengthen the APD. Similar to the effects of lidocaine, acceleration of repolarization of Purkinje fibers is most marked in areas of the ventricular conduction system where the APD is greatest.

Propranolol slows the sinus discharge rate in humans by 10% to 20%, although severe bradycardia occasionally results if the heart is particularly dependent on sympathetic tone or if sinus node dysfunction is present. The PR interval lengthens, as do AV nodal conduction time and AV nodal effective and functional refractory periods (at a constant heart rate), but refractoriness and conduction in the normal His-Purkinje system remain unchanged, even after high doses of propranolol. Beta blockers do not affect conduction or repolarization in normal ventricular muscle, as evidenced by their lack of effect on the QRS complex and QT interval, respectively.

Because administration of beta blockers that do not have direct membrane action prevents many arrhythmias resulting from activation of the autonomic nervous system, it is thought that the beta-blocking action is responsible for their antiarrhythmic effects. Nevertheless, the possible importance of the direct membrane effect of some of these drugs cannot be discounted totally because beta blockers with direct membrane actions can affect the transmembrane potentials of diseased cardiac fibers at much lower concentrations than are needed to affect normal fibers directly. However, indirect actions on the arrhythmogenic effects of ischemia are probably the most important.

Hemodynamic Effects.

Beta blockers exert negative inotropic effects and can precipitate or worsen heart failure. However, beta blockers clearly improve survival in patients with heart failure (**see Chapter 25**). By blocking beta receptors, these drugs may allow unopposed alpha-adrenergic effects to produce peripheral vasoconstriction and exacerbate coronary artery spasm or pain from peripheral vascular disease in some patients.

Pharmacokinetics.

Although various types of beta blockers exert similar pharmacologic effects, their pharmacokinetics

differ substantially. Propranolol is almost 100% absorbed, but the effects of first-pass hepatic metabolism reduce its bioavailability to approximately 30% and produce significant interpatient variability in plasma concentration with a given dose (**see Table 36.4**). Reduced hepatic blood flow, as in patients with heart failure, decreases the hepatic extraction of propranolol; in these patients, propranolol may further decrease its own elimination rate by reducing cardiac output and hepatic blood flow. Beta blockers eliminated by the kidneys tend to have longer half-lives and exhibit less interpatient variability in drug concentration than do beta blockers metabolized by the liver.

Dosage and Administration.

The appropriate dose of propranolol is best determined by a measure of the patient's physiologic response, such as changes in resting heart rate or prevention of exercise-induced sinus tachycardia, because wide individual differences exist between the observed physiologic effect and plasma concentration. For example, IV dosing is best achieved by titration of the dose to clinical effect, beginning with doses of 0.25 to 0.50 mg, increasing to 1.0 mg if necessary, and administering doses every 5 minutes until either a desired effect or toxicity is produced or a total of 0.15 to 0.20 mg/kg has been given. In many cases, the short-acting effects of esmolol are preferred. Orally, propranolol is given in four divided doses, usually ranging from 40 to 160 mg/day to more than 1 g/day (**see Table 36.4**). Some beta blockers, such as carvedilol and pindolol, need to be given twice daily; many are available as once-daily long-acting preparations. In general, if one agent in adequate doses does not produce the desired effect, other beta blockers will also be ineffective. Conversely, if one agent produces the desired physiologic effect but a side effect develops, another beta blocker can often be substituted successfully.

Indications.

Arrhythmias associated with thyrotoxicosis or pheochromocytoma and arrhythmias largely related to excessive cardiac adrenergic stimulation, such as those initiated by exercise or emotion, often respond to beta-blocker therapy. Beta-blocking drugs do not usually convert chronic atrial flutter or AF to normal sinus rhythm but may do so if the arrhythmia is of recent onset and in patients who have recently undergone cardiac surgery. The atrial rate during atrial flutter or fibrillation is not changed, but the ventricular response decreases because beta blockade prolongs AV nodal conduction time and refractoriness. Esmolol can be used intravenously for rapid control of the heart rate. For reentrant SVTs using the AV node as one of the reentrant pathways, such as AV nodal reentrant tachycardia (AVNRT) and orthodromic reciprocating tachycardia in WPW syndrome or inappropriate sinus tachycardia, or for AT, beta blockers can slow or terminate the tachycardia and can be used prophylactically to prevent a recurrence (**see Chapters 37 and 38**). Combining beta blockers with digitalis, quinidine, or various other agents can be effective when the beta blocker as a single agent fails. Metoprolol and esmolol may be useful in patients with multifocal AT. These agents must be used with caution in patients with this arrhythmia, however, because a common setting for AT is advanced lung disease, often with a bronchospastic component.

Beta blockers can be effective for digitalis-induced arrhythmias such as AT, nonparoxysmal AV junctional tachycardia, PVCs, or VT. If a significant degree of AV block is present during digitalis-induced arrhythmia, lidocaine or phenytoin may be preferable to propranolol. Beta blockers can also be useful to treat ventricular arrhythmias associated with prolonged–QT interval syndrome (**see Chapter 33**) and with mitral valve prolapse (**see Chapter 69**). For patients with ischemic heart disease, beta blockers do not generally prevent the episodes of recurrent monomorphic VT that occur in the absence of

acute ischemia. It is well accepted that several beta blockers reduce the incidence of both total and sudden death after MI (**see Chapters 58 and 59**). The mechanism of this reduction in mortality is not entirely clear and may be related to reduction of the extent of ischemic damage, autonomic effects, a direct antiarrhythmic effect, or combinations of these factors. Beta blockers may have been protective against proarrhythmic responses in CAST.

Adverse Effects.

Adverse cardiovascular effects from beta blockers include unacceptable hypotension, bradycardia, and congestive heart failure. The bradycardia can be caused by sinus slowing or AV block. Sudden withdrawal of propranolol in patients with angina pectoris can precipitate or worsen angina and cardiac arrhythmias and cause acute MI, possibly as a result of the heightened sensitivity to beta agonists caused by previous beta blockade (receptor upregulation). Heightened sensitivity may begin several days after cessation of beta-blocker therapy and can last 5 or 6 days. Other adverse effects of beta blockers include worsening of asthma or chronic obstructive pulmonary disease, intermittent claudication, Raynaud phenomenon, mental depression, increased risk for hypoglycemia in insulin-dependent diabetic patients, easy fatigability, disturbingly vivid dreams or insomnia, and impaired sexual function. Many of these side effects were noted less frequently with the use of $beta_1$-selective agents, but even so-called cardioselective beta blockers can exacerbate asthma or diabetic control in individual patients.

Class III Agents

Amiodarone

Amiodarone is an iodinated benzofuran derivative approved by the FDA for the treatment of patients with life-threatening ventricular tachyarrhythmias when other drugs are ineffective or not tolerated.

Electrophysiologic Actions.

With long-term oral administration, amiodarone prolongs the APD and refractoriness of all cardiac fibers without affecting resting membrane potential (**see Tables 36.1, 36.2, 36.3, and 36.5** and **Chapter 34**). When acute effects are evaluated, amiodarone and its metabolite desethylamiodarone prolong the APD of ventricular muscle but shorten the APD of Purkinje fibers. Injected into the sinus and AV node arteries, amiodarone reduces sinus and junctional discharge rates and prolongs AV nodal conduction time. It depresses Vmax in ventricular muscle in a rate- or use-dependent manner by blocking of inactivated sodium channels, an effect that is accentuated by depolarized and reduced by hyperpolarized membrane potentials. Amiodarone depresses conduction at fast rates more than at slow rates (use dependence). It does not prolong repolarization more at slow than at fast rates (i.e., does not demonstrate reverse use dependence) but does exert time-dependent effects on refractoriness, which may in part explain its high antiarrhythmic efficacy and low incidence of TdP.

Desethylamiodarone has relatively greater effects on fast-channel tissue, which probably contributes to its antiarrhythmic efficacy. The delay in building up adequate concentrations of this metabolite may in part explain the delay in amiodarone's antiarrhythmic action.

Amiodarone noncompetitively antagonizes alpha and beta receptors and blocks conversion of thyroxine (T_4) to triiodothyronine (T_3), which may account for some of its electrophysiologic effects. Amiodarone exhibits slow channel–blocking effects; with oral administration, it slows the sinus rate by

20% to 30% and prolongs the QT interval, at times changing the contour of the T wave and producing U waves.

The ERP of all cardiac tissues is prolonged. The H-V interval increases, and the QRS duration lengthens, especially at fast rates. Amiodarone given intravenously modestly prolongs the refractory period of atrial and ventricular muscle. The PR interval and AV nodal conduction time lengthen. The duration of the QRS complex lengthens at increased rates but less than after oral amiodarone. Thus the increase in prolongation of conduction time (except for AV node), duration of repolarization, and refractoriness is much less after IV administration than after the oral route. Considering these actions, it is clear that amiodarone has class I (blocks I_{Na}), class II (antiadrenergic), and class IV (blocks $I_{Ca.L}$) actions in addition to its class III effects (blocks I_K). Amiodarone's actions approximate those of a theoretically ideal drug that exhibits use-dependent Na^+ channel blockade with fast diastolic recovery from block and use-dependent prolongation of the APD. It does not increase and may decrease QT dispersion. Catecholamines can partially reverse some of the effects of amiodarone.

Hemodynamic Effects.

Amiodarone is a peripheral and coronary vasodilator. When administered intravenously (150 mg over 10 minutes, then a 1-mg/min infusion), amiodarone decreases the heart rate, systemic vascular resistance, left ventricular contractile force, and left ventricular dP/dt. Oral doses of amiodarone sufficient to control cardiac arrhythmias do not depress the left ventricular EF, even in patients with reduced EF, and the EF and cardiac output may increase slightly. However, because of the antiadrenergic actions of amiodarone and because it does exert some negative inotropic action, it should be given cautiously, particularly intravenously, to patients with marginal cardiac compensation.

Pharmacokinetics.

Amiodarone is slowly, variably, and incompletely absorbed, with a systemic bioavailability of 25% to 65% (**see Table 36.4**). Plasma concentrations peak 3 to 6 hours after a single oral dose. There is a minimal first-pass effect, indicating minimal hepatic extraction. Elimination is by hepatic excretion into bile with some enterohepatic recirculation. Extensive hepatic metabolism occurs, with desethylamiodarone being a major metabolite. Both accumulate extensively in the liver, lung, fat, “blue” skin, and other tissues. The concentration in myocardium is 10 to 50 times that found in plasma. Plasma clearance of amiodarone is low, and renal excretion is negligible. Doses need not be reduced in patients with renal disease. Amiodarone and desethylamiodarone are not dialyzable. The volume of distribution is large but variable, with an average of 60 L/kg. Amiodarone is highly protein bound (96%), crosses the placenta (10% to 50%), and is found in breast milk.

The onset of action after IV administration generally occurs within 1 to 2 hours. After oral administration, the onset of action may require 2 to 3 days, often 1 to 3 weeks, and on occasion even longer. Loading doses reduce this time interval. Plasma concentrations relate well to oral doses during chronic treatment and average approximately 0.5 mg/mL for each 100 mg/day at doses between 100 and 600 mg/day. Amiodarone's elimination half-life is multiphasic, with an initial 50% reduction in plasma concentration 3 to 10 days after cessation of drug ingestion (probably representing elimination from well-perfused tissues), followed by a terminal half-life of 26 to 107 days (mean, 53 days), with most patients in the 40- to 55-day range. To achieve a steady-state concentration without a loading dose takes about 265 days. Interpatient variability in these pharmacokinetic parameters mandates close monitoring of the patient. Therapeutic serum concentrations range from 0.5 to 1.5 mg/mL. Greater suppression of arrhythmias may occur with up to 3.5 mg/mL, but the risk for side effects increases.

Dosage and Administration.

There is no standard dosing schedule for amiodarone applicable to all patients. One recommended approach is to treat with 800 to 1200 mg/day for 1 to 3 weeks, 400 mg/day for the next several weeks, and finally after 2 to 3 months of treatment, a maintenance dose of 300 mg or less per day (**see Table 36.4**). Maintenance drug can be given once or twice daily and should be titrated to the lowest effective dose to minimize the occurrence of side effects; in general, the earlier during drug loading that arrhythmia control is achieved, the lower the maintenance dose can be. Doses as low as 100 mg every other day can be effective in some patients. Regimens must be individualized for a given patient and clinical situation. To achieve more rapid loading and effect in emergencies, amiodarone can be administered intravenously at initial doses of 15 mg/min for 10 minutes, followed by 1 mg/min for 6 hours and then 0.5 mg/min for the remaining 18 hours and the next several days as necessary. Supplemental infusions of 150 mg over a 10-minute period can be used for breakthrough VT or VF. IV infusions can be continued safely for 2 to 3 weeks. IV amiodarone is generally well tolerated, even in patients with left ventricular dysfunction. Patients with depressed EF should receive IV amiodarone with great caution because of hypotension. High-dose oral loading (800 to 2000 mg/day to maintain trough serum concentrations of 2 to 3 mg/mL) may suppress ventricular arrhythmias in 1 to 2 days.

Indications.

Amiodarone has been used to suppress a wide spectrum of supraventricular and ventricular tachyarrhythmias in utero, in adults, and in children, including AV node and AV reentry, junctional tachycardia, atrial flutter and fibrillation, VT and VF associated with coronary artery disease, and hypertrophic cardiomyopathy. Success rates vary widely, depending on the population of patients, arrhythmia, underlying heart disease, length of follow-up, definition and determination of success, and other factors. In general, however, the efficacy of amiodarone equals or exceeds that of all other AADs and may be in the range of 60% to 80% for most supraventricular tachyarrhythmias and 40% to 60% for ventricular tachyarrhythmias. Amiodarone may be useful in improving survival in patients with hypertrophic cardiomyopathy, asymptomatic ventricular arrhythmias after MI, and ventricular tachyarrhythmia during and after resuscitation from cardiac arrest. Amiodarone given before open heart surgery, as well as postoperatively, has been shown to decrease the incidence of postoperative AF. Amiodarone is superior to class I AADs and sotalol in maintaining sinus rhythm in patients with recurrent AF.

Patients who have an ICD receive fewer shocks if they are treated with amiodarone than if treated with conventional drugs. Amiodarone has little effect on the pacing threshold but typically increases the electrical defibrillation threshold modestly and slows the rate of VT (sometimes below the ICD's detection rate).

Several prospective, randomized controlled trials and meta-analyses have demonstrated improved survival with amiodarone therapy versus placebo. However, amiodarone has been shown to result in inferior survival compared with ICD therapy, and in the SCD-HeFT population (NYHA Class II or III heart failure; EF, 35%), survival of amiodarone-treated patients was no different than for the placebo group. The drug may still be used adjunctively in ICD-treated patients to decrease the frequency of shocks from VT and VF episodes or to control supraventricular tachyarrhythmias that elicit device therapy (**see Chapter 37**). As noted, the drug can slow the ventricular rate during spontaneous VT episodes beneath the detection rate of the device; careful patient assessment and, occasionally, device reprogramming and testing are necessary. It also can be used to slow the ventricular rate during AF and atrial flutter.

Because of the serious nature of the arrhythmias being treated, the unusual pharmacokinetics of the

drug, and its adverse effects, consideration should be given to starting amiodarone therapy with the patient hospitalized and monitored for at least several days. Combining other AADs with amiodarone may improve efficacy in some patients.

Adverse Effects.

Adverse effects are reported by about 75% of patients treated with amiodarone for 5 years, and these effects compel stopping the drug in 18% to 37%. The most frequent side effects requiring drug discontinuation involve pulmonary and GI complaints or abnormal test results. Most adverse effects are reversible with dose reduction or cessation of treatment. Adverse effects are more common when therapy is continued in the long term and at higher doses. Of the noncardiac adverse reactions, pulmonary toxicity is the most serious[9]; in one study, it occurred in 33 of 573 patients between 6 days and 60 months of treatment, with three deaths. The mechanism is unclear but may involve a hypersensitivity reaction, widespread phospholipidosis, or both. Dyspnea, nonproductive cough, and fever are common symptoms, along with crackles on examination, hypoxia, abnormal gallium scan results, reduced carbon monoxide diffusion capacity (D_{LCO}), and radiographic evidence of pulmonary infiltrates. Amiodarone must be discontinued if such pulmonary inflammatory changes occur. Corticosteroids can be tried, but no controlled studies have been done to support their use. Up to 10% mortality results in patients with pulmonary inflammatory changes, often in those with unrecognized pulmonary involvement that is attributed to other causes and is thus allowed to progress. Chest radiography or pulmonary function testing, including D_{LCO}, at 3-month intervals for the first year and then twice a year for several years have been recommended. At maintenance doses lower than 300 mg/day, pulmonary toxicity is uncommon but can occur. Advanced age, high drug maintenance dose, and reduced predrug D_{LCO} are risk factors for the development of pulmonary toxicity. An unchanged D_{LCO} on therapy may be a negative predictor of pulmonary toxicity.

Although asymptomatic elevations in liver enzyme levels are found in most patients, amiodarone is not stopped unless values exceed two or three times normal in a patient with initially normal values. Cirrhosis occurs infrequently but may be fatal.[10] Neurologic dysfunction, photosensitivity (perhaps minimized by sunscreens), bluish skin discoloration, gastroenterologic disturbances, and hyperthyroidism (1% to 2%) or hypothyroidism (2% to 4%) can occur. Because amiodarone appears to inhibit the peripheral conversion of T_4 to T_3, chemical changes result and are characterized by a slight increase in T_4, reverse T_3, and thyroid-stimulating hormone (TSH) and a slight decrease in T_3 levels. The reverse T_3 concentration has been used as an index of drug efficacy. During hypothyroidism the TSH level increases greatly, whereas the level of T_3 increases in hyperthyroidism. Thyroid function tests should be performed approximately every 3 months for the first year while amiodarone is being taken and once or twice yearly thereafter, or sooner if symptoms develop that are consistent with thyroid dysfunction. Corneal microdeposits occur in almost 100% of adults receiving the drug longer than 6 months. More serious ocular reactions, including optic neuritis and atrophy with visual loss, have been reported but are rare, and causation by amiodarone has not been firmly established.[11]

Cardiac side effects include symptomatic bradycardias in approximately 2% of patients; worsening of ventricular tachyarrhythmias with the occasional development of TdP in 1% to 2%, possibly higher in women; and worsening of congestive heart failure in 2%. Possibly because of interactions with anesthetics, complications have been reported after open heart surgery, including pulmonary dysfunction, hypotension, severe bradycardia, hepatic dysfunction, and low cardiac output.

In general, the lowest possible maintenance dose of amiodarone that is still effective should be used to

avoid significant adverse effects. Many supraventricular arrhythmias can be managed successfully with daily dosages of 200 mg or less, whereas ventricular arrhythmias generally require higher doses. Adverse effects are uncommon at dosages of 200 mg/day or less but can still occur. Because of potential toxicity in various organ systems, special multidisciplinary amiodarone clinics have been used by some in an attempt to prevent adverse outcomes when the drug is used.[12]

Important interactions with other drugs occur, and when given concomitantly with amiodarone, the doses of warfarin, digoxin, and other AADs should be reduced by one third to one half and the patient observed closely. Drugs with synergistic actions, such as beta blockers or calcium channel blockers, must be given cautiously. The safety of amiodarone during pregnancy is controversial but categorized currently as class D. It should be used in pregnant patients only if no alternatives exist but should be avoided during breastfeeding.

Dronedarone

Dronedarone is approved by the FDA to facilitate maintenance of sinus rhythm in patients with atrial flutter and AF.

Electrophysiologic Actions.

As with amiodarone, dronedarone alters the activity of multiple cardiac ion channels (**see Tables 36.1, 36.2, 36.3, and 36.5**). It is a more potent blocker of I_{Na} than amiodarone and exhibits similar effects on the L-type calcium current. Blockade of both I_{Kr} and I_{Ks} by dronedarone is also similar to that by amiodarone, whereas its effect on atrial $I_{K.Ach}$ and antiadrenergic effects (via noncompetitive binding) are significantly more potent than for amiodarone. Sinus node function is depressed to a minor degree. Pacing and defibrillation thresholds are slightly increased.

Hemodynamic Effects.

Dronedarone has minimal effect on cardiac performance except in patients with compromised ventricular systolic function and should not be used in those with clinical signs of heart failure.

Pharmacokinetics.

Dronedarone is 70% to 90% absorbed after oral administration, with peak plasma concentrations achieved in 3 to 4 hours; absorption is enhanced by food (**see Table 36.4**). Unlike the very long half-life of amiodarone, the elimination half-life of dronedarone is 13 to 19 hours, with 85% of the drug being excreted unchanged in feces and the remainder in urine. Dronedarone is metabolized by and slightly inhibits the activity of CYP3A4 (as well as CYP2D6) and should not be used in conjunction with other agents that strongly inhibit these enzyme systems. There is minimal warfarin interaction, but dronedarone increases serum levels of dabigatran.

Dosage and Administration.

The standard recommended dose of dronedarone is 400 mg every 12 hours with food (**see Table 36.4**). No parenteral form is currently available.

Indications.

Dronedarone is indicated to facilitate cardioversion of atrial flutter or AF or to maintain sinus rhythm after restoration of sinus rhythm. It is slightly less effective than amiodarone and type IC drugs in this

regard.[13] In the ANDROMEDA (Antiarrhythmic Trial with Dronedarone in Moderate-to-Severe Congestive Heart Failure Evaluating Morbidity Decrease) study, dronedarone-treated patients had a mortality rate more than twice that of the placebo group (8.1% versus 3.8%). Similarly, in the PALLAS (Permanent Atrial Fibrillation Outcome Study Using Dronedarone on Top of Standard Therapy) trial, patients with permanent AF who were taking dronedarone had a greater than twofold higher risk for death, stroke, systemic embolism, or MI than did control patients. Thus the medication should not be used in patients with current or recent episodes of clinical heart failure or in those with permanent AF (as a rate control agent). Patients taking dronedarone should be evaluated periodically to ensure that permanent AF or heart failure has not developed.[14]

Adverse Effects.

A transient, predictable increase in serum creatinine, without adversely affecting actual glomerular filtration or other measures of renal function, occurs with standard dosing and is not a reason to alter the dose or to discontinue use of dronedarone. As noted, patients with New York Heart Association (NYHA) Class III or IV heart failure, as well as those with permanent AF, should not be given the drug because these patients have higher mortality. Patients with severe liver dysfunction should not generally receive dronedarone. The QT interval is predictably prolonged, but proarrhythmic effects from this or other mechanisms are rare (although sinus bradycardia is sometimes seen). Rash, photosensitivity, nausea, diarrhea, dyspepsia, headache, and asthenia have occurred in treated patients at higher frequency than in controls. Absence of the iodine molecule appears to account for the lower prevalence of lung and thyroid toxicity in dronedarone-treated patients than in those taking amiodarone. Dronedarone should not be used during pregnancy (category X, evidence or risk of fetal harm) and is possibly unsafe for breastfeeding.

Sotalol

Sotalol is a nonspecific beta adrenoceptor blocker without intrinsic sympathomimetic activity that prolongs repolarization. It is approved by the FDA to treat patients with life-threatening ventricular tachyarrhythmias and those with AF.

Electrophysiologic Actions.

Both the *d*- and *l*-isomers have similar effects on prolonging repolarization, whereas the *l*-isomer is responsible for almost all the beta-blocking activity (**see Tables 36.1, 36.2, 36.3, and 36.5**). Sotalol does not block alpha adrenoceptors and does not block I_{Na} (no membrane-stabilizing effects) but does prolong atrial and ventricular repolarization times by reducing I_{Kr}, thus prolonging the plateau of the action potential. Action potential prolongation is greater at slower rates (reverse use dependence). Resting membrane potential, action potential amplitude, and Vmax are not significantly altered. Sotalol prolongs atrial and ventricular refractoriness, A-H and QT intervals, and sinus cycle length (**see Chapter 37**).

Hemodynamics.

Sotalol exerts a negative inotropic effect only through its beta-blocking action. Although it can slightly increase the strength of contraction by prolonging repolarization, which occurs maximally at slow heart rates, the negative inotropic effects predominate. In patients with reduced cardiac function, sotalol can decrease the cardiac index, increase filling pressure, and precipitate overt heart failure. Therefore, it

must be used cautiously in patients with marginal cardiac compensation but is well tolerated in those with normal cardiac function.

Pharmacokinetics.

Sotalol is completely absorbed and not metabolized, thus making it 90% to 100% bioavailable. It is not bound to plasma proteins, is excreted unchanged primarily by the kidneys, and has an elimination half-life of 10 to 15 hours (**see Table 36.4**). Peak plasma concentrations occur 2.5 to 4 hours after oral ingestion. Over the dose range of 160 to 640 mg, sotalol displays dose proportionality with plasma concentration (usually in the range of 2.5 µg/mL). The dose must be reduced in patients with renal disease. The beta-blocking effect is half-maximal at 80 mg/day and maximal at 320 mg/day.

Dosage.

The typical oral dose is 80 to 160 mg every 12 hours, with 2 to 3 days between dose adjustments to attain a steady-state concentration and to monitor the ECG for arrhythmias and QT prolongation (**see Table 36.4**). Doses exceeding 320 mg/day can be used in patients when the potential benefits outweigh the risk for proarrhythmia. Because of its ability to prolong significantly the QT interval in some patients and cause TdP or provoke severe bradycardia, consideration should be given to inpatient initiation of the drug, especially in those with AF (in whom conversion to sinus bradycardia may cause syncope and/or further QT prolongation at slow rates), as well as in women (with longer baseline QT intervals).

Indications.

Approved by the FDA to treat patients with ventricular tachyarrhythmias and AF, sotalol is also useful to prevent recurrence of a wide variety of SVTs, including atrial flutter, AT, AV node reentry, and AV reentry (**see Chapter 37**). It slows the ventricular response to atrial tachyarrhythmias but rarely causes conversion to sinus rhythm. Sotalol appears to be more effective than conventional AADs and may be comparable to amiodarone in the treatment of patients with ventricular tachyarrhythmias, as well as in prevention of recurrences of AF after cardioversion. Sotalol has been used successfully to decrease the incidence of AF after cardiac surgery. It may be effective in fetal and pediatric patients and young adults with congenital heart disease.[15] Unlike most other antiarrhythmic drugs, sotalol may decrease the frequency of ICD discharges and reduce the defibrillation threshold but typically does not slow VT rates.

Adverse Effects.

Proarrhythmia is the most serious adverse effect. Overall, new or worsened ventricular tachyarrhythmias occur in approximately 4% of patients taking sotalol; this response is the result of TdP in approximately 2.5% but increases to 4% in patients with a history of sustained VT and is dose related (only 1.6% at 320 mg/day but 4.4% at 480 mg/day). This proarrhythmic effect was probably the cause of excess mortality in patients given *d*-sotalol (the enantiomer lacking a beta-blocking effect) after acute MI in the SWORD (Survival With Oral *d*-Sotalol) trial. Other adverse effects typically seen with other beta blockers also apply to sotalol. Sotalol should be used with caution or not at all in combination with other drugs that prolong the QT interval. However, such combinations have occasionally been used successfully.

Ibutilide

Ibutilide is an agent released for acute termination of episodes of atrial flutter and AF (**see Chapter 38**).

Electrophysiologic Actions.

As with other class III agents, ibutilide prolongs repolarization (**see Tables 36.1, 36.2, 36.3, and 36.5**). Although similar to other class III agents that block outward potassium currents, such as I_{Kr}, ibutilide is unique in that it also activates a slow inward sodium current. IV ibutilide causes mild slowing of the sinus rate and has minimal effects on AV conduction or QRS duration, but the QT interval is characteristically prolonged. Ibutilide has no significant effect on hemodynamics.

Pharmacokinetics.

Ibutilide is administered intravenously and has a large volume of distribution (**see Table 36.4**). Clearance is predominantly renal, with a drug half-life averaging 6 hours, but with considerable interpatient variability. Protein binding is approximately 40%. One of the drug's metabolites has weak class III effects.

Dosage and Administration.

Ibutilide is given as an IV infusion of 1 mg over 10 minutes (**see Table 36.4**). It should not be given in the presence of a QTc interval longer than 440 milliseconds or other drugs that prolong the QT interval or in patients with uncorrected hypokalemia, hypomagnesemia, or bradycardia. A second 1-mg dose may be given after the first dose is finished if the arrhythmia persists. Patients must have continuous electrocardiographic monitoring throughout the dosing period and for 6 to 8 hours thereafter because of the risk for ventricular arrhythmias. Pretreatment with IV magnesium may decrease the risk for ventricular arrhythmias and enhance efficacy in treating some atrial arrhythmias.[16] Up to 60% of patients with AF and 70% of those with atrial flutter convert to sinus rhythm after 2 mg of ibutilide has been administered.

Indications.

Ibutilide is indicated for termination of an established episode of atrial flutter or AF. It should not be used in patients with frequent short paroxysms of AF because it merely terminates episodes and is not useful for long-term prevention. Patients whose condition is hemodynamically unstable should proceed to direct-current (DC) cardioversion. Ibutilide has been used safely and effectively in patients who were already taking amiodarone or propafenone but should be used with caution in these cases. Ibutilide has been administered at transthoracic electrical cardioversion to increase the likelihood of termination of AF. In one study, all 50 patients given ibutilide before attempted electrical cardioversion achieved sinus rhythm, whereas only 34 of 50 who did not receive the drug converted to sinus rhythm. Of note, all 16 patients who did not respond to electrical cardioversion without ibutilide were successfully electrically cardioverted to sinus rhythm when a second attempt was made after ibutilide pretreatment.

Ibutilide prolongs accessory pathway refractoriness and can temporarily slow the ventricular rate during preexcited AF. The drug can also occasionally terminate episodes of organized AT, as well as sustained, uniform-morphology VT.

Adverse Effects.

The most significant adverse effect of ibutilide is QT prolongation–related TdP, which occurs in approximately 2% of patients given the drug (twice as often in women as in men). This effect develops within the first 4 to 6 hours of dosing, after which the risk is negligible. Thus, patients must undergo electrocardiographic monitoring for up to 8 hours after dosing. This requirement makes using ibutilide in emergency departments or private offices problematic. The safety of ibutilide during pregnancy has not

been well studied, and its use in pregnant women should be restricted to those in whom no safer alternative exists.

Dofetilide

Dofetilide is approved for the acute conversion of AF to sinus rhythm, as well as for chronic suppression of recurrent AF.

Electrophysiologic Actions.
The sole electrophysiologic effect of dofetilide is block of the rapid component of the delayed rectifier potassium current (I_{Kr}), important in repolarization (**see Tables 36.1, 36.2, 36.3, and 36.5**). This effect is more prominent in the atria than in the ventricles—30% increase in the atrial refractory period versus 20% in the ventricle. The effect of dofetilide on I_{Kr} is prolongation of refractoriness without slowing conduction, which is believed to be largely responsible for its antiarrhythmic effect. It is also responsible for prolongation of the QT interval on the ECG, which averages 11% but can be much greater. This effect on the QT interval is dose dependent and linear. No other important electrocardiographic changes are observed with the drug. It has no significant hemodynamic effects. Dofetilide is more effective than quinidine at converting AF to sinus rhythm. Its long-term efficacy is similar to that of other agents.[17]

Pharmacokinetics.
Oral dofetilide is absorbed well, and more than 90% is bioavailable. Its mean elimination half-life is 7 to 13 hours, with 50% to 60% excreted unchanged in urine (**see Table 36.4**). The remainder of the drug undergoes hepatic metabolism to inert compounds. Significant drug-drug interactions have been reported in patients taking dofetilide; cimetidine, verapamil, ketoconazole, and trimethoprim, alone or in combination with sulfamethoxazole, cause a significant elevation in the dofetilide serum concentration and should not be used with this drug.

Dosage and Administration.

Dofetilide is available only as an oral preparation. Dosing is from 0.125 to 0.5 mg twice daily and must be initiated in a hospital setting with continuous electrocardiographic monitoring to ensure that inordinate QT prolongation and TDP do not develop (**see Table 36.4**). Physicians must be specially certified to prescribe the drug. Its dosage must be decreased in the presence of impaired renal function or an increase in the QT interval of more than 15%, or 500 milliseconds. Dofetilide should not be given to patients with a creatinine clearance lower than 20 mL/min or a baseline QTc interval longer than 440 milliseconds.

Indications.

Oral dofetilide is indicated for prevention of episodes of supraventricular tachyarrhythmias, particularly atrial flutter and fibrillation. The role of dofetilide in the treatment of ventricular arrhythmias is less clear; it has been shown to decrease the defibrillation threshold in patients with an ICD, as well as decrease the frequency of ICD therapies for ventricular arrhythmias.

Adverse Effects.

The most significant adverse effect of dofetilide is QT interval prolongation–related TdP, which occurs in

2% to 4% of patients. Risk is highest in patients with a baseline prolonged QT interval, in those who are hypokalemic, in those taking some other agent that prolongs repolarization, and after conversion from AF to sinus rhythm.[18] Because the risk for TdP is highest at drug initiation, it should be used continuously and not as intermittent outpatient dosing. The drug is otherwise well tolerated, with few side effects. Its use in pregnancy has not been studied extensively, and it should probably be avoided in pregnant women if possible.

Class IV Agents

Calcium Channel Antagonists: Verapamil and Diltiazem

Verapamil, a synthetic papaverine derivative, is the prototype of a class of drugs that block the slow calcium channel and reduce $I_{Ca.L}$ in cardiac muscle (**see Chapter 34**). Diltiazem has electrophysiologic actions similar to those of verapamil. Nifedipine and other dihydropyridine agents exhibit minimal electrophysiologic effects at clinically used doses; these drugs are not discussed here.

Electrophysiologic Actions.

By blocking $I_{Ca.L}$ in all cardiac fibers, verapamil reduces the plateau height of the action potential, slightly shortens muscle action potential at pharmacologic concentrations, and slightly prolongs Purkinje fiber action potential (**see Tables 36.1, 36.2, 36.3, and 36.5**). It does not appreciably affect the action potential amplitude, Vmax of phase 0, or resting membrane voltage in cells that have fast-response characteristics related to I_{Na} (e.g., atrial and ventricular muscle, His-Purkinje system). Verapamil suppresses slow responses elicited by various experimental methods, as well as sustained triggered activity and early and late afterdepolarizations. Verapamil and diltiazem suppress electrical activity in the normal sinus and AV nodes. Verapamil depresses the slope of diastolic depolarization in sinus node cells, Vmax of phase 0, and maximum diastolic potential and prolongs conduction time and refractory periods of the AV node. The AV node–blocking effects of verapamil and diltiazem are more apparent at faster rates of stimulation (use dependence) and in depolarized fibers (voltage dependence). Verapamil slows activation of the slow channel and delays its recovery from inactivation.

Verapamil does exert some local anesthetic activity because the *d*-isomer of the clinically used racemic mixture exerts slight blocking effects on I_{Na}. The *l*-isomer blocks the slow inward current carried by calcium, as well as other ions, traveling through the slow channel. Verapamil does not affect calcium-activated adenosine triphosphatase (ATPase), nor does it block beta receptors, but it may block alpha receptors and potentiate vagal effects on the AV node. Verapamil can also cause other effects that indirectly alter cardiac electrophysiology, such as decreasing platelet adhesiveness or reducing the extent of myocardial ischemia.

In humans, verapamil prolongs conduction time through the AV node (the A-H interval) and lengthens AV nodal anterograde and retrograde refractory periods without affecting the P wave or QRS duration or the H-V interval. The spontaneous sinus rate may decrease slightly, an effect only partially reversed by atropine. More often, the sinus rate does not change significantly because verapamil causes peripheral vasodilation, transient hypotension, and reflex sympathetic stimulation, which mitigates any direct slowing effect that verapamil exerts on the sinus node. If verapamil is given to a patient who is also receiving a beta blocker, the sinus node discharge rate may slow because reflex sympathetic stimulation

is blocked. Verapamil does not exert a significant direct effect on atrial or ventricular refractoriness or on the anterograde or retrograde properties of accessory pathways. However, reflex sympathetic stimulation after IV verapamil administration may increase the ventricular response over the accessory pathway during AF in patients with WPW syndrome, sometimes dangerously so.

Hemodynamic Effects.

Because verapamil interferes with excitation-contraction coupling, it inhibits vascular smooth muscle contraction and causes marked vasodilation in coronary and other peripheral vascular beds. The reflex sympathetic effects of verapamil may reduce its marked negative inotropic action on isolated cardiac muscle, but the direct myocardial depressant effects of verapamil may predominate when the drug is given in high doses. In patients with well-preserved left ventricular function, combined therapy with propranolol and verapamil appears to be well tolerated, but beta blockade can accentuate the hemodynamic depressant effects produced by oral verapamil. Patients with reduced left ventricular function may not tolerate the combined blockade of beta receptors and calcium channels; thus, in these patients, verapamil and a beta blocker should be used in combination either cautiously or not at all. Verapamil reduces myocardial oxygen demand while decreasing coronary vascular resistance. Such changes may be indirectly antiarrhythmic.

Peak alterations in hemodynamic variables occur 3 to 5 minutes after completion of a verapamil injection, with the major effects dissipating within 10 minutes. Systemic resistance and mean arterial pressure decrease, as does left ventricular dP/dt_{max}, and left ventricular end-diastolic pressure increases. Heart rate, cardiac index, and mean pulmonary artery pressure do not change significantly in individuals with normal resting left ventricular systolic function. Thus the afterload reduction produced by verapamil significantly counterbalances its negative inotropic action, so the cardiac index may not be reduced. In addition, when verapamil slows the ventricular rate in a patient with tachycardia, hemodynamics may also improve. Nevertheless, caution should be exercised in giving verapamil to patients with severe myocardial depression or those receiving beta blockers or disopyramide because hemodynamic deterioration may progress in some patients.

Pharmacokinetics.

After single oral doses of verapamil, measurable prolongation of AV nodal conduction time occurs in 30 minutes and lasts 4 to 6 hours (**see Table 36.4**). After IV administration, AV nodal conduction delay occurs within 1 to 2 minutes and A-H interval prolongation is still detectable after 6 hours. After oral administration, absorption is almost complete, but its overall bioavailability of 20% to 35% suggests substantial first-pass metabolism in the liver, particularly of the *l*-isomer. Verapamil's elimination half-life is 3 to 8 hours, with up to 70% of the drug excreted by the kidneys. Norverapamil is a major metabolite that may contribute to the electrophysiologic actions of verapamil. Serum protein binding is approximately 90%. With diltiazem, the percentage of heart rate reduction in AF is related to its plasma concentration.

Dosage and Administration.

For acute termination of SVT or rapid achievement of ventricular rate control during AF, the most common IV dose of verapamil is 10 mg infused over 1 to 2 minutes while cardiac rhythm and blood pressure are monitored (**see Table 36.4**). A second injection of an equal dose may be given 30 minutes later. The initial effect achieved with the first bolus injection, such as slowing of the ventricular response during AF, can be maintained by continuous infusion of the drug at a rate of 0.005 mg/kg/min. The oral dose is 240 to 480 mg/day in divided doses. Diltiazem is given intravenously at a dose of 0.25 mg/kg as a

bolus over 2 minutes, with a second dose in 15 minutes if necessary. Because it is generally better tolerated (less hypotension) with long-term administration, such as for control of the ventricular rate during AF, diltiazem is preferred over verapamil in this setting. Significant hypotension resulting from intravenous diltiazem can be countered by volume expansion or the judicious use of a pure vasoconstrictor agent such as phenylephrine. Orally, doses must be adjusted to the patient's needs, with a 120- to 360-mg range. Various long-acting preparations (once daily) are available for verapamil and diltiazem.

Indications.

After simple vagal maneuvers have been tried and adenosine has been given, IV verapamil or diltiazem is the next treatment of choice for termination of sustained AV node reentry or orthodromic AV reciprocating tachycardia associated with an accessory pathway (**see Chapter 37**). Verapamil is as effective as adenosine for termination of these arrhythmias. Assuming that the patient is stable, verapamil should definitely be tried before termination is attempted by digitalis administration, pacing, electrical DC cardioversion, or acute blood pressure elevation with vasopressors. Verapamil and diltiazem terminate 60% to 90% or more episodes of paroxysmal SVT within several minutes. Verapamil may also be of use in some fetal SVTs. Although IV verapamil has been given along with IV propranolol, this combination should be used only with great caution because of combined adverse hemodynamic effects.

Verapamil and diltiazem decrease the ventricular response over the AV node during AF or atrial flutter, possibly converting a small number of episodes to sinus rhythm, particularly if the atrial flutter or AF is of recent onset. In addition, verapamil may prevent early recurrence of AF after electrical cardioversion. AF can occur in some patients with atrial flutter after verapamil administration. As noted earlier, in patients with preexcited ventricular complexes during AF associated with WPW syndrome, IV verapamil may accelerate the ventricular response; therefore the IV route is contraindicated in this situation. Verapamil can terminate some ATs. Even though verapamil can often terminate an idiopathic left septal VT, hemodynamic collapse can occur if IV verapamil is given to patients with the more common forms of VT because these generally occur in the setting of decreased left ventricular systolic function. A general rule for avoiding complications, however, is not to administer verapamil intravenously to any patient with wide-QRS tachycardia unless one is certain of the nature of the tachycardia and its probable response to verapamil.

Orally, verapamil or diltiazem can prevent the recurrence of AV node reentrant and orthodromic AV reciprocating tachycardias associated with an accessory pathway, as well as help maintain a decreased ventricular response during atrial flutter or AF in patients without an accessory pathway. Verapamil has not generally been effective in treating patients who have recurrent ventricular tachyarrhythmias, although it may suppress some forms of VT, such as left septal VT (noted earlier). It can also be useful in about two thirds of patients with idiopathic VT that has a left bundle branch block morphology (right ventricular outflow tract origin), patients with hypertrophic cardiomyopathy who have experienced cardiac arrest, those with a short-coupled variant of polymorphic VT, and patients with ventricular arrhythmias related to coronary artery spasm. Calcium channel blockers have not been shown to reduce mortality or to prevent sudden cardiac death in patients after acute MI, except for diltiazem in those with non–ST-segment elevation infarctions (**see Chapter 60**).

Adverse Effects.

Verapamil must be used cautiously in patients with significant hemodynamic impairment or in those receiving beta blockers, as noted earlier. Hypotension, bradycardia, AV block, and asystole are more

likely to occur when the drug is given to patients who are already receiving beta-blocking agents. Hemodynamic collapse has been noted in infants, and verapamil should be used cautiously in children younger than 1 year. Verapamil should also be used with caution in patients with sinus node abnormalities because marked depression of sinus node function or asystole can result in some of these patients. IV isoproterenol, calcium, glucagon, dopamine, or atropine, which may be only partially effective, or temporary pacing may be necessary to counteract some of the adverse effects of verapamil. Isoproterenol may be more effective for the treatment of bradyarrhythmias, and calcium may be used for the treatment of hemodynamic dysfunction secondary to verapamil. AV node depression is common in overdoses. Contraindications to the use of verapamil and diltiazem include the presence of advanced heart failure, second- or third-degree AV block without a pacemaker in place, AF and anterograde conduction over an accessory pathway, significant sinus node dysfunction, most VTs, cardiogenic shock, and other hypotensive states. Although these drugs should probably not be used in patients with overt heart failure, if it is caused by one of the supraventricular tachyarrhythmias noted earlier, verapamil or diltiazem may restore sinus rhythm or significantly decrease the ventricular rate and thereby lead to hemodynamic improvement. Also, verapamil can decrease the excretion of digoxin by approximately 30%. Hepatotoxicity may occur on occasion. Verapamil crosses the placental barrier; its use in pregnancy has been associated with impaired uterine contraction, fetal bradycardia, and possibly fetal digital defects. It should therefore be used only if no effective alternatives exist.

Other Antiarrhythmic Agents

Adenosine

Adenosine is an endogenous nucleoside present throughout the body and has been approved by the FDA to treat patients with SVTs.

Electrophysiologic Actions.
Adenosine interacts with A_1 receptors present on the extracellular surface of cardiac cells and activates K^+ channels ($I_{K.Ach}$, $I_{K.Ado}$) in a manner similar to that produced by acetylcholine (**see Tables 36.1, 36.2, 36.3, and 36.5**). The increase in K^+ conductance shortens the atrial APD, hyperpolarizes the membrane potential, and decreases atrial contractility. Similar changes occur in the sinus and AV nodes. In contrast to these direct effects mediated through the guanine nucleotide regulatory proteins G_i and G_o, adenosine antagonizes catecholamine-stimulated adenylate cyclase to decrease accumulation of cyclic adenosine monophosphate (AMP) and to decrease $I_{Ca.L}$ and the pacemaker current I_f in sinus node cells along with a decrease in Vmax. Shifts in the pacemaker site within the sinus node and sinus exit block may occur. Adenosine slows the sinus rate in humans, followed within seconds by a reflex increase in the sinus rate. In the AV node, adenosine produces transient prolongation of the A-H interval, often with transient first-, second-, or third-degree AV node block lasting up to a few seconds. The delay in AV nodal conduction is rate dependent. His-Purkinje conduction is not generally affected directly. Adenosine does not affect conduction in normal accessory pathways. Conduction may be blocked in unusual accessory pathways that have long conduction times or decremental conduction properties. Patients with heart transplants exhibit a supersensitive response to adenosine. Adenosine may mediate the phenomenon of ischemic preconditioning.

Pharmacokinetics.

Adenosine is removed from the extracellular space by washout, enzymatically by degradation to inosine, by phosphorylation to AMP, or by reuptake into cells through a nucleoside transport system (**see Table 36.4**). The vascular endothelium and erythrocytes contain these elimination systems, which result in very rapid clearance of adenosine from the circulation. Its elimination half-life is 1 to 6 seconds. Most of adenosine's effects are produced during its first passage through the circulation. Important drug interactions occur; methylxanthines are competitive antagonists, and therapeutic concentrations of theophylline totally block the exogenous effects of adenosine. Dipyridamole is a nucleoside transport blocker that blocks reuptake of adenosine, thus delaying its clearance from the circulation or interstitial space and potentiating its effect. Smaller adenosine doses should be used in patients receiving dipyridamole.

Dosage and Administration.

To terminate tachycardia, a bolus of adenosine is rapidly injected intravenously at doses of 6 to 12 mg, followed by a flush (**see Table 36.4**). Pediatric (<50 kg) dosing should be 0.05 to 0.3 mg/kg. When it is injected into a central vein and in patients after heart transplantation or those receiving dipyridamole, the initial dose should be reduced to 3 mg. Transient sinus slowing or AV node block results but lasts less than 5 seconds. Doses higher than 18 mg are unlikely to revert a tachycardia and should not be used.

Indications.

Adenosine has become the drug of first choice to terminate an SVT acutely, such as AV node or AV reentry (**see Chapter 37**), and is useful in pediatric patients. Adenosine can produce AV nodal block or terminate ATs and sinus node reentry. It results in only transient AV block during atrial flutter or fibrillation and is thus useful only for diagnosis, not therapy. Adenosine terminates a group of VTs whose maintenance depends on adrenergic drive, which is most often located in the right ventricular outflow tract but can be found at other sites as well; however, idiopathic left septal VT rarely responds. When properly administered, adenosine usually causes transient hypotension, chest discomfort, and dyspnea; if tachycardia persists in the absence of these effects, the drug may not have been given correctly. Adenosine has less potential than verapamil for producing prolonged hypotension, should tachycardia persist after injection.

Doses as low as 2.5 mg terminate some tachycardias; doses of 12 mg or less terminate 92% of SVTs, usually within 30 seconds. Successful termination rates with adenosine are comparable to those achieved with verapamil. Because of its effectiveness and extremely short duration of action, adenosine is preferable to verapamil in most cases, particularly in patients who have previously received IV beta adrenoceptor blockers, in those with poorly compensated heart failure or severe hypotension, and in neonates. Verapamil might be chosen first in patients receiving drugs such as theophylline (which is known to interfere with adenosine's actions or metabolism), in patients with active bronchoconstriction, and in those with inadequate venous access.

Adenosine may be useful to help differentiate among causes of wide-QRS tachycardias because it terminates many SVTs with aberrancy or reveals the underlying atrial mechanism and does not block conduction over an accessory pathway or terminate most VTs. In rare cases, however, adenosine terminates some VTs, characteristically those of right ventricular outflow tract origin as noted earlier, and therefore tachycardia termination is not completely diagnostic of an SVT. This agent may predispose to the development of AF and might transiently increase the ventricular response in patients with AF

conducting over an accessory pathway. Adenosine may also be useful in differentiating conduction over the AV node from that over an accessory pathway during ablative procedures designed to interrupt the accessory pathway. However, this distinction is not absolute because adenosine can block conduction in slowly conducting accessory pathways and does not always produce block in the AV node.

Adverse Effects.

Transient side effects occur in almost 40% of patients with SVT given adenosine and usually consist of flushing, dyspnea, and chest pressure. These symptoms are fleeting, lasting less than 1 minute, and are well tolerated. PVCs, transient sinus bradycardia, sinus arrest, and AV block are common when an SVT is terminated abruptly. AF is occasionally observed (12% in one study) with adenosine administration, perhaps because of the drug's effect in shortening atrial refractoriness. Induction of AF can be problematic in patients with WPW syndrome and rapid AV conduction over the accessory pathway.

Digoxin

Cardiac actions of digitalis glycosides have been recognized for centuries. In adults, digoxin is used mainly for control of the ventricular rate during AF, whereas its use in pediatrics is in a broader range of arrhythmias. Use of digoxin has decreased because of the availability of agents with greater and more reliable efficacy and a wider therapeutic to toxic drug concentration range. Its use is generally discouraged in adults.[19]

Electrophysiologic Actions.

Digoxin acts mainly through the autonomic nervous system, in particular by enhancing both central and peripheral vagal tone. These actions are confined largely to slowing of the sinus node discharge rate, shortening of atrial refractoriness, and prolongation of AV nodal refractoriness (**see Tables 36.1, 36.2, 36.3, and 36.5**). Electrophysiologic effects on the His-Purkinje system and ventricular muscle are minimal, except with toxic concentrations. In studies of denervated hearts, digoxin has relatively little effect on the AV node and causes a mild increase in atrial refractoriness.

The sinus rate and P wave duration are minimally changed in most patients taking digoxin. The sinus rate may decrease in patients with heart failure whose left ventricular performance is improved by the drug; individuals with significant underlying sinus node disease also have slower sinus rates or even sinus arrest. Similarly, the PR interval is generally unchanged, except in patients with underlying AV node disease. The QRS and QT intervals are unaffected. The characteristic ST and T wave abnormalities seen with use of digoxin do not represent toxicity.

Pharmacokinetics.

IV digoxin yields some electrophysiologic effect within minutes, with a peak effect occurring after 1.5 to 3 hours (**see Table 36.4**). After oral dosing, the peak effect occurs in 4 to 6 hours. The extent of digoxin absorption after oral administration varies according to the preparation; tablet forms are 60% to 75% absorbed, whereas encapsulated gel forms are almost completely absorbed. Ingestion of cholestyramine or an antacid preparation at the same time as digoxin ingestion decreases its absorption. The serum half-life of digoxin is 36 to 48 hours, and the drug is excreted unchanged by the kidneys.

Dosage and Administration.

In acute loading doses of 0.5 to 1.0 mg, digoxin can be given orally or intravenously (**see Table 36.4**). Chronic daily oral dosing should be adjusted on the basis of clinical indications and the extent of renal dysfunction. Most patients require 0.125 to 0.25 mg/day as a single dose. However, some patients undergoing renal dialysis need as little as 0.125 mg every other day, whereas young patients may require as much as 0.5 mg/day. Serum digoxin levels may be used to monitor compliance with therapy, as well as to determine whether digitalis toxicity is the cause of new symptoms compatible with the diagnosis. However, routine monitoring of digoxin levels is not warranted in patients whose ventricular rate is controlled during AF and who have no symptoms of toxicity.

Indications.

Digoxin can be used intravenously to slow the ventricular rate during atrial fibrillation (AF) and atrial flutter; it was formerly used in an attempt to convert SVTs to sinus rhythm, but its onset of action is much slower and its success rate less than that of adenosine, verapamil, or beta blockers. Thus it is now rarely used in this fashion. Digoxin is more often used orally to control the ventricular rate in permanent ("chronic") AF. When a patient with AF is at rest and vagal tone predominates, the ventricular rate can be maintained between 60 and 100 beats/min in 40% to 60% of cases. However, when the patient begins to exercise, the decrease in vagal tone and increase in adrenergic tone combine to diminish the beneficial effects of digoxin on AV nodal conduction. Patients can experience a marked increase in ventricular rate with even mild exertion. Digoxin is therefore rarely used as a single agent to control the ventricular rate in AF. The drug has little ability to prevent episodes of paroxysmal AF or to control the ventricular rate during episodes and may even provoke episodes in patients with so-called vagal AF. Furthermore, digoxin is no more effective than placebo in terminating episodes of acute- or recent-onset AF.

Adverse Effects.

One major reason that use of digoxin has decreased is its potential for serious adverse effects and the narrow window between therapeutic and toxic concentrations. Digitalis toxicity produces various symptoms and signs, including headache, nausea and vomiting, altered color perception, halo vision, and generalized malaise. Less common but more serious than these are digitalis-related arrhythmias, which include bradycardias related to a greatly enhanced vagal effect (e.g., sinus bradycardia or arrest, AV node block) and tachyarrhythmias that may be caused by DAD-mediated triggered activity (e.g., atrial, junctional, and fascicular or ventricular tachycardia). Worsening renal function, advanced age, hypokalemia, chronic lung disease, hypothyroidism, and amyloidosis increase a patient's sensitivity to digitalis-related arrhythmias. The diagnosis of toxicity can be confirmed by determination of the serum digoxin level. Therapy for most bradycardias consists of withdrawal of digoxin; atropine or temporary pacing may be needed in symptomatic patients. Phenytoin can be used to control atrial tachyarrhythmias, whereas lidocaine has been successful in treating infranodal tachycardias. Life-threatening arrhythmias can be treated with digoxin-specific antibody fragments. Electrical DC cardioversion should be performed only when absolutely necessary in a digitalis-toxic patient because life-threatening VT or VF can result and can be difficult to control. Some data incriminate digoxin in increasing mortality in patients with AF.[19]

Ranolazine

Ranolazine, approved by the FDA for the treatment of chronic angina, has significant electrophysiologic properties. It has been shown to decrease the incidence of AF, SVT, and ventricular arrhythmias relative to controls in trials of the drug's antianginal effects.

Electrophysiologic Actions.

Ranolazine blocks I_{Kr}, as well as the late Na current; at higher concentrations, the L-type Ca current is mildly affected (**see Tables 36.1, 36.2, 36.3, 36.5**). The drug prolongs atrial and ventricular refractoriness and induces postrepolarization refractoriness; the P wave, PR interval, and QRS are unaffected, but the QT interval is mildly prolonged. Unlike other I_{Kr}-blocking drugs, ranolazine does not induce EADs. Its effects are more pronounced on atrial than on ventricular myocardium, and the drug shows promise for the treatment of AF, particularly when combined with dronedarone.[20]

Hemodynamic Effects.

Ranolazine has no important hemodynamic effects; it does not appear to produce meaningful changes in contractility or vascular resistance.

Pharmacokinetics.

Absorption of oral ranolazine is mediated in part by the P-glycoprotein system, modulators of which may increase or decrease drug exposure. About 75% of a dose is bioavailable, with peak levels reached in 2 to 5 hours (**see Table 36.4**). Absorption is not affected by food. Its half-life is approximately 7 hours; hepatic metabolism to minimally or wholly inactive products occurs via the CYP3A and, to a lesser extent, the CYP2D6 pathways. Approximately 75% of the drug is excreted in urine, the remainder in feces.

Dosage and Administration.

The typical oral dose of ranolazine is 500 mg twice daily, to a maximum of 1000 mg twice daily. The dose should be decreased in the setting of moderate liver disease. It should not be used in conjunction with strong inhibitors of CYP3A, which could increase the drug's serum concentration threefold.

Adverse Effects.

The most widely known potential adverse effect of ranolazine is QTc prolongation, which averages 6 to 15 milliseconds (sometimes more in patients with severe liver failure), because of inhibition of I_{Kr}. Despite this effect on the QT interval, TdP is rare, probably in part because of only modest QT prolongation combined with the drug's inhibition of the late inward Na current, which mitigates the QT effect. As noted, ranolazine does not cause EADs or increases in transmural dispersion of refractoriness, which are believed to be prerequisites for torsades. Ranolazine produces a mild elevation in measured serum creatinine (0.1 mg/dL) without changing the actual glomerular filtration rate. The drug is pregnancy category C; its concentration in breast milk is unknown.

Antiarrhythmic Effects of Nonantiarrhythmic Drugs

Several medications commonly used for other indications also have some degree of antiarrhythmic effect. In some cases, physicians can use these drugs for their standard indications and achieve additional, although often small, amounts of benefit in treating the patient's rhythm disturbance. These drugs include angiotensin-converting enzyme (ACE) inhibitors and angiotensin receptor–blocking agents; aldosterone antagonists such as eplerenone, statins, and omega-3 fatty acids (prevention of sudden death); and these same classes of drugs with the addition of nondihydropyridine calcium channel blockers and ranolazine (less AF and perhaps VF). The mechanisms whereby these drugs exert their attenuating effect on arrhythmias is not clear in most cases, and they should not be relied on as the sole form of antiarrhythmic

therapy. In patients who have arrhythmias, as well as another disorder that requires drug therapy (hypertension, heart failure), one of these medications may be preferable to agents that treat the primary disorder but do not possess antiarrhythmic effects.

New Antiarrhythmic Agents

Eleclazine

Eleclazine hydrochloride (dihydrobenzoxazepinone) is selective blocker of late I_{Na} with a half maximal inhibitory concentration (IC50) value of 0.7 μM and minimal effect on other currents in the heart. In experimental models of LQT3, eleclazine shortens the APD and reduces the dispersion of repolarization.[21] The drug (currently not available for clinical use) is being developed for use in LQT3 and hypertrophic cardiomyopathy.

Vernakalant

Vernakalant is a mixed potassium and sodium channel blocker used intravenously for conversion of AF to sinus rhythm. The drug, currently available in Europe, is a use-dependent inhibitor of I_{Na} and blocks the atrial-specific potassium current I_{Kur} as well as $I_{K.ACh}$ and I_{to}. Vernakalant prolongs atrial APD and refractoriness. The safety for IV conversion of AF (initial dose of 3 mg/kg over 10 minutes followed by 2 mg/kg over 15 minutes for persistent arrhythmia) have been demonstrated in the Atrial Arrhythmia Conversion Trials 1 and 3 (ACT1, ACT3).[22] The drug was well tolerated in these studies, with minimal side effects and no TdP episodes. Transient hypotension and bradycardia were observed in 5% to 10% of patients.

Electrotherapy for Cardiac Arrhythmias

Direct-Current Electrical Cardioversion

Cardioversion is a general term used to indicate the termination of an arrhythmia, usually a tachyarrhythmia, by various means, including electrical, pharmacologic, or manual/surgical. *Electrical cardioversion* refers to the delivery of an electrical shock to the heart to terminate a tachycardia, flutter, or fibrillation and includes the technique of both synchronous cardioversion (see below) and defibrillation. It offers obvious advantages over drug therapy because under conditions optimal for close supervision and monitoring, a precisely regulated “dose” of electricity can restore sinus rhythm immediately and safely. The distinction between supraventricular and ventricular tachyarrhythmias, crucial to the proper medical management of arrhythmias, becomes less significant, and the time-consuming titration of drugs with potential side effects is obviated.

Mechanisms.

Electrical cardioversion is most effective in terminating tachycardias related to reentry, such as atrial flutter and many cases of atrial fibrillation (AF), AV node reentry, reciprocating tachycardias associated with WPW syndrome, most forms of VT, ventricular flutter, and VF. The electrical shock, by depolarizing all excitable myocardium and possibly by prolonging refractoriness, interrupts reentrant circuits and

establishes electrical homogeneity, which terminates reentry. The mechanism by which a shock successfully terminates VF has not been completely explained. If the precipitating factors are no longer present, interruption of the tachyarrhythmia for only the brief time produced by the shock may prevent its return for long periods, even though the anatomic and electrophysiologic substrates required for the tachycardia are still present.

Tachycardias thought to be caused by disorders of impulse formation (automaticity) include parasystole, some forms of AT, junctional tachycardia (with or without digitalis toxicity), accelerated idioventricular rhythm, and relatively uncommon forms of VT (**see Chapters 34 and 39**). An attempt to cardiovert these tachycardias electrically is not indicated in most cases because they typically recur within seconds after the shock; release of endogenous catecholamines consequent to the shock can further exacerbate the arrhythmia. It has not been established whether cardioversion can terminate tachycardias caused by enhanced automaticity or triggered activity.

Technique

Synchronous cardioversion refers to a specific technique of delivering an electrical shock, usually of lower energy and timed to the QRS complex ("R wave"), to avoid the vulnerable period of the T wave. Before elective synchronous cardioversion, careful physical examination should be performed, including palpation of limb pulses and inspection of the chest wall and airway. A 12-lead ECG is usually obtained before and after cardioversion, as well as a rhythm strip during the electroshock. The patient, who should be informed completely about what to expect, is in a fasting state and metabolically balanced; that is, respiratory function and electrolyte values should be normal, with no evidence of drug toxicity. Withholding of digitalis for several days before elective cardioversion in patients without clinical evidence of digitalis toxicity is not necessary, although patients in whom digitalis toxicity is suspected should not be electrically cardioverted until this situation has been corrected. Administration of maintenance antiarrhythmic drugs 1 to 2 days before planned electrical cardioversion of patients with AF can revert some patients to sinus rhythm, help prevent recurrence of AF once sinus rhythm is restored, and assist in determining the patient's tolerance of the drug for long-term use.[23] There is also evidence that statin drugs,[24] as well as ACE inhibitors and angiotensin receptor blockers, may help prevent recurrence of fibrillation, especially in patients with ventricular dysfunction.

Self-adhesive patches applied in the standard apicoanterior or anteroposterior paddle positions have transthoracic impedances similar to those of paddles and are useful in elective synchronous cardioversions or other situations in which time is available for their application. Patches 12 to 13 cm in diameter can be used to deliver maximum current to the heart, but the benefits of these patches versus patches 8 to 9 cm in diameter have not been clearly established. Larger patches may distribute the intracardiac current over a wider area and reduce shock-induced myocardial injury.

A synchronized shock (i.e., one delivered during the QRS complex; **Fig. 36.1**) is used for all cardioversions except for very rapid ventricular tachyarrhythmias, such as ventricular flutter or VF. For defibrillation of the latter, energies greater than those for synchronous cardioversion are required, and synchronization is not necessary because there is no vulnerable period of the T wave to avoid. Although generally minimal, shock-related myocardial damage increases directly with increases in applied energy, and thus the minimum effective shock should be used. Therefore, shocks are "titrated" when the clinical situation permits. Except for AF, shocks in the range of 25 to 50 joules (J) successfully terminate most SVTs and should be tried initially. If the shock is unsuccessful, a second shock of higher energy can be delivered. The starting level to terminate AF with older monophasic machines should be no less than 100

J, but with newer biphasic systems, a shock as low as 25 J may succeed. Delivered energy can be increased in stepwise fashion; up to 360 J can be used safely. It is critical to remember to resynchronize the defibrillator to the QRS complex after an unsuccessful shock before delivery of another shock to avoid initiation of VF (machines typically revert to the asynchronous mode after each shock). Anteroposterior patches may have a higher efficacy rate by placing more of the atrial mass in the shock vector than is the case with apicoanterior patches.[25] If a shock of 360 J fails to convert the rhythm, repeated shocks at the same energy may succeed by decreasing chest wall impedance; reversing patch polarity can occasionally help as well. Administration of ibutilide has been shown to facilitate electrical cardioversion of AF to sinus rhythm. Intracardiac or transesophageal defibrillation can be tried if all attempts at external cardioversion fail. For patients with stable VT, starting levels in the range of 25 to 50 J can be used. If there is some urgency to terminate the tachyarrhythmia, the clinician can begin with higher energies. To terminate VF, 100 to 200 J (biphasic; 200 to 360 J with monophasic machines) is generally used, although much lower energies (<50 J) terminate VF when the shock is delivered soon after onset of the arrhythmia, for example, using adhesive patches in the electrophysiology laboratory.

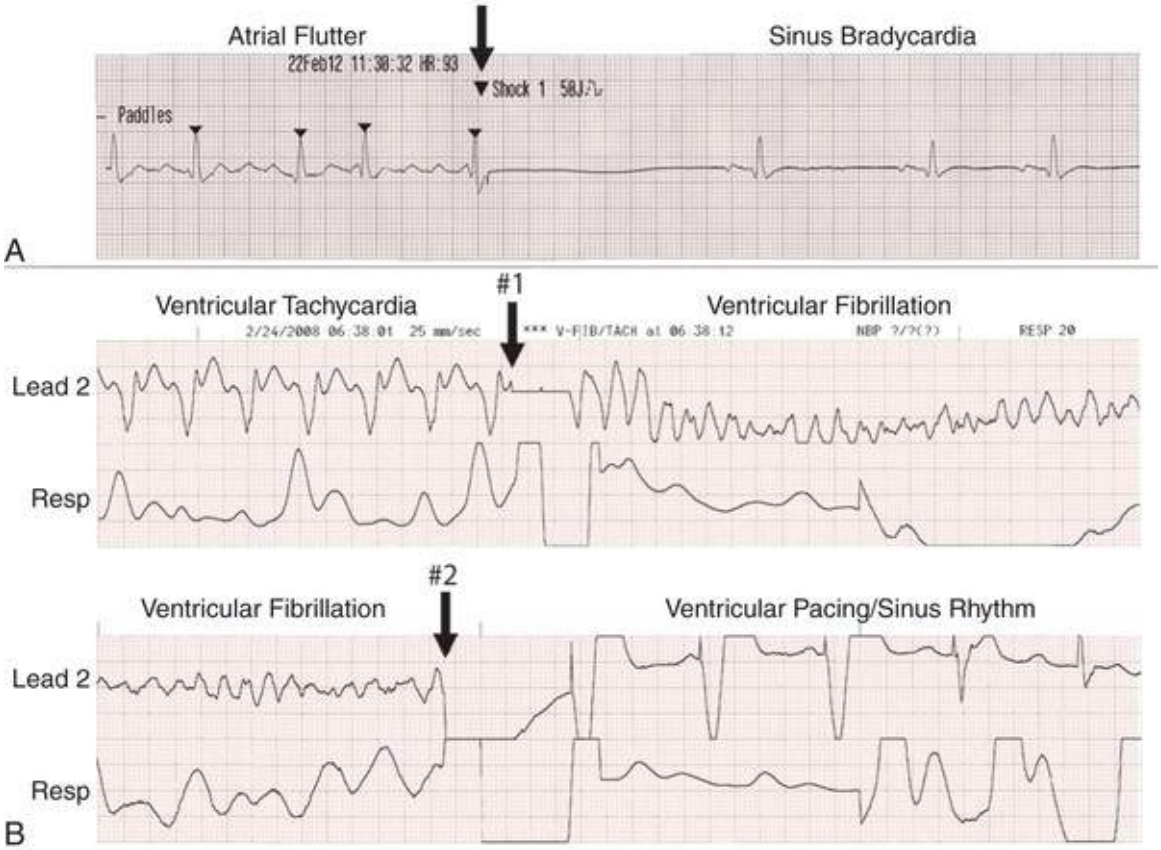

FIGURE 36.1 Cardioversions. In **A,** a synchronized shock (note the synchronization mark in the apex of the QRS complex, *arrowhead*) during atrial flutter is followed by sinus bradycardia. In **B, top panel,** a shock (#1) is delivered during VT but asynchronously (on the T wave); this results in VF, which is then treated with a second, asynchronous shock (#2) that results in sinus rhythm with tracked ventricular pacing. *Resp,* Respirations.

During elective cardioversion, a short-acting barbiturate such as methohexital, a sedative such as propofol, or an amnesic such as diazepam or midazolam can be used. A physician skilled in airway management should be in attendance; an IV route should be established; and pulse oximetry, the ECG, and blood pressure should be monitored. All equipment necessary for emergency resuscitation should be immediately accessible. Before cardioversion, 100% oxygen may be administered for 5 to 15 minutes by

nasal cannula or facemask and is continued throughout the procedure. Manual ventilation of the patient may be necessary to avoid hypoxia during periods of deepest sedation. Adequate sedation of the patient undergoing even urgent cardioversion is essential.

In up to 5% of patients with AF, sinus rhythm cannot be restored by external countershock despite all the preceding measures, including ibutilide pretreatment and biphasic shocks. It is important to distinguish between inability to attain sinus rhythm, indicating failure of the shock to convert the arrhythmia, and inability to maintain sinus rhythm after transient termination of fibrillation; the latter condition (early reinitiation of AF) does not respond to higher-energy shocks because fibrillation has already been terminated but quickly recurs. Pretreatment with an AAD may help maintain sinus rhythm after subsequent shocks. Patients in whom AF simply cannot be terminated with an external shock tend to be very obese or have severe obstructive lung disease. In such patients, internal cardioversion can be performed with the use of specially configured catheters that have multiple large electrodes covering several centimeters of the distal portion of the catheter for distributing the shock energy. By standard percutaneous access, these catheters can be situated in the lateral part of the right atrium and coronary sinus to achieve a shock vector across most of the atrial mass. With such configurations, internal shocks of 2 to 15 J can terminate AF in more than 90% of patients whose arrhythmia was refractory to transthoracic shock. Esophageal cardioversion has also been reported. Rarely, simultaneous shocks from two defibrillators have been reported to terminate refractory VF.

Indications

As a general rule, any nonsinus tachycardia that produces hypotension, congestive heart failure, mental status changes, or angina and does not respond promptly to medical management should be terminated electrically. Very rapid ventricular rates in patients with AF and WPW syndrome are often best treated by electrical cardioversion. In almost all cases, the patient's hemodynamic status improves after cardioversion. Rarely, a patient may experience hypotension, reduced cardiac output, or congestive heart failure after the shock. This problem may be related to complications of the cardioversion, such as embolic events, myocardial depression resulting from the anesthetic agent or the shock itself, hypoxia, lack of restoration of left atrial contraction despite return of electrical atrial systole, or postshock arrhythmias. DC countershock of digitalis-induced tachyarrhythmias is contraindicated (see earlier).

Favorable candidates for electrical cardioversion of AF include patients who (1) have symptomatic AF of less than 12 months' duration, (2) continue to have AF after the precipitating cause has been removed (e.g., after treatment of thyrotoxicosis), (3) have a rapid ventricular rate that is difficult to slow, or (4) have symptoms of decreased cardiac output (e.g., fatigue, lightheadedness, dyspnea) attributable to lack of atrial contraction's contribution to ventricular filling. In patients who have indications for chronic warfarin therapy to prevent stroke, the hope of avoiding anticoagulation by restoring sinus rhythm is not a reason to attempt cardioversion, because these patients are still at increased risk for thromboembolic events. Several large trials have shown that maintenance of sinus rhythm confers no survival advantage over rate control and anticoagulation; thus not all patients with newly discovered AF warrant an attempt at restoration of sinus rhythm. Treatment must be determined individually (**see Chapter 38**).

Unfavorable candidates include patients with (1) digitalis toxicity; (2) no symptoms and a well-controlled ventricular rate without therapy; (3) sinus node dysfunction and various unstable supraventricular tachyarrhythmias or bradyarrhythmias—often bradycardia-tachycardia syndrome—in whom AF finally develops and is maintained, which in essence represents a cure for sick sinus syndrome; (4) little or no symptomatic improvement with normal sinus rhythm who promptly revert to AF after cardioversion despite drug therapy; (5) a large left atrium and longstanding AF; (6) episodes of AF that

revert spontaneously to sinus rhythm; (7) no mechanical atrial systole after the return of electrical atrial systole; (8) AF and advanced heart block; (9) cardiac surgery planned in the near future; and (10) antiarrhythmic drug intolerance. AF is more likely to recur after cardioversion in patients who have significant chronic obstructive lung disease, congestive heart failure, mitral valve disease (particularly mitral regurgitation), AF present longer than 1 year, and an enlarged left atrium (echocardiographic diameter >4.5 cm).

In patients with atrial flutter, slowing the ventricular rate by administration of beta or calcium channel blockers or terminating the flutter with an antiarrhythmic agent may be difficult, and electrical cardioversion is often the initial treatment of choice. For patients with other types of SVT, electrical cardioversion may be used when (1) vagal maneuvers or simple medical management (e.g., IV adenosine and verapamil) has failed to terminate the tachycardia and (2) the clinical setting indicates that fairly prompt restoration of sinus rhythm is desirable because of hemodynamic decompensation or electrophysiologic consequences of the tachycardia. Similarly, in patients with VT, the hemodynamic and electrophysiologic consequences of the arrhythmias determine the need for and urgency of DC cardioversion. Electrical countershock is the initial treatment of choice for ventricular flutter or VF. Speed is essential (**see Chapter 42**).

If reversion of the arrhythmia to sinus rhythm does not occur after the first shock, a higher energy level should be tried. When transient ventricular arrhythmias result after an unsuccessful shock, a bolus of lidocaine can be given before delivery of a shock at the next energy level. If sinus rhythm returns only transiently and is promptly supplanted by the tachycardia, a repeated shock can be tried, depending on the tachyarrhythmia being treated and its consequences. Administration of an AAD intravenously may be useful before delivery of the next cardioversion shock (e.g., ibutilide for resistant AF). After cardioversion, the patient should be monitored, at least until full consciousness has been restored and preferably for 1 hour or more thereafter, depending on the duration of recovery from the particular form of sedation or anesthesia used. If ibutilide has been given, the ECG should be monitored for up to 8 hours because TdP can develop in the first few hours after administration.

Results

Electrical cardioversion restores sinus rhythm in up to 95% of patients, depending on the type of tachyarrhythmia. However, sinus rhythm remains after 12 months in less than one third to one half of patients with longstanding persistent AF. Thus, maintenance of sinus rhythm, once established, is the difficult problem, not immediate termination of the tachyarrhythmia. The likelihood of maintaining sinus rhythm depends on the particular arrhythmia, the presence of underlying heart disease, and the response to AAD therapy. Atrial size often decreases after termination of AF and restoration of sinus rhythm, and functional capacity improves.

Complications

Arrhythmias induced by electrical cardioversion are generally caused by inadequate synchronization, with the shock occurring during the ST segment or T wave (**see Fig. 36.1**). On occasion, even a properly synchronized shock can produce VF. Postshock arrhythmias are usually transient and do not require therapy. Asystole is rare and typically lasts no more than a few seconds before a sinus or junctional rhythm ensues; most defibrillators are also capable of transcutaneous pacing if needed. Embolic episodes are reported to occur in 1% to 3% of patients converted from AF to sinus rhythm. Prior therapeutic anticoagulation with warfarin (international normalized ratio [INR], 2.0 to 3.0) or newer agents such as

dabigatran, rivaroxaban, or apixaban should be used consistently for at least 3 weeks by patients who have no contraindication to such therapy and have had AF for longer than 2 to 3 days or of indeterminate duration. It is important to note that 3 weeks of therapeutic anticoagulation is not the same as simply administering warfarin for 3 weeks, because the warfarin dose may not achieve a therapeutic INR. The newer agents confer almost immediate anticoagulation, such that 3 weeks of treatment equals 3 weeks of anticoagulation. Anticoagulation for at least 4 weeks afterward is recommended because restoration of atrial mechanical function lags behind that of electrical systolic function, and thrombi can still form in largely akinetic atria, although they are electrocardiographically in sinus rhythm. Exclusion of left atrial thrombi by transesophageal echocardiography immediately before cardioversion may not always preclude embolism days or weeks after cardioversion of AF. Atrial thrombi can be present in patients with non–fibrillation-related atrial tachyarrhythmias, such as atrial flutter and AT in patients with congenital heart disease. The same precardioversion and postcardioversion anticoagulation recommendations apply to these patients as to those with AF. Although DC shock has been demonstrated in animals to cause myocardial injury, studies in humans have indicated that elevations in myocardial enzymes after cardioversion are not common. ST-segment elevation, sometimes dramatic, can occur immediately after elective DC cardioversion and can last for 1 to 2 minutes, although cardiac enzymes and myocardial scintigraphy may be unremarkable. ST elevation lasting longer than 2 minutes usually indicates myocardial injury unrelated to the shock. A decrease in serum K^+ and Mg^{2+} levels can occur after cardioversion of VT.

Cardioversion of VT can also be achieved by a chest thump. Its mechanism of termination is probably related to a mechanically induced PVC that interrupts a tachycardia circuit and may be related to commotio cordis (**see Chapter 53**). The thump cannot be timed accurately and is probably effective only when delivered during a nonrefractory part of the cardiac cycle. The thump can alter a VT and possibly induce ventricular flutter or VF if it occurs during the vulnerable period of the T wave. Because there may be a slightly greater likelihood of converting a stable VT to VF than of terminating VT to sinus rhythm, chest thump cardioversion should not be attempted unless a defibrillator is simply unavailable.

Implantable Electrical Devices for Treatment of Cardiac Arrhythmias

Implantable devices that monitor the cardiac rhythm and can deliver competing pacing stimuli and low- and high-energy shocks have been used effectively in selected patients (**see Chapter 41**).

Ablation Therapy for Cardiac Arrhythmias

The purpose of catheter ablation is to destroy myocardial tissue by delivery of energy, generally electrical energy or cryoenergy, through electrodes on a catheter placed next to an area of the myocardium integrally related to onset or maintenance of the arrhythmia. For tachycardias with an apparent focal origin (e.g., automatic, triggered activity, microreentry), the focus itself (<5 mm in diameter) is targeted. In macroreentrant AT and VT, inexcitable scar tissue typically separates strands of surviving myocardium, and wavefronts propagate around these scars. The target for ablation is a narrow portion of myocardium between inexcitable areas (e.g., scar, valve annulus; **Fig. 36.2**). The first catheter ablation procedures were performed with DC shocks, but this energy source has been supplanted by radiofrequency (RF) energy, which is delivered from an external generator and destroys tissue by controlled heat production.

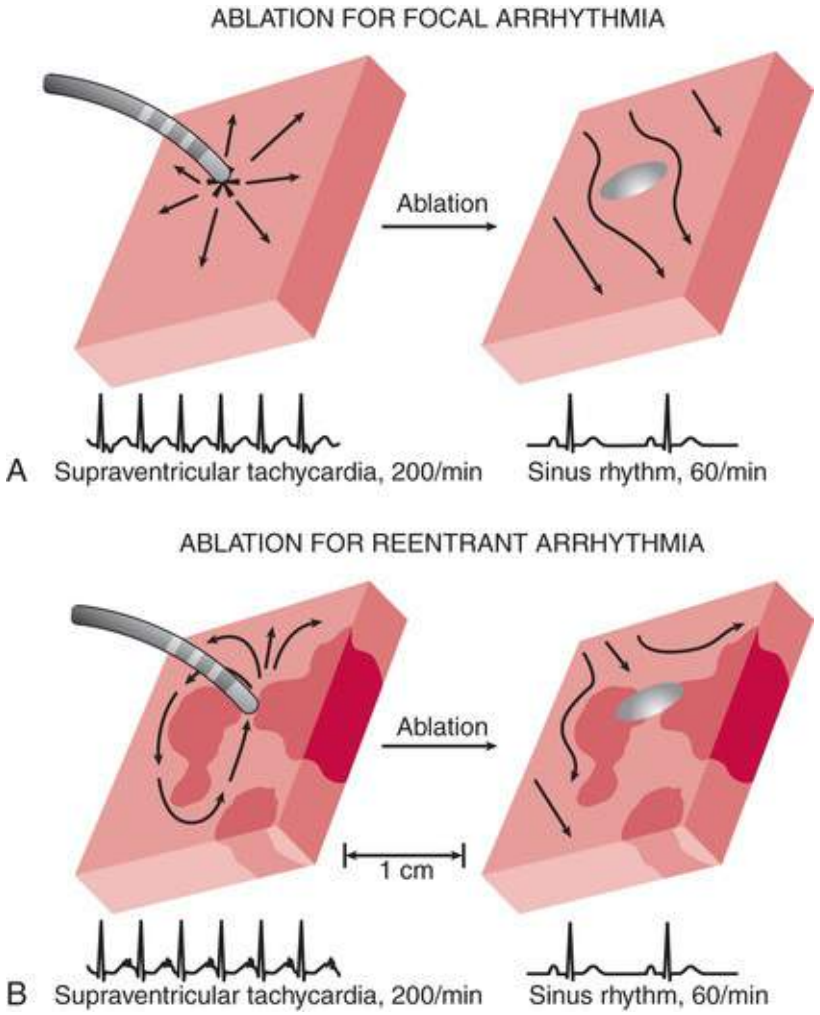

FIGURE 36.2 Strategies for catheter ablation. **A,** Focal tachycardia. **Left,** SVT is caused by an atrial focus, with activation emanating in all directions. **Right,** Ablation of the focus eliminates the arrhythmia with minimal disruption of normal activation. **B,** Macroreentrant SVT in setting of previous atrial damage resulting in scar formation. **Left,** During SVT, a wavefront circulates around a scarred area and through a narrow isthmus between this and another area of scar. **Right,** Ablation at this critical site prevents further reentry.

Lasers and microwave energy sources have been used, but not frequently; cryothermal catheter ablation has been approved for use in humans. When a target tissue has been identified by EPS, the tip of the ablation catheter is maneuvered into apposition with this tissue. After stable catheter position and recordings have been ensured, RF energy is delivered between the catheter tip and an indifferent electrode, usually an electrocautery-type grounding pad on the skin of the patient's thigh. Because energies in the RF portion of the electromagnetic spectrum are poorly conducted by cardiac tissue, RF energy instead causes resistive heating in the cells close to the tip of the catheter (i.e., these cells transduce the electrical energy into thermal energy). When tissue temperature exceeds 50°C, irreversible cellular damage and tissue death occur. An expanding front of conducted heat emanates from the region of resistive heating while RF delivery continues over the next 30 seconds and results in the production of a homogeneous, roughly hemispheric lesion of coagulative necrosis 3 to 5 mm in diameter (**Fig. 36.3A**). RF-induced heating of tissue that has inherent automaticity (e.g., His bundle, foci of automatic tachycardias) results in initial acceleration of a rhythm, whereas RF delivery during a reentrant arrhythmia typically causes slowing and termination of the arrhythmia. In most cases, RF delivery is painless, although ablation of atrial or right ventricular tissue can be uncomfortable for some patients.

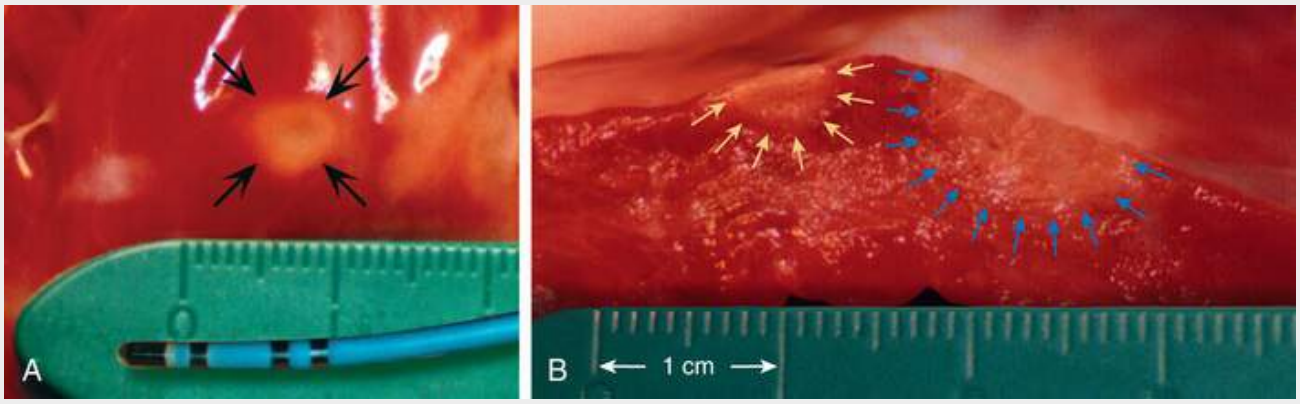

FIGURE 36.3 Radiofrequency lesion in human ventricular myocardium (explanted heart at transplantation). **A,** Energy was applied for 30 seconds at the location denoted by arrows, with the tip of the catheter shown. The lesion is 5 mm in diameter and has a well-demarcated border. A central depression in the lesion results from partial desiccation of tissue. **B,** Extent of radiofrequency lesions (cut surface of specimen in **A**). The lesion outlined by *yellow arrows* was made with a standard electrode (15 W for 30 sec); the lesion outlined by *blue arrows* was made with an irrigated catheter, cooling the tip to allow more power delivery (50 W for 30 sec). The lesion made by the irrigated catheter is more than twice the diameter and 12 times the volume of the standard catheter lesion.

Cooled-Tip Radiofrequency Ablation

In some situations the catheter can be delivered to the correct location, but conventional RF energy delivery cannot eliminate the tachycardia. In some of these cases the amount of damage—depth or breadth—caused by standard RF energy is inadequate. With the use of standard RF energy, power delivery is usually regulated to maintain a preset catheter tip temperature (typically, 55°C to 70°C). Tip temperatures higher than 90°C are associated with coagulation of blood elements on the electrode, which precludes further energy delivery and could also cause this material to become detached and embolize. Cooling of the catheter tip by internal circulation of liquid or continuous fluid infusion through small holes in the tip electrode can prevent excessive heating of the tip and allow delivery of higher power, thus producing a larger lesion (**Fig. 36.3B**) and potentially enhancing efficacy.[26] Cooled-tip ablation has been used to good advantage in cases in which standard (4-mm tip) catheter ablation has failed, as well as for primary therapy for atrial flutter and fibrillation and VT associated with structural heart disease, in which additional damage to already-diseased areas is not harmful and may be required to achieve the desired result.

Catheter-delivered cryoablation causes tissue damage by freezing cellular structures. Nitrous oxide is delivered to the tip of the catheter, where it is allowed to internally boil and cool the tip electrode, after which the gas is circulated back to the delivery console. Catheter tip temperature can be regulated, with cooling to as low as −80°C. Cooling to 0°C causes reversible loss of function and can be used as a diagnostic test (i.e., termination of a tachycardia when the catheter is in contact with a group of cells critical to its perpetuation, or determining its effect on normal conduction when close to the AV node). The catheter tip can then be cooled more deeply to produce permanent damage and thus cure of the arrhythmia. Cryoablation has been used for pulmonary vein isolation to treat paroxysmal AF by situating a collapsed balloon at the end of a catheter near a pulmonary vein ostium and inflating the balloon with nitrous oxide at −80°C. During cryoballoon occlusion of the vein for 3 to 4 minutes at a time, pulmonary vein isolation can usually be effected with one or two applications.[27] Real-time recordings can be done

simultaneously to monitor conduction. Cryoablation appears to cause less endocardial damage than RF energy does and may thus engender less risk for thromboemboli after ablation, as well as less chance of esophageal injury with ablation of AF (although it is not eliminated). However, balloon cryotherapy to isolate right pulmonary veins for the treatment of AF has resulted in phrenic nerve injury, and care must be taken to establish the location of the phrenic nerve. Residual arrhythmias can result (Videos 36.1 and 36.2).

Radiofrequency Catheter Ablation of Accessory Pathways

Location of Pathways

The safety, efficacy, and cost-effectiveness of RF catheter ablation of an accessory AV pathway have made ablation the treatment of choice in most adult and many pediatric patients who have AV reentrant tachycardia (AVRT) or atrial flutter or fibrillation associated with a rapid ventricular response over the accessory pathway (**see Chapter 37**). When RF energy is delivered to an immature heart, the lesion size can increase as the heart grows; however, this has not been shown to cause problems later in life.

An EPS is performed initially to determine that the accessory pathway is part of the tachycardia circuit or capable of rapid AV conduction during AF and to localize the accessory pathway (the optimal site for ablation). Pathways can exist in the right or left free wall or the septum of the heart (**Fig. 36.4**). Septal accessory pathways are further classified as superoparaseptal, midseptal, and posterior paraseptal. Pathways classified as posterior paraseptal are posterior to the central fibrous body within the so-called pyramidal space, which is bounded by the posterosuperior process of the left ventricle and the inferomedial aspects of both atria and is behind (posterior to) the true atrial septum. Superoparaseptal pathways are found near the His bundle, and accessory pathway activation potential as well as His bundle potential can be recorded simultaneously from a catheter placed at the His bundle region. Midseptal pathways are close to the AV node and can usually be ablated from a right-sided approach; rarely, a left atrial approach is needed. Right posterior paraseptal pathways insert along the tricuspid ring in the vicinity of the coronary sinus ostium, whereas left posterior paraseptal pathways are further into the coronary sinus and may be located at a subepicardial site around the proximal coronary sinus, within a middle cardiac vein or coronary sinus diverticulum, or subendocardially along the ventricular aspect of the mitral annulus.

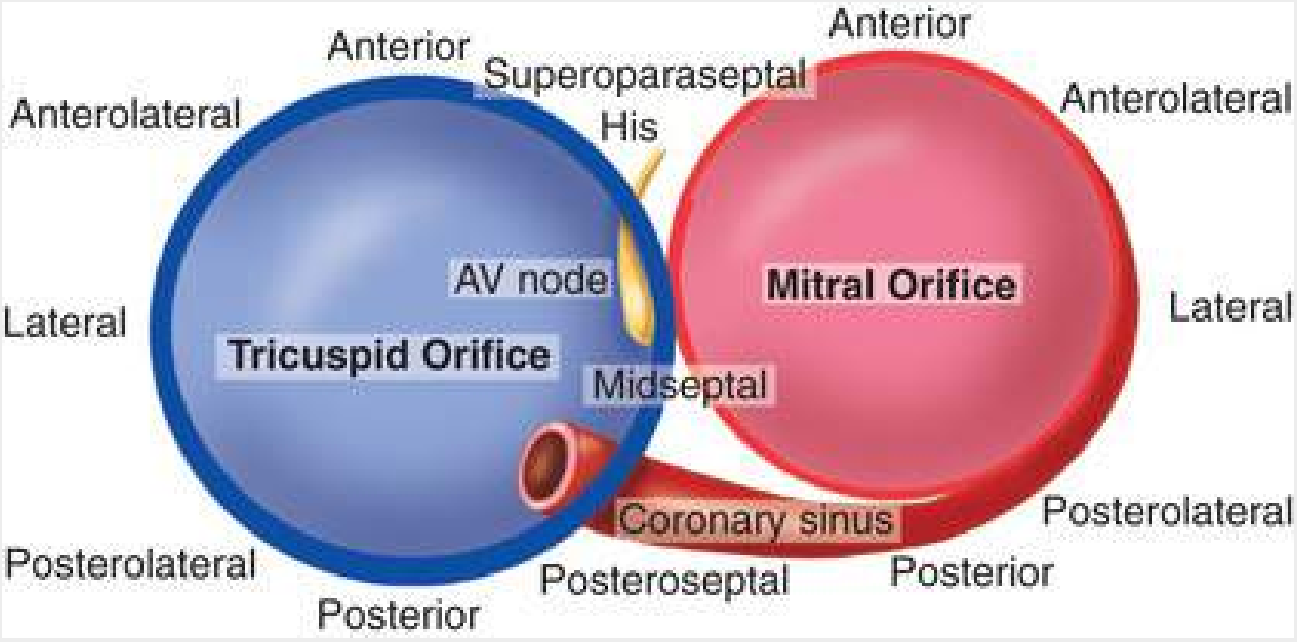

FIGURE 36.4 Locations of accessory pathways by anatomic region. The tricuspid and mitral valve annuli are depicted in a left anterior oblique view. Locations of the coronary sinus, AV node, and bundle of His are shown. Accessory pathways may connect the atrial to the ventricular myocardium in any of the regions shown.

Pathways at all locations and in all age groups can be ablated successfully. Multiple pathways are present in about 5% of patients. Occasional pathways with epicardial locations may be more easily approached from within the coronary sinus. Rarely, pathways can connect an atrial appendage with adjacent ventricular epicardium, 2 cm or more from the AV groove.

Ablation Site.

The optimal ablation site can be found by direct recordings of the accessory pathway (**Fig. 36.5**), although deflections that mimic accessory pathway potentials can be recorded at other sites. The ventricular insertion site can be determined by finding the site of the earliest onset of the ventricular electrogram in relation to the onset of the delta wave. Other helpful guidelines include unfiltered unipolar recordings that register a QS wave and an accessory pathway signal during preexcitation. A major ventricular potential synchronous with onset of the delta wave can be a target site in left-sided preexcitation, whereas earlier ventricular excitation in relation to the delta wave can be found for right-sided preexcitation. The atrial insertion site of manifest or concealed pathways (i.e., delta wave present or absent, respectively) can be found by locating the site showing the earliest atrial activation during retrograde conduction over the pathway. Reproducible mechanical inhibition of accessory pathway conduction during catheter manipulation and subthreshold stimulation has also been used to determine the optimal site. Accidental catheter trauma should be avoided, however, because it can hide the target for prolonged periods. Right free wall and superoparaseptal pathways are particularly susceptible to catheter trauma.

FIGURE 36.5 Wolff-Parkinson-White syndrome. Surface ECG leads 1, 3, V_1, and V_6 are shown, with intracardiac recordings from high right atrium (HRA), distal His (His_{dist}) bundle region, proximal (CS_{prox}) and distal (CS_{dist}) coronary sinus, right ventricular apex (RVA), and unipolar (Abl_{uni}) and bipolar (Abl_{bi}) tip electrodes of the ablation catheter. RF power in watts (RF_{Watts}) is also shown. **A,** Two beats of atrial pacing are conducted over the accessory pathway (*blue arrowheads* in the Abl_{bi} recording from the site of the accessory pathway) and resulted in a delta wave on the ECG. A premature atrial stimulus (*center*) encounters accessory pathway refractoriness (*red arrowhead*) and instead is conducted over the AV node and bundle of His and resulted in a narrow QRS complex and started an episode of AVRT. After each narrow QRS complex is an atrial deflection, the earliest portion of which is recorded at the ablation site (*green arrowheads*). **B,** Ablation of this pathway by delivery of RF energy from the ablation catheter tip. The *blue arrowhead* denotes the onset of delivery of RF energy; two QRS complexes later, the delta wave is abruptly lost (*green arrowhead* in lead 3) because of elimination of conduction over the accessory pathway.

Left-sided accessory pathways typically cross the mitral annulus obliquely. Consequently, the earliest site of retrograde atrial activation and the earliest site of anterograde ventricular activation are not directly across the AV groove from each other (i.e., ventricular insertion closer to coronary sinus ostium). Identification of the earliest site of atrial activation is usually performed during orthodromic AVRT or relatively rapid ventricular pacing so that retrograde conduction using the AV node does not confuse assessment of the location of the earliest atrial activation.

Successful ablation sites should exhibit anatomic/fluoroscopic stability and consistent electrical characteristics. During sinus rhythm, local ventricular activation at the successful ablation site precedes onset of the delta wave on the ECG by 10 to 35 milliseconds; during orthodromic AVRT, the interval between onset of ventricular activation in any lead and local atrial activation is usually 70 to 90 milliseconds (**see Fig. 36.5**). When temperature-measuring ablation catheters are used, a stable rise in catheter tip temperature is a helpful indicator of catheter stability and adequate contact between the electrode and tissue. In such a case, tip temperature generally exceeds 50°C. The retrograde transaortic and transseptal approaches have been used with equal success to ablate accessory pathways located along the mitral annulus. Routine performance of an EPS weeks after the ablation procedure is not generally indicated but may be considered in patients who have a recurrent delta wave or symptoms of tachycardia. Catheter-delivered cryoablation can be useful in patients with septal accessory pathways (located near AV node or His bundle). With use of this system, the catheter tip and adjacent tissue can be reversibly cooled to test a potential site. If accessory pathway conduction fails while normal AV conduction is preserved, deeper cooling can be performed at the site to complete the ablation. If, however, normal AV conduction is worsened, permanent damage is almost always averted by allowing the catheter quickly to rewarm quickly.

Atriofascicular accessory pathways have connections consisting of a proximal, AV node–like portion, which is responsible for conduction delay and decremental conduction properties, and a long distal segment located along the endocardial surface of the right ventricular free wall, which has electrophysiologic properties similar to those of the right bundle branch. The distal end of the right atriofascicular accessory pathway can insert into the apical region of the right ventricular free wall, close to the distal right bundle branch, or can actually fuse with the latter. Right atriofascicular accessory pathways might represent a duplication of the AV conduction system and can be localized for ablation by recording potentials from the rapidly conducting distal component, which crosses the tricuspid annulus (analogous to the His bundle) and extends to the apical region of the right ventricular free wall. Ablation at such a site on the annulus is usually successful; these pathways are very sensitive to catheter trauma,

and the operator must use great care to avoid such trauma.

Indications

Ablation of accessory pathways is indicated in patients who have symptomatic AVRT that is drug resistant or who are drug intolerant or do not desire long-term drug therapy. It is also indicated in patients who have AF or other atrial tachyarrhythmias and a rapid ventricular response, by means of an accessory pathway when the tachycardia is drug resistant, or in those who are drug intolerant or do not desire long-term drug therapy. Other potential candidates with an accessory pathway include the following: (1) patients with AVRT or AF with rapid ventricular rates identified during an EPS for another arrhythmia; (2) asymptomatic patients with ventricular preexcitation whose livelihood, profession, important activities, insurability, or mental well-being and the public safety would be affected by spontaneous tachyarrhythmias or by the presence of the electrocardiographic abnormality; (3) patients with AF and a controlled ventricular response by means of the accessory pathway; and (4) patients with asymptomatic preexcitation and a family history of sudden cardiac death. Controversy remains whether all patients with accessory pathways (even those without symptoms) need treatment; however, ablation has such a high success rate and low complication rate that in most centers, patients who need any form of therapy are referred for catheter ablation.

Results

Currently, in the hands of an experienced operator, the success rate for accessory pathway ablation is greater than 95% (slightly less for right free wall pathways, in which stable catheter-tissue contact is more problematic), with a 2% recurrence rate after an apparently successful procedure. There is a 1% to 2% complication rate, including bleeding, vascular damage, myocardial perforation with cardiac tamponade, valve damage, stroke, and MI. Heart block occurs in less than 3% of septal pathways. Procedure-related death is very rare.

Radiofrequency Catheter Modification of AV Node for AV Nodal Reentrant Tachycardias

Atrioventricular node reentry is a common cause of SVT episodes (**see Chapters 34 and 37**). Although controversy still exists about the exact nature of the tachycardia circuit, abundant evidence has indicated that two pathways in the region of the AV node participate, one with relatively fast conduction but long refractoriness and the other with shorter refractoriness but slower conduction. Premature atrial complexes can encounter refractoriness in the fast pathway, conduct down the slow pathway, and reenter the fast pathway retrogradely, thereby initiating AV nodal reentrant SVT (**Fig. 36.6**). Although this is the most common manifestation of AV node reentry, some patients have what appears to be propagation in the opposite direction in this circuit (anterograde fast, retrograde slow), as well as a “slow-slow” variant. Other, much less common types have been described. Two or more of these variants can exist in the same patient (**Fig. 36.7**).

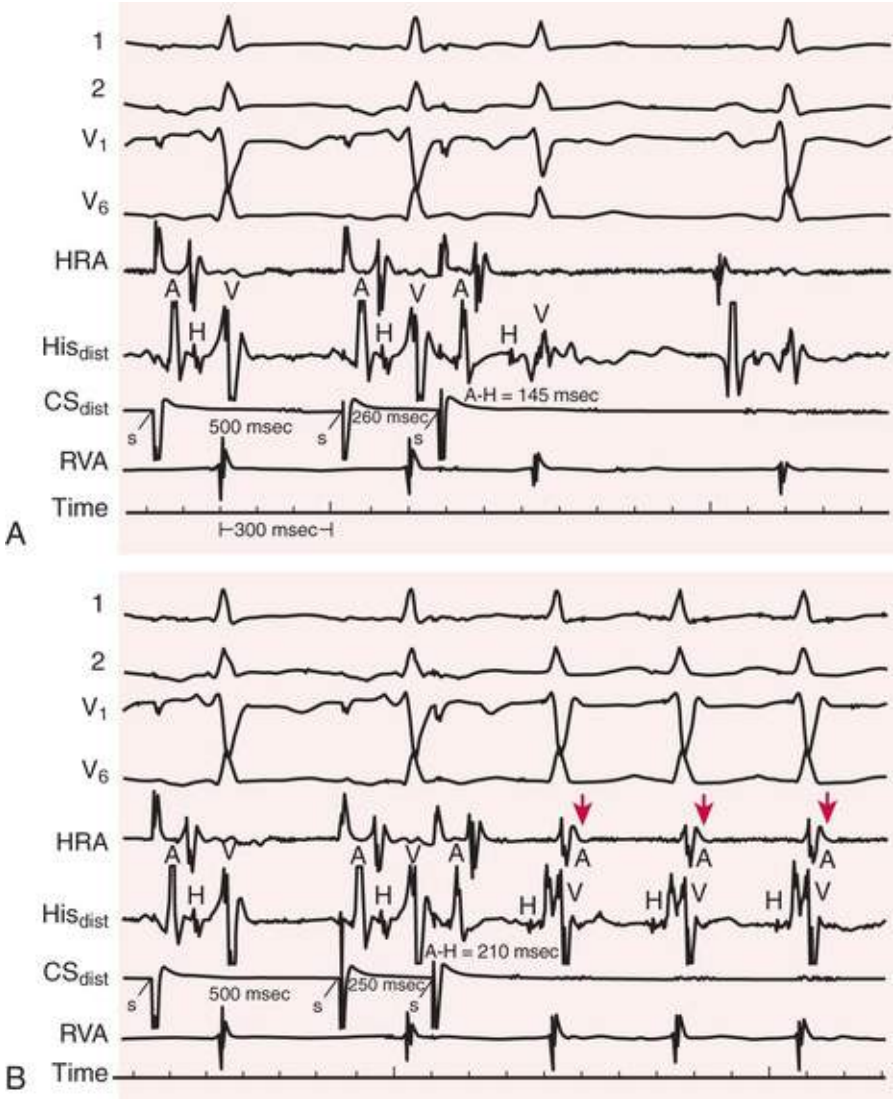

FIGURE 36.6 Atrioventricular node reentry. **A,** Two atrial paced complexes from the coronary sinus (CS) are followed by an atrial premature stimulus at a coupling interval of 260 milliseconds and resulted in an A-H interval of 145 milliseconds. **B,** The same atrial drive train is followed by an atrial extrastimulus 10 milliseconds earlier than before (250 msec). This resulted in a marked increase in the A-H interval to 210 milliseconds, after which AVNRT ensues because the extrastimulus encounters block in a "fast" AV node pathway, conducts down a "slow" pathway, and then conducts back up the fast pathway in a repeating fashion. *Red arrowheads* denote atrial electrograms coincident with QRS complexes, characteristic of the most common type of AV node reentry. Recording was done as in previous figures.

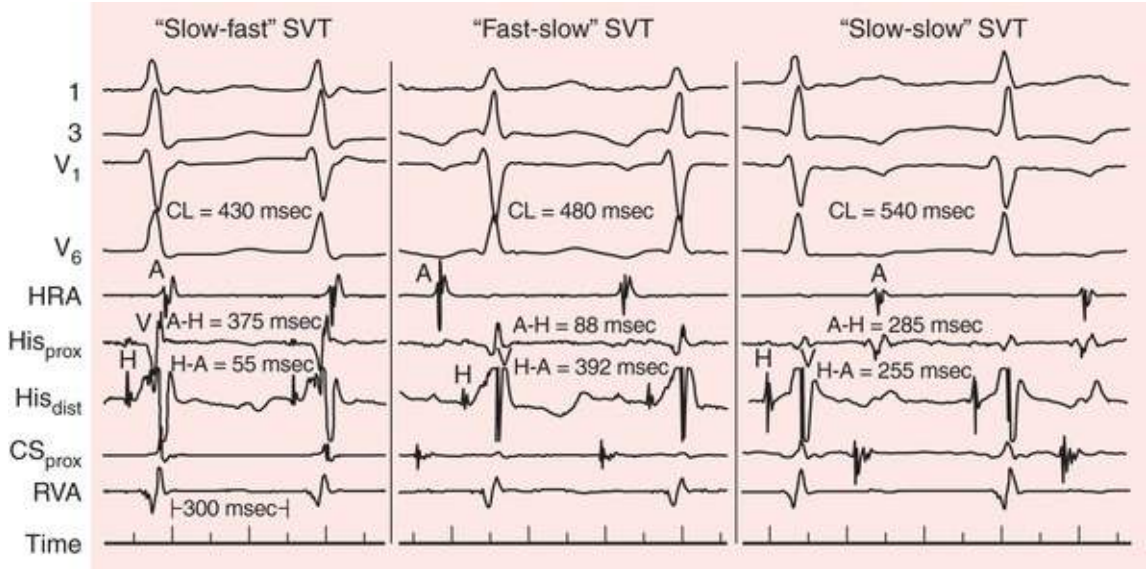

FIGURE 36.7 Three variants of AV node reentrant SVT in the same patient. **Left,** Most common type of AV node SVT (anterograde slow pathway, retrograde fast). Atrial activation is coincident with ventricular activation. **Center,** "Atypical" AV node reentry with anterograde fast pathway conduction and retrograde conduction over a slow pathway. **Right,** A rare variety is shown that consists of anterograde conduction over a slow pathway and retrograde conduction over a second slow pathway. Note the similar atrial activation sequences in the last two (coronary sinus before the right atrium), as distinct from that of slow-fast AV node reentry (coronary sinus and right atrial activation almost simultaneous). Note also the different P-QRS relationships, from simultaneous activation (left, short RP interval) to P in front of the QRS (middle, long RP interval) and P midway in the cardiac cycle (right). Recording was done as in previous figures. *CL,* Cycle length.

Fast Pathway Ablation.

Ablation can be performed to eliminate conduction in the fast pathway or the slow pathway. Currently, fast pathway ablation is rarely performed because it is associated with a prolonged PR interval, a higher recurrence rate (10% to 15%), and a slightly higher risk for complete AV block (2% to 5%) than with slow pathway ablation. One uncommon situation in which fast pathway ablation may be preferred is for patients who have a greatly prolonged PR interval at rest and no evidence of anterograde fast pathway conduction. In such patients, ablation of the anterograde slow pathway may produce complete AV block, whereas retrograde fast pathway ablation can eliminate SVT without altering AV conduction.

Slow Pathway Ablation.

The slow pathway can be located by mapping along the posteromedial tricuspid annulus close to the coronary sinus os. Electrographic recordings are obtained with an atrial-to-ventricular electrogram ratio of less than 0.5 and either a multicomponent atrial electrogram or a recording consistent with a possible slow pathway potential. In the anatomic approach, target sites are selected fluoroscopically. A single RF application eliminates slow pathway conduction in many cases, but in others, serial RF applications may be needed, starting at the most posterior site (near the coronary sinus os) and progressing along the tricuspid annulus more anteriorly. An accelerated junctional rhythm usually occurs when RF energy is applied at a site that will result in successful elimination of SVT (**Fig. 36.8**). The success rate is equivalent with the anatomic and electrographic mapping approaches, and most often, combinations of both are used and yield success rates of greater than 95%, with less than a 1% chance of complete heart block. Catheter-delivered cryoablation has been used for the treatment of AV node reentrant tachycardia (AVNRT) with excellent results and is considered by some to be safer than RF (less chance of permanent

AV block) but in most series has a higher rate of SVT recurrence after apparent successful ablation.

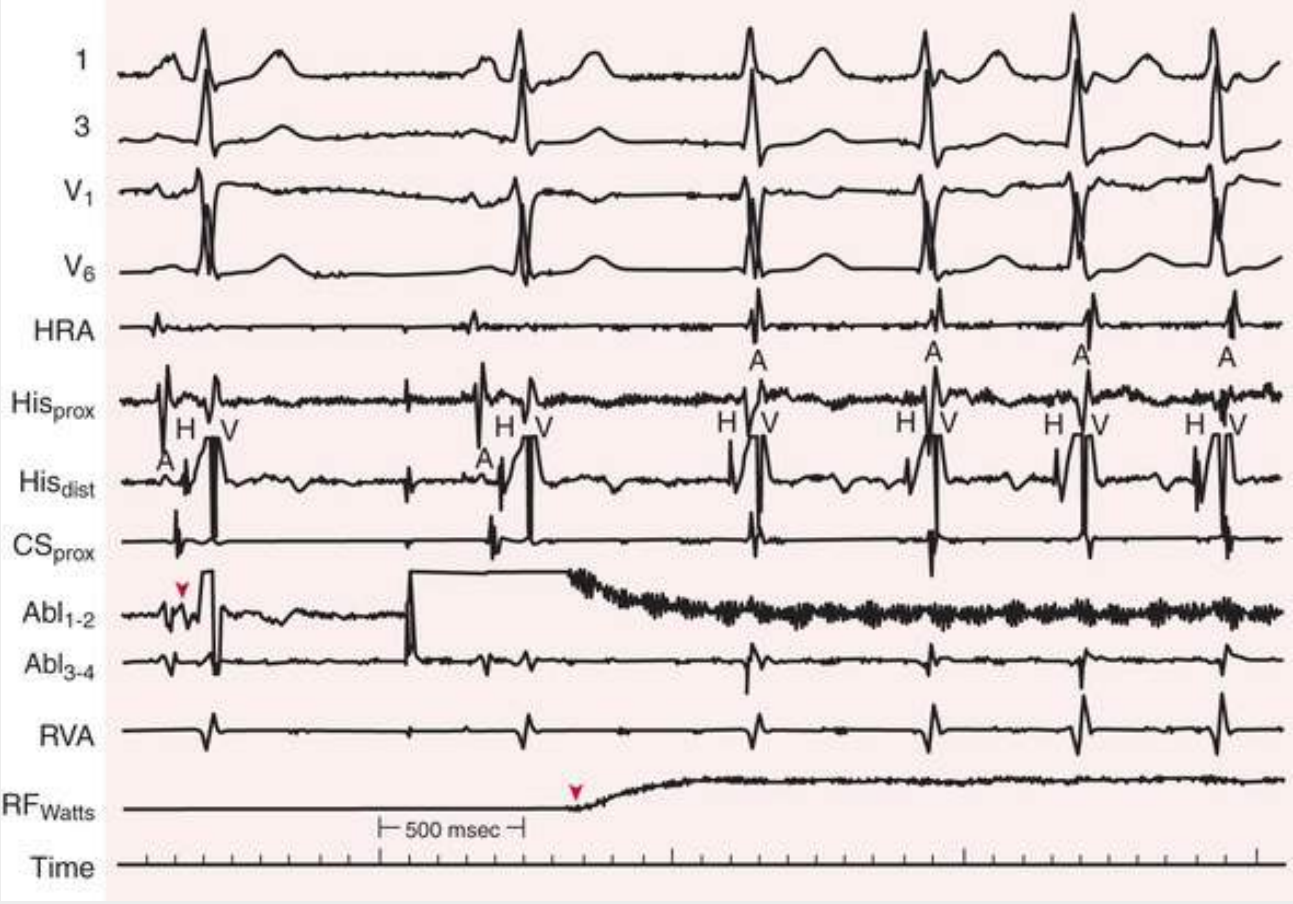

FIGURE 36.8 Atrioventricular node slow pathway modification for cure of AV node reentrant SVT. The ablation recording (*arrowhead* in Abl_{1-2}) shows a slurred deflection between the atrial and ventricular electrogram components; this may represent the AV node slow pathway deflection (but it is not the bundle of His deflection, which is instead recorded from a separate catheter 15 mm away). Shortly after the onset of RF delivery (*arrowhead* in RF_{Watts}), an accelerated junctional rhythm begins and gradually speeds up further. Retrograde conduction is present during the junctional rhythm. *Abl_{3-4}*, Proximal electrode recording from ablation catheter. Recording was done as in previous figures.

Patients in whom slow pathway conduction is completely eliminated almost never have recurrent SVT episodes. Approximately 40% of patients can have evidence of residual slow pathway function after successful elimination of sustained AVNRT, usually manifested as persistent dual–AV node physiology and single–AV node echoes during atrial extrastimulation. The surest endpoint for slow pathway ablation is elimination of sustained AVNRT, with and without an infusion of isoproterenol.

AVNRT recurs in approximately 5% of patients after slow pathway ablation; repeat ablation is almost always successful. In some patients the ERP of the fast pathway decreases after slow pathway ablation, possibly because of electrotonic interaction between the two pathways. Atypical forms of reentry can result after ablation, as can apparent parasympathetic denervation, and result in inappropriate sinus tachycardia. This usually resolves within 3 months after ablation.

At present, the slow pathway approach is the preferred method for ablation of typical AVNRT. Ablation of the slow pathway is also a safe and effective means for the treatment of atypical forms of AVNRT. In patients with AVNRT undergoing slow pathway ablation, junctional ectopy during application of the RF energy is a sensitive but nonspecific marker of successful ablation; it occurs in longer bursts at effective than at ineffective target sites. Ventriculoatrial conduction should be expected during the

junctional ectopy, and poor ventriculoatrial conduction or actual block may herald subsequent anterograde AV block. Junctional ectopic rhythm is caused by heating of the AV node and does not occur with cryoablation.

Indications

RF catheter ablation for AVNRT can be considered in patients with recurrent, symptomatic, sustained AVNRT that is drug resistant or who are drug intolerant or do not desire long-term drug treatment. The procedure can also be considered for patients with sustained AVNRT identified during EPS or catheter ablation of another arrhythmia, or when EPS reveals dual–AV node pathway physiology and atrial echoes but without AVNRT in patients with suspected AVNRT clinically.

Results

Most centers currently use slow pathway ablation, which results in a procedural success rate of 98%, a recurrence rate of less than 5%, and an incidence of heart block requiring permanent pacing of 1% or less. Late development of heart block (months to years later) is rare.

Junctional Tachycardia

Junctional tachycardia, often called ectopic junctional tachycardia (although if the location is junctional, by definition it is ectopic) is a rare form of SVT in which the ECG resembles that in AVNRT but is distinct in that (1) the mechanism is automatic, not reentrant, and (2) the atrium is clearly not involved in the tachycardia. This disorder is most often observed in young healthy individuals, in women more often than in men, and is usually catecholamine dependent. Ablation must be carried out close to the His bundle, and the risk for heart block requiring pacemaker insertion exceeds 5%.

Radiofrequency Catheter Ablation of Arrhythmias Related to the Sinus Node

Inappropriate sinus tachycardia is a syndrome characterized by high sinus rates with exercise and at rest. Patients complain of palpitations at all times of day that correlate with inappropriately high sinus rates. They may not respond well to beta-blocker therapy because of lack of desired effect or occurrence of side effects. Ivabradine, which blocks I_f (principal pacemaker current in sinus node) is indicated for treatment of heart failure but has been used with some success in patients with inappropriate sinus tachycardia.[28] When the sinus node area is to be ablated because of drug-refractory symptoms, it can be identified anatomically and electrophysiologically, and ablative lesions are usually placed between the superior vena cava and crista terminalis at sites of early atrial activation. Intracardiac echocardiography can help in defining the anatomy and in positioning the ablation catheter. Isoproterenol may be helpful in "forcing" the site of impulse formation to cells with the most rapid discharge rate. Care must be taken to apply RF energy at the most cephalad sites first; initial ablation performed farther down the crista terminalis does not alter the atrial rate at the time but can damage any subsidiary pacemaker regions that may be needed after the sinus node has eventually been ablated.

Indications

Patients with *persistent* inappropriate sinus tachycardia should be considered for ablation only after clear failure of medical therapy, because the results of ablation are often less than completely satisfactory.

Whenever ablation is performed in the region of the sinus node, the patient should be apprised of the chance of needing a pacemaker after the procedure. Phrenic nerve damage and superior vena caval stenosis are also possibilities.

Results

Although a good technical result may be obtained at the time of the procedure for inappropriate sinus tachycardia, symptoms often persist because of recurrence of rapid sinus rates (at or near preablation rates) or for nonarrhythmic reasons. In some, after the atrial rate decreases, an inappropriately rapid junctional rhythm (80 to 90/min) is present; this may indicate an overall increased sensitivity of cells with pacemaker capacity to catecholamines in these patients. Multiple ablation sessions are needed in some patients, and approximately 20% eventually undergo pacemaker implantation; however, not all these patients have relief of symptoms, including palpitations, despite a normal heart rate.

Radiofrequency Catheter Ablation of Atrial Tachycardia

Atrial tachycardias are a heterogeneous group of disorders; causative factors include rapid discharge of a focus (focal tachycardia) and reentry. The former can occur in anyone, regardless of the presence of structural abnormalities of the atria, whereas reentrant ATs almost always occur in the setting of structurally damaged atria. Symptoms vary from none, with relatively infrequent or slow ATs in patients without heart disease, to syncope (rapid AT with compromised cardiac function) or heart failure (incessant AT over weeks or months). All forms of AT are amenable to catheter ablation (**see Chapter 37**).

Focal Atrial Tachycardia.

In focal ATs (automatic or triggered foci or microreentry), activation mapping is used to determine the source of the AT by recording the earliest onset of local activation. These tachycardias can behave capriciously and can be practically noninducible during EPS despite the patient complaining of multiple daily episodes before the EPS. Approximately 10% of patients can have multiple atrial foci. Sites tend to cluster near the pulmonary veins in the left atrium and the mouths of the atrial appendages and along the right atrial crista terminalis (**Figs. 36.9A, 36.10, and 36.11**; **also see Fig. 35.15**). Activation times at these sites typically occur only 15 to 40 milliseconds before onset of the P wave on the ECG. Care must be taken to avoid inadvertent damage to the phrenic nerve (**Fig. 36.11**); its location can be determined by pacing at high current at a candidate site of ablation while observing for diaphragmatic contraction. Ablation should not be performed at a site at which this is seen, if at all possible.

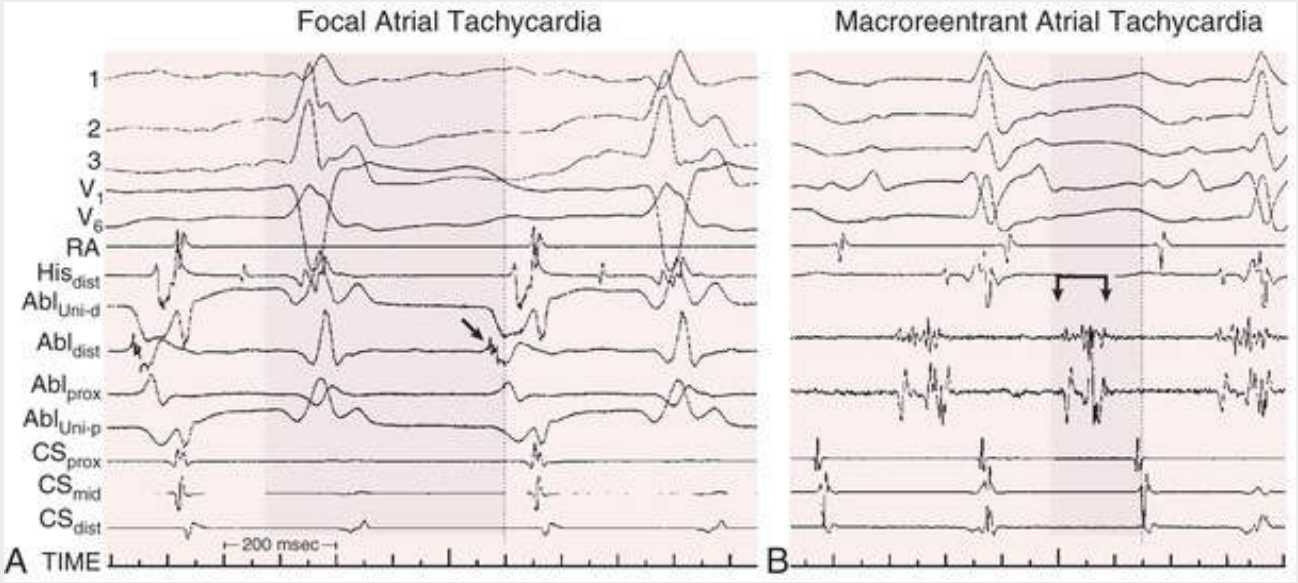

FIGURE 36.9 Atrial tachycardia. In both panels the interval from the end of one P wave to the beginning of the next (atrial diastole) is in *gray*. A *dashed line* denotes onset of the P wave during tachycardia. **A,** Focal AT arising in the right atrium. Two tachycardia complexes are shown; the earliest site found (Abl_{dist}, at which ablation eliminated the tachycardia) is shown as a multicomponent recording that starts only approximately 40 milliseconds before onset of the P wave. The unipolar recording (Abl_{Uni-d}) has a deep negative deflection (indicating propagation away from the electrode). The activation sequence of recordings is very different from that during sinus rhythm, in which the right atrial (RA) recording is at the onset of the P wave. **B,** Macroreentrant AT in a patient who had undergone repair of an atrial septal defect years earlier. The ablation catheter is in the posterior right atrium, where a fragmented signal (between *arrows*) is recorded that almost fills atrial diastole. Ablation at this site terminated the tachycardia. Recording was done as in previous figures.

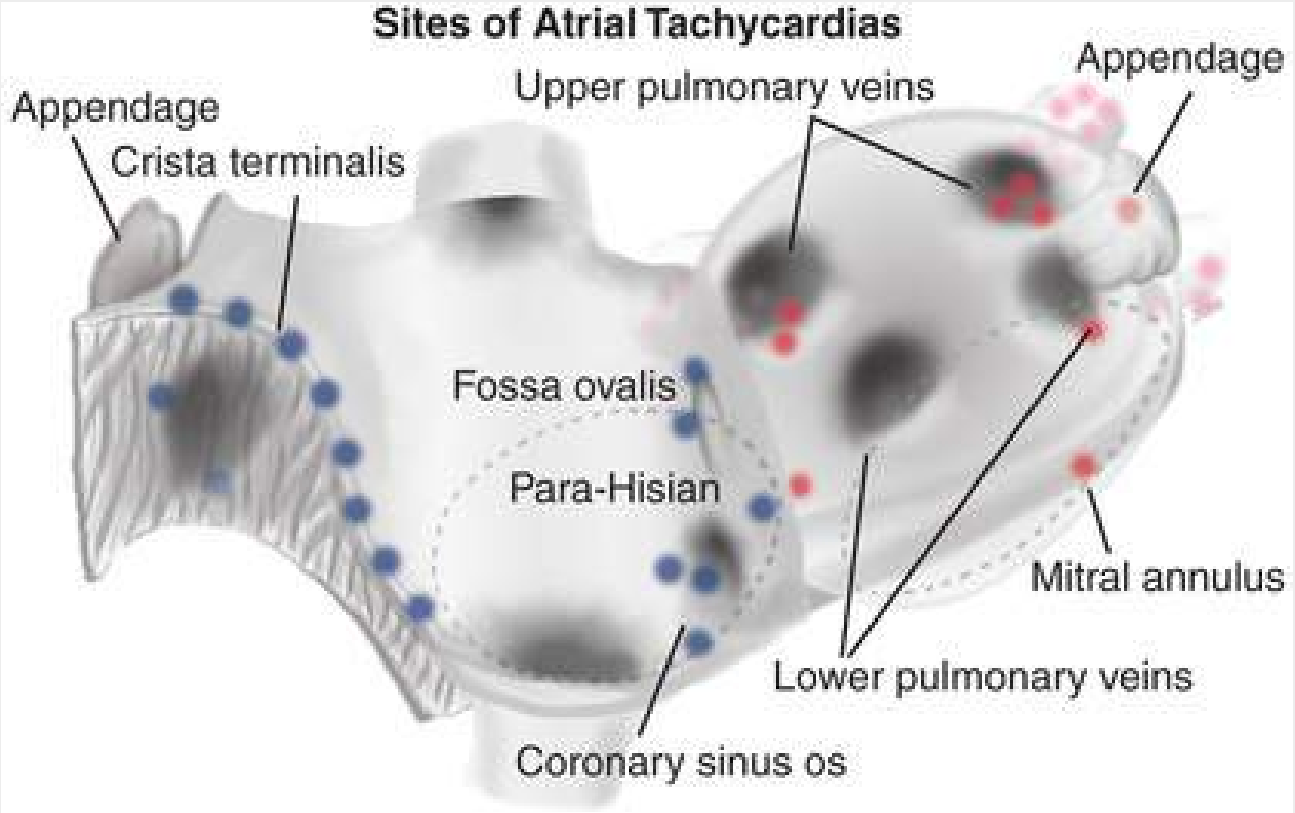

FIGURE 36.10 Locations of origins of focal atrial tachycardias. The atria are viewed from the front with the right atrial free wall retracted to show the interior. Structures are labeled as shown; right atrial foci appear in shades of *blue,* left atrial foci in shades of *red.*

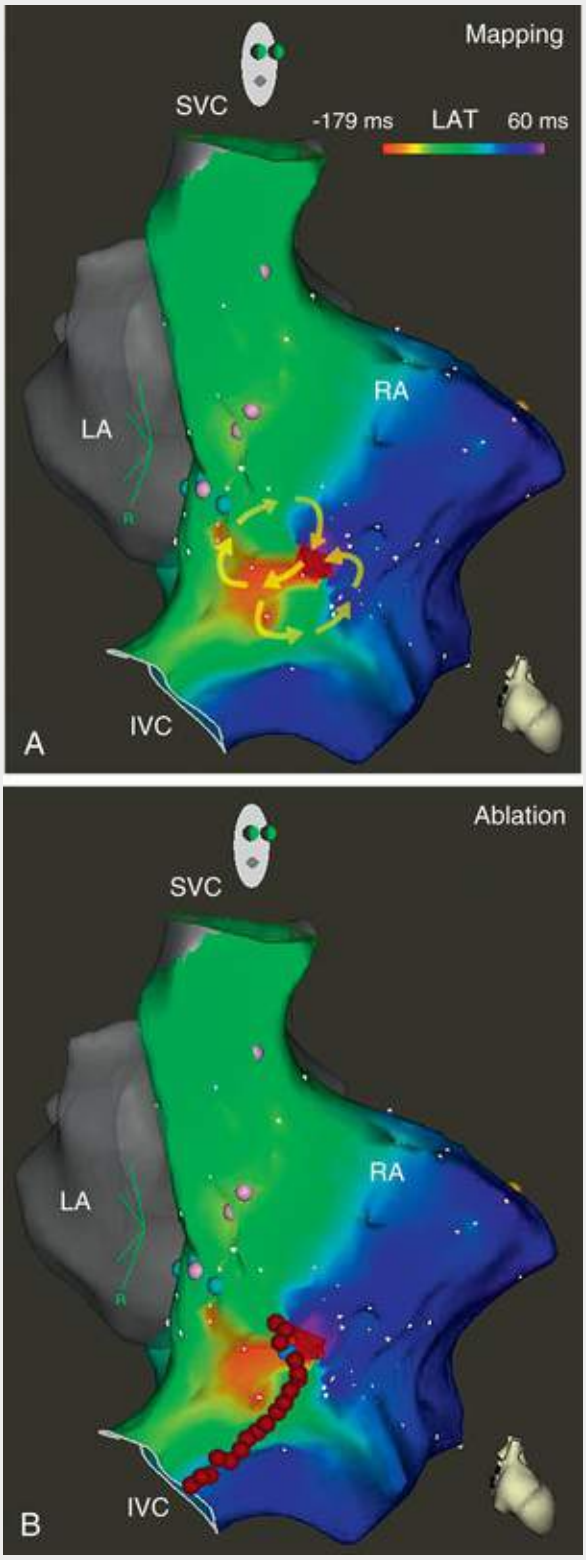

FIGURE 36.11 Reentrant atrial tachycardia. **A,** Electroanatomic activation map of the right atrium (*RA*) is shown in a patient with a previous right atrial incision for closure of an atrial septal defect. *Arrows* depict a double loop of reentry around presumed scars with a common diastolic pathway between scars. The *color bar* shows progression of activation times during AT (from *red* through *green*, *blue*, and *purple*). The tachycardia cycle length (240 msec) is entirely represented in the range of colors. **B,** *Red dots* denote ablation sites connecting scars (transecting diastolic pathway) and connecting one scar to the inferior vena cava (*IVC*) to preclude reentry around all barriers. *LA,* Left atrium; *SVC,* superior vena cava.

Reentrant Atrial Tachycardia.

As noted, these ATs usually occur in the setting of structural heart disease, especially after previous surgery involving an atrial incision (repair of congenital heart disease such as an atrial septal defect, Mustard or Senning repair of transposed great vessels, or one of a variety of Fontan repairs for tricuspid atresia and other disorders), or previous atrial ablation (e.g., for AF). The region of slow conduction is

typically related to an end of an atriotomy or previous ablation scar, the location of which varies from patient to patient. Therefore, preprocedural review of operative and ablation procedure reports and careful electrophysiologic mapping are essential. Because reentry within a complete circuit is occurring, activation can be recorded throughout the entire cardiac cycle. The ablation strategy is to identify regions with mid-diastolic atrial activation during tachycardia (**Fig. 36.11**; **also see Fig. 36.9B**) that can be proved by pacing techniques to be integral to the tachycardia. Such sites are attractive ablation targets because they are composed of relatively few cells—thus electrical silence on the surface ECG in diastole—and so are more easily eliminated by the small amount of damage effected by a typical application of RF energy. Focal ablation of these sites can then be performed, but often tachycardia can still be initiated (usually at a slower rate) or recurs after the procedure. Because these sites are typically located at a relatively narrow zone between the ends of previous scars, surgical incisions, or ablation lines and another nonconducting barrier (e.g., another scar, caval orifice, valve annulus), a line of ablative lesions is generally made from the end of the scar to the nearest electrical barrier; thus reentry can be prevented. This technique is analogous to that used in curing atrial flutter (see later). Because these patients frequently have extensive atrial disease with islands of scar that could serve as barriers for additional ATs, specialized mapping techniques may be needed to locate these regions and preemptively connect them with ablative lesions to prevent future AT episodes.

Indications

Catheter ablation for ATs should be considered in patients who have recurrent episodes of symptomatic sustained ATs that are drug resistant, or who are drug intolerant or do not desire long-term drug treatment.

Results

Success rates for ablation of focal AT range from 80% to 95%, largely depending on the ability to induce episodes at EPS. When episodes can be initiated with pacing, isoproterenol, or other means, the AT can usually be ablated. Reentrant ATs, although more readily induced by an EPS, are often more difficult to eliminate completely; initial success rates are high (90%), but recurrences are seen in up to 20% of patients and necessitate drug therapy or another ablation procedure. Complications, which occur in 1% to 2% of patients, include phrenic nerve damage, cardiac tamponade, and heart block (with rare perinodal ATs).

Radiofrequency Catheter Ablation of Atrial Flutter

Atrial flutter can be defined electrocardiographically (most typically, negative sawtooth waves in leads II, III, and aVF at a rate of approximately 300 beats/min) or electrophysiologically (rapid, organized macroreentrant AT, the circuit for which is anatomically determined). Understanding of the reentrant pathway in all forms of atrial flutter is essential for development of an ablation strategy (**see Chapter 37**).

Reentry in the right atrium, with the left atrium passively activated, constitutes the mechanism of the typical electrocardiographic variety of atrial flutter, with caudocranial activation along the right atrial septum and craniocaudal activation of the right atrial free wall (**Fig. 36.12A**). Ablating tissue in a line between any two anatomic barriers that transects a portion of the circuit necessary for perpetuation of

reentry can be curative. Typically, this is across the isthmus of atrial tissue between the inferior vena caval orifice and the tricuspid annulus (the cavotricuspid isthmus), a relatively narrow point in the circuit. Locations for RF delivery can be guided anatomically or electrophysiologically. Less frequently, the direction of wavefront propagation in this large right atrial circuit is reversed ("clockwise" flutter proceeding cephalad up the right atrial free wall and caudad down the septum, with upright flutter waves in the inferior leads; **Fig. 36.12A, left panel**). These two arrhythmias constitute cavotricuspid isthmus–dependent flutter, can be ablated by cavotricuspid isthmus interruption, and are distinct from other rapid atrial arrhythmias that may have a similar appearance on the ECG but use different (and often multiple) circuits in other parts of the right or left atrium. Ablation can be more difficult in these cases, which often occur in the setting of advanced lung disease or previous cardiac surgery or ablation. A common theme in these complex reentrant arrhythmias is the presence of an anatomically determined zone of inexcitability around which an electrical wavefront can circulate. Specialized mapping tools and skills are necessary to achieve successful ablation in these cases.

FIGURE 36.12 **A,** Two forms of atrial flutter in the same patient are shown. A halo catheter with 10 electrode pairs is situated on the atrial side of the tricuspid annulus (*TA*), with recording sites displayed from the top of the annulus (12:00) to the inferomedial aspect (5:00), as shown in the fluoroscopic views in **B.** On the **left,** the wavefront of atrial activation proceeds in a clockwise fashion (*arrows*) along the annulus, whereas on the **right,** the direction of propagation is the reverse. **B,** Ablation of the isthmus of atrial tissue between the tricuspid annulus and the inferior vena caval orifice for cure of atrial flutter. Recordings are displayed from the multipolar catheter around much of the circumference of the tricuspid annulus (see the left anterior oblique fluoroscopic images). Ablation of this isthmus is performed during coronary sinus pacing. In the two beats on the **left,** atrial conduction proceeds in two directions around the tricuspid annulus, as indicated by arrows and recorded along the halo catheter. In the two beats on the **right,** ablation has interrupted conduction in the floor of the right atrium, thereby eliminating one path for transmission along the tricuspid annulus. The halo catheter now records conduction, proceeding all the way around the annulus. This finding demonstrates a unidirectional block in the isthmus; block in the other direction may be demonstrated by pacing from one of the halo electrodes and observing a similar lack of isthmus conduction. (The bundle of His recording in the **right panel** is lost because of catheter movement.)

In patients with AF, an antiarrhythmic drug can slow intra-atrial conduction to such an extent that atrial flutter results and fibrillation is no longer observed. In some of these patients, ablation of atrial flutter and continued AAD therapy can prevent recurrences of these atrial arrhythmias.

The endpoint of atrial flutter ablation procedures was initially termination of atrial flutter, with RF application accompanied by noninducibility of the arrhythmia. However, with use of these criteria, up to 30% of patients had recurrent flutter because of lack of complete and permanent conduction block in the cavotricuspid isthmus. Thus the current endpoint of ablation has changed to ensuring a line of bidirectional block is present in this region, usually by pacing from opposite sides of the isthmus (**Fig. 36.12B**). With use of these criteria, recurrence rates have fallen to less than 5%.

Indications

Candidates for RF catheter ablation include patients with recurrent episodes of atrial flutter that are drug resistant, those who are drug intolerant, and those who do not desire long-term drug therapy. Many patients who undergo AF ablation (**see Chapter 38**) also have episodes of flutter during the procedure that can be treated by ablation of the cavotricuspid isthmus at the same setting.

Results

Regardless of circuit location, atrial flutter can be ablated successfully in more than 90% of cases, although patients with complex right or left atrial flutter require more extensive and complex procedures. Recurrence rates are less than 5% except in patients with extensive atrial disease, in whom new circuits can develop over time as new areas of conduction delay and block form. Complications are rare and include inadvertent heart block and phrenic nerve paralysis.

Ablation and Modification of Atrioventricular Conduction for Atrial Tachyarrhythmias

In some patients who have rapid ventricular rates despite optimal drug therapy during complex atrial tachyarrhythmias that are less amenable to ablation, RF ablation can be used to eliminate or modify AV conduction and control the ventricular rates.

To achieve this, a catheter is placed across the tricuspid valve and positioned to record a small His bundle electrogram associated with a large atrial electrogram. RF energy is applied until complete AV block has been achieved and is continued for an additional 30 to 60 seconds (**Fig. 36.13**). If no change in AV conduction is observed after 15 seconds of RF ablation despite good contact, the catheter is repositioned and the attempt repeated. In occasional patients, attempts at RF ablation via this right-sided approach fail to achieve heart block. These patients can undergo an attempt from the left ventricle with a catheter positioned along the posterior interventricular septum, just beneath the aortic valve, to record a large His bundle electrogram. Success rates currently approach 100%, with AV conduction recurring in less than 5% of cases. Improved left ventricular function can result from control of the ventricular rate during AF and withdrawal of rate-controlling medications with negative inotropic action. Permanent ventricular or AV pacing is required after ablation. With continuing advances in direct ablation of complex atrial arrhythmias, AV nodal ablation is less often used currently. Whereas in some cases the AV junction can be modified to slow the ventricular rate without producing complete AV block by ablation in the region of the slow pathway (as described with AV node modification for AV node reentry), this strategy is almost never used at present.

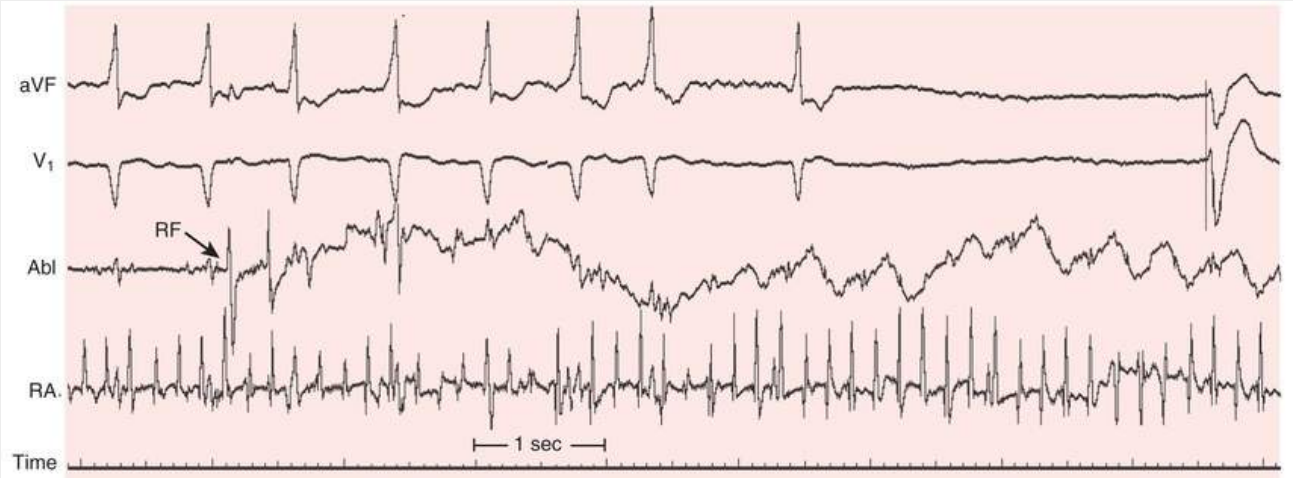

FIGURE 36.13 Atrioventricular nodal ablation for rate control of atrial fibrillation (AF). The ECG shows rapidly conducted AF; application of radiofrequency (*RF*) energy (*arrow*) results in complete AV block within seconds, followed by a ventricular paced complex.

Indications

Ablation and modification of AV conduction can be considered in the following cases: (1) patients with symptomatic atrial tachyarrhythmias who have inadequately controlled ventricular rates, unless primary ablation of the atrial tachyarrhythmia is possible (especially when a permanent pacemaker is already present for treatment of bradycardia-tachycardia syndrome); (2) similar patients when drugs are not tolerated or patients do not choose to take them, even though the ventricular rate can be controlled; (3) patients with symptomatic, nonparoxysmal junctional tachycardia that is drug resistant or in whom drugs are not tolerated or are not desired; (4) patients resuscitated from sudden cardiac death related to atrial flutter or AF with a rapid ventricular response in the absence of an accessory pathway; and (5) patients with a dual-chamber pacemaker and pacemaker-mediated tachycardia that cannot be treated effectively by drugs or reprogramming of the pacemaker. The last three situations are rarely encountered.

Results

As previously noted, successful interruption of AV conduction can be achieved in almost all cases; recurrent conduction is observed in less than 5%. Significant complications occur in 1% to 2%. In early studies, up to 4% of patients had an episode of sudden death after AV junction ablation despite adequate pacemaker function, presumably because of relative bradycardia after long periods of rapid ventricular rates serving as the setting for repolarization-related ventricular arrhythmias. Since then, backup pacing rates are set to 80 to 90/min for the first 1 to 3 months after ablation in most cases, which has almost entirely eliminated this problem. Improvements in quality-of-life indices, as well as in cost-effectiveness, have been demonstrated for this procedure.

Radiofrequency Catheter Ablation of Atrial Fibrillation

See Chapters 37 and 38.

Radiofrequency Catheter Ablation of Ventricular Arrhythmias

In general, the success rate for ablation of VTs is lower than that for AV node reentry or AV reentry because of the heterogeneity of substrates and presentations. In the ideal case, induction of the VT must be reproducible, with uniform QRS morphology from beat to beat, and VT must be sustained and hemodynamically stable so that the patient can tolerate the VT long enough during the procedure to undergo the extensive mapping necessary to localize optimal ablation target sites. These conditions are often not met. Patients with several electrocardiographically distinct, uniform morphologies of VT can still be candidates for ablation, because in many cases a common reentrant pathway is shared by two or more VT morphologies. Also, the target for ablation must be fairly circumscribed and preferably endocardially situated, although catheter mapping and ablation from the epicardial surface after percutaneous pericardial access is performed in many centers. Very rapid VT, polymorphic VT, and infrequent, nonsustained VT can be addressed with catheter ablation using different strategies.

Location and Ablation.

RF catheter ablation of VT can be divided into idiopathic VT, which occurs in patients with essentially structurally normal hearts and includes patients with isolated PVCs; VT that occurs in various disease settings but without coronary artery disease (CAD); and VT in patients with CAD and usually previous MI. In the first group, VTs/PVCs can arise in either ventricle. Right ventricular tachycardias most frequently originate in the outflow tract and have a characteristic left bundle branch block–like, inferior axis morphology (**see Chapter 39**); less often, VTs/PVCs arise in the inflow tract or free wall. Initiation of tachycardia can often be facilitated by catecholamines. Most left VTs in structurally normal hearts are septal in origin and have a characteristic QRS configuration (i.e., right bundle branch block, superior axis). Other VTs/PVCs also occur and arise from different areas of the left ventricle, including the left ventricular outflow region and the aortic sinuses of Valsalva, and are similar in electrocardiographic appearance and clinical behavior to those arising in the right ventricular outflow tract. VTs in abnormal hearts without CAD can be the result of either intramyocardial or bundle branch reentry, most often observed in patients with dilated cardiomyopathy, or as a focal process. Epicardial foci and circuits are more common in this than in other groups. In patients with bundle branch reentry, ablation of the right bundle branch eliminates the tachycardia. VT can occur in patients with right ventricular dysplasia (**see**

Chapter 33), sarcoidosis, Chagas disease, hypertrophic cardiomyopathy (**Chapters 77 and 78**), and a host of other noncoronary disease states.

Activation mapping and pace mapping are effective in patients with idiopathic VTs/PVCs to locate the site of origin of the VT. In *activation mapping* the timing of endocardial electrograms sampled by the mapping catheter is compared with the onset of the surface QRS complex. Sites that are activated 20 to 40 milliseconds before onset of the surface QRS are near the origin of the arrhythmia (**see Fig. 35.13**). In idiopathic VT/PVCs, ablation at a site at which the unipolar electrogram shows a QS complex may yield greater success than if an rS potential is observed (**Fig. 36.14**). *Pace mapping* involves stimulation of various ventricular sites to produce a QRS contour that duplicates the QRS contour of the spontaneous VT or PVC, thus establishing the apparent site of origin of the arrhythmia (**Fig. 36.15**). This technique is limited by several methodologic problems but may be useful when the arrhythmia cannot be initiated and when a 12-lead ECG has been obtained during spontaneous episodes. Presystolic Purkinje potentials, as well as very-low-amplitude mid-diastolic signals, can be recorded during VT from sites at which ablation cures VT in most patients with left ventricular VTs that have a right bundle branch block superior axis; this VT characteristically terminates with IV verapamil and is the only significant reentrant idiopathic VT. Localization of optimal ablation sites for VT in patients with CAD and previous MI can be more challenging than in patients with structurally normal hearts because of the altered anatomy and electrophysiology. Pace mapping has a lower sensitivity and specificity than for idiopathic VT. Furthermore, reentry circuits can sometimes be large and resistant to the relatively small lesions produced by RF catheter ablation in scarred endocardium.

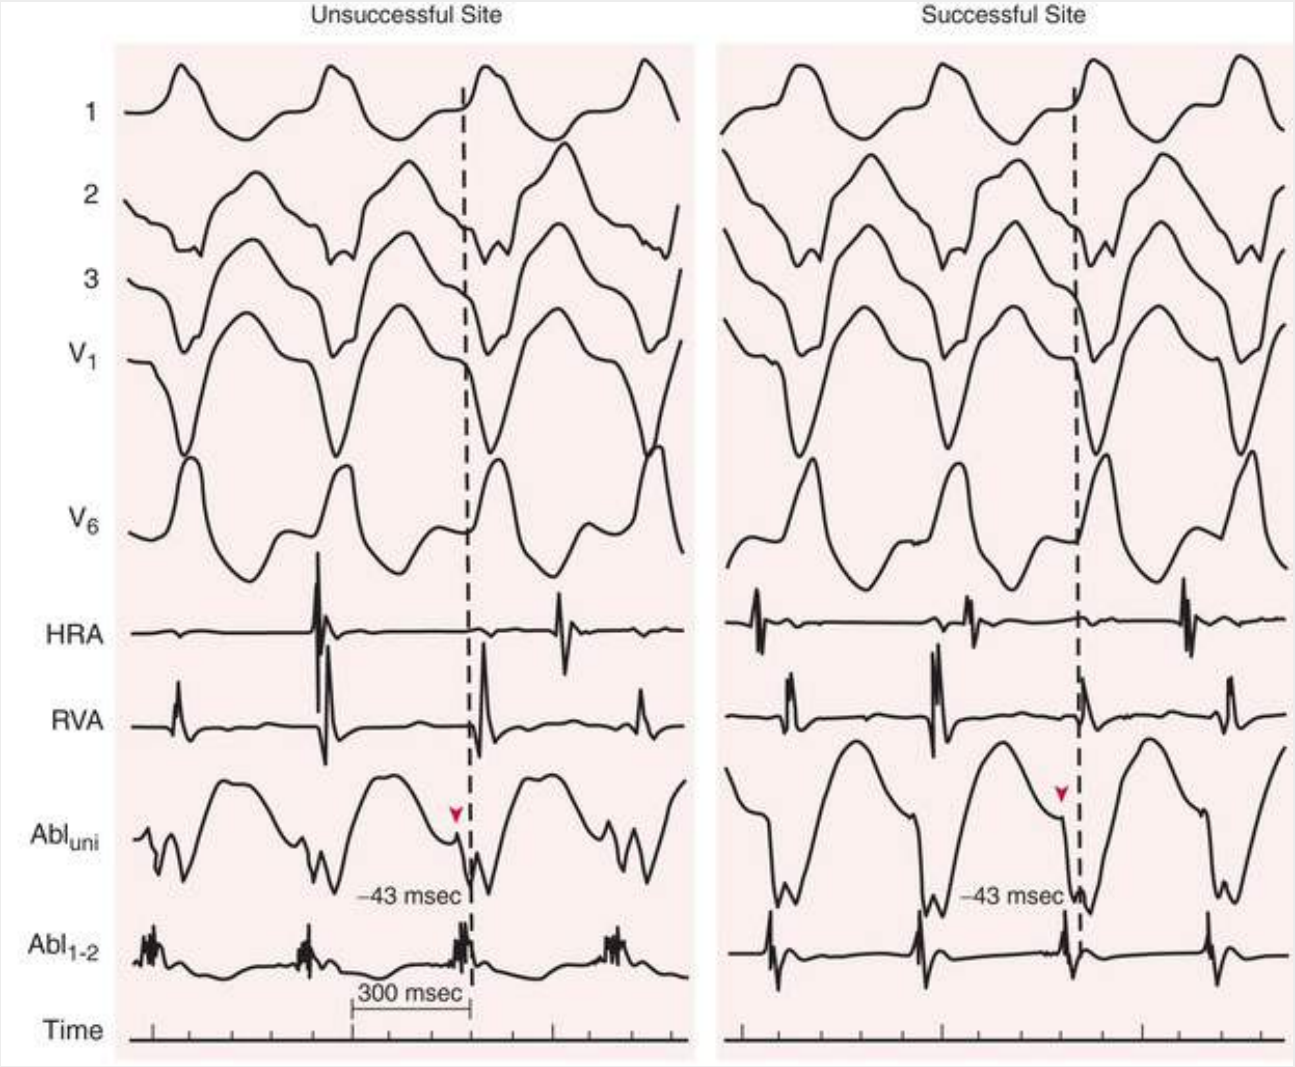

FIGURE 36.14 Recordings from unsuccessful and successful ablation sites in a patient with idiopathic ventricular tachycardia arising in the inferior right ventricular wall. In the recordings from the unsuccessful ablation site, the unipolar signal (*arrowhead*) has a small r wave, which indicates that a portion of the wavefront from the focus of tachycardia is approaching the site from elsewhere. At the successful site, the unipolar recording has a QS configuration, thus indicating that all depolarization is emanating from this site. In each site the bipolar recording (Abl_{1-2}) occurs an identical 43 milliseconds before onset of the QRS (*dashed lines*).

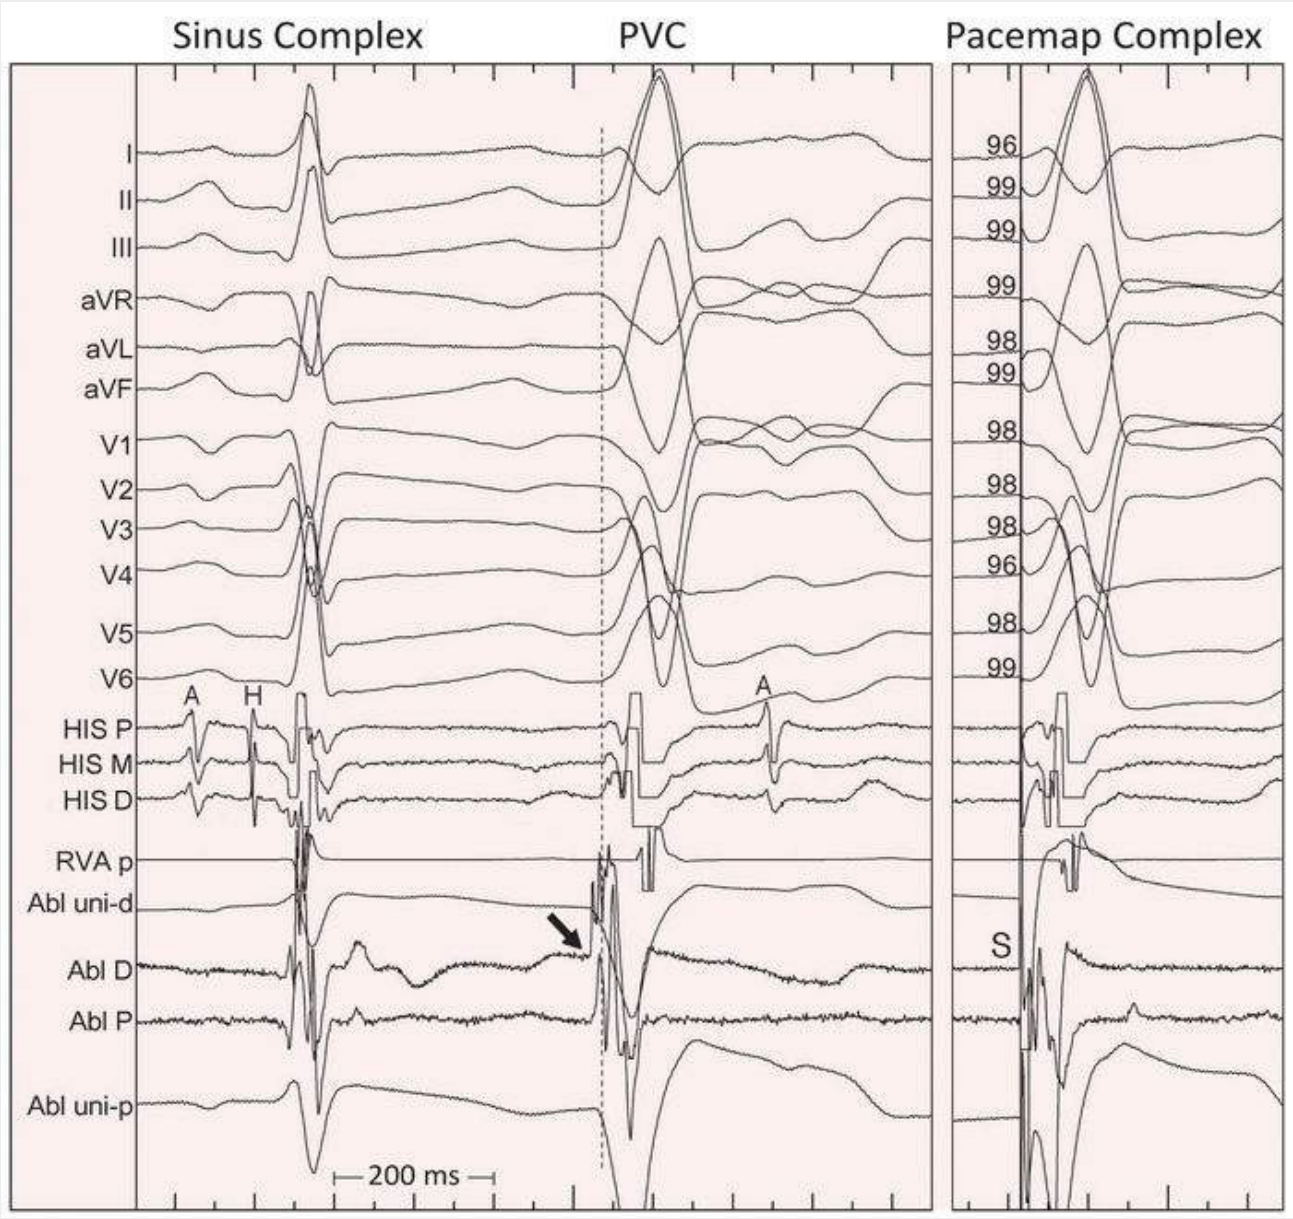

FIGURE 36.15 Premature ventricular complex (PVC) and pace mapping. All 12 surface ECG leads are shown, along with intracardiac recordings in sinus rhythm, a spontaneous PVC, and pacing (*S*) at the site of Abl D (distal recordings of ablation catheter). The Abl D recording shows a sharp deflection (*arrow*) occurring about 25 milliseconds before onset of the QRS (*dashed line*). In the **right panel,** pacing is performed from this site. This produces an identical QRS complex in each lead, with a short stimulus–QRS interval; numbers indicate percentage of "match" between PVC and paced QRS complexes using an algorithm in the recording system. Ablation at this site eliminated VT in 2 seconds. *uni,* Unipolar recording; *A,* atrial electrogram; *H,* His electrogram.

In scar-based VT (e.g., after MI, cardiomyopathies), finding a protected region of diastolic activation used as a critical part of the reentrant circuit is desirable because ablation at this site has a good chance of eliminating the tachycardia (**Fig. 36.16**). As a result of the extensive derangement in electrophysiology caused by the previous damage (e.g., infarct, myopathy), many areas of the ventricle may have diastolic activation but may not be relevant to perpetuation of the VT. These "bystander sites" make activation mapping more difficult. Pacing techniques such as entrainment can be used to test whether a site is actually part of a circuit or is a bystander. *Entrainment* involves pacing for several complexes during a tachycardia at a rate slightly faster than the VT rate; after pacing is stopped and the same tachycardia resumes, the timing of the first complex relative to the last paced beat is an indicator of how close the pacing site is to a part of the VT circuit (**Fig. 36.17**). During entrainment, part of the ventricle is activated by the paced wavefront and part by the VT wavefront being forced to exit earlier than it normally would, thereby resulting in a fusion complex on the ECG. Pacing from within a critical portion of the circuit

itself produces an exact QRS match with the VT; fusion occurs only within the circuit and is “concealed” (not evident on the surface ECG). Sites with a low-amplitude, isolated, mid-diastolic potential that cannot be dissociated from the tachycardia by pacing perturbations, at which entrainment with concealed fusion can be demonstrated, are highly likely to be successful ablation sites.

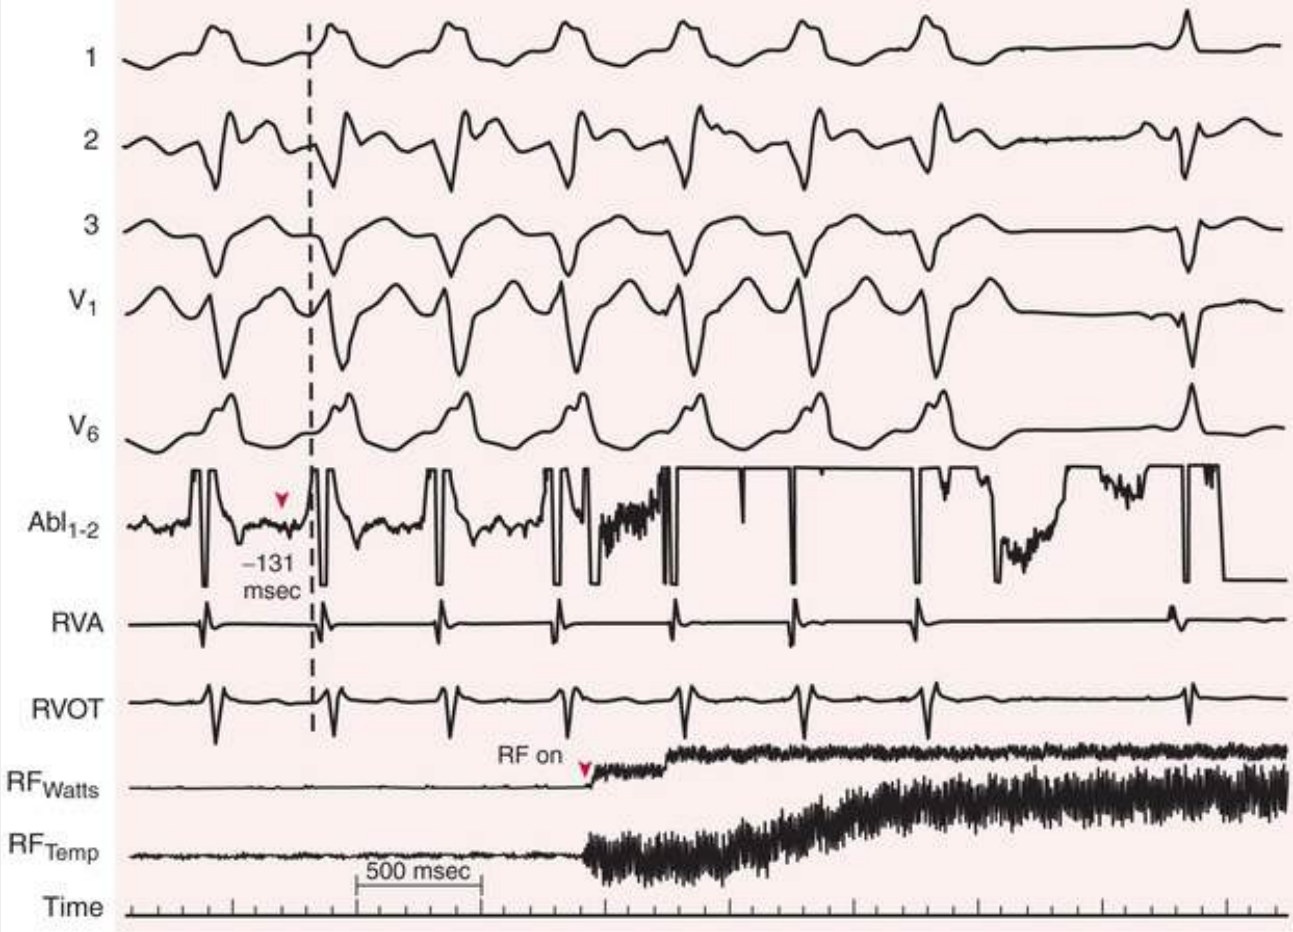

FIGURE 36.16 Radiofrequency ablation of postinfarction ventricular tachycardia. The electrogram in the ablation recording (Abl_{1-2}, *arrowhead*) precedes onset of the QRS (*dashed line*) by 131 milliseconds. Ablation here (RF on) results in slight deceleration of VT before termination in 1.3 seconds. Temperature monitored from the catheter tip had just peaked (approximately 70°C) at the time that VT terminated. Recording was done as in previous figures.

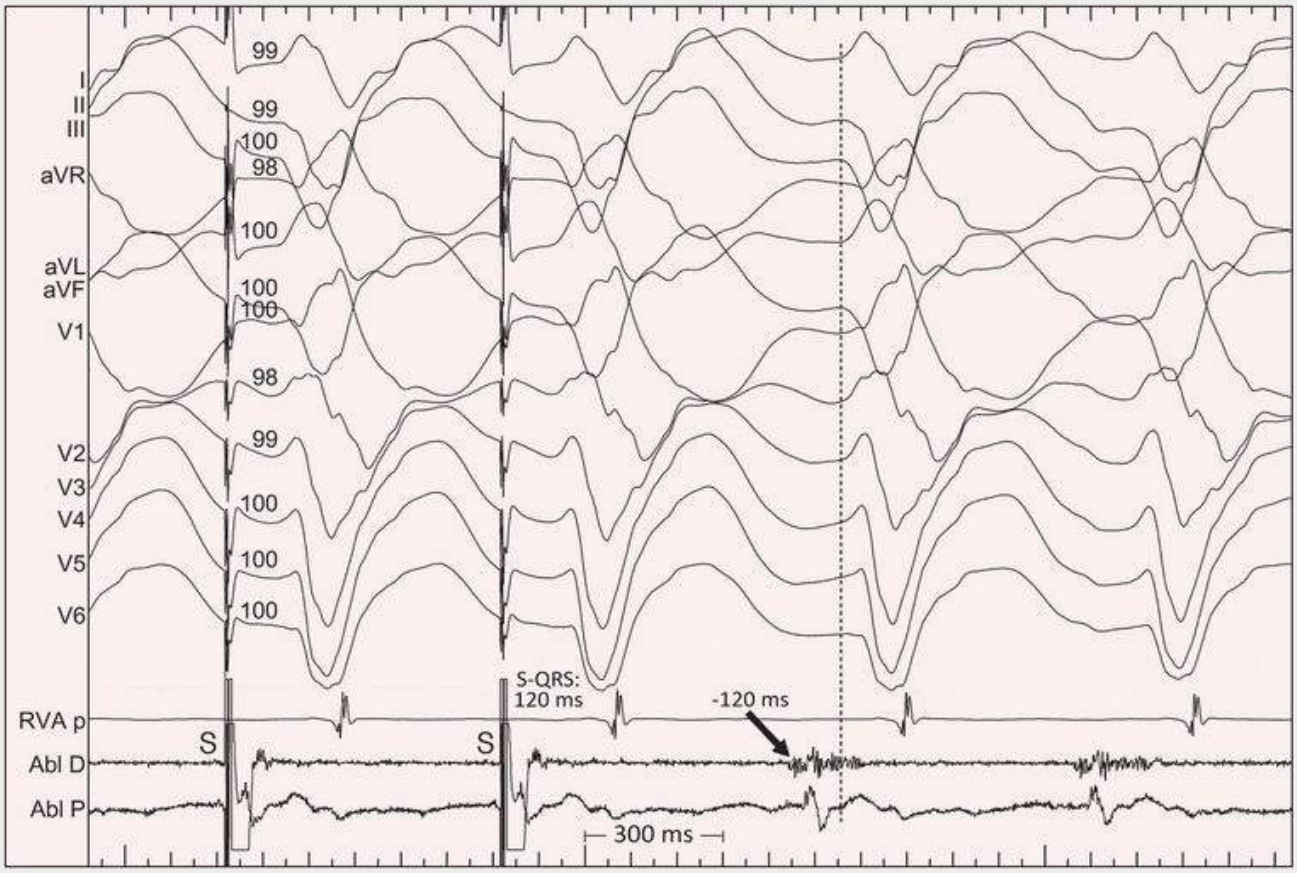

FIGURE 36.17 "Concealed" entrainment of postinfarction ventricular tachycardia. The two complexes on the *left* are pacing during VT, with a stimulus (*S*)-QRS interval 120 milliseconds; after pacing ends, VT resumes. The electrogram (*arrow*) in Abl D (distal electrode pair of the ablation catheter) is 120 milliseconds before QRS onset (*dotted line*). The paced and VT QRS complexes are almost identical (numbers above paced complexes indicate algorithmic "match" assessed by recording system). Ablation at this site quickly terminated VT. *RVA p,* Right ventricular recording; *Abl P,* recording from proximal electrodes on ablation catheter.

In a significant proportion of patients with VT and structural heart disease, activation mapping and entrainment cannot be performed because of poor hemodynamic tolerance of the arrhythmia or inability to initiate sustained tachycardia during an EPS. In these situations, additional methods can be used that are categorized as *substrate mapping*, in which areas of low electrical voltage or from which very delayed potentials are recorded during sinus rhythm, or at which pacing closely replicates a known VT 12-lead ECG morphology (pace mapping) are targeted for ablation without needing any mapping during VT (**Fig. 36.18**). These methods, usually requiring very extensive ablation in diseased areas, have yielded very good results in many cases. In other patients, hemodynamic support in the form of catecholamine infusion, intra-aortic balloon counterpulsation, or a percutaneous temporary ventricular assist device or extracorporeal membrane oxygenation has been used to facilitate mapping during VT.[29]

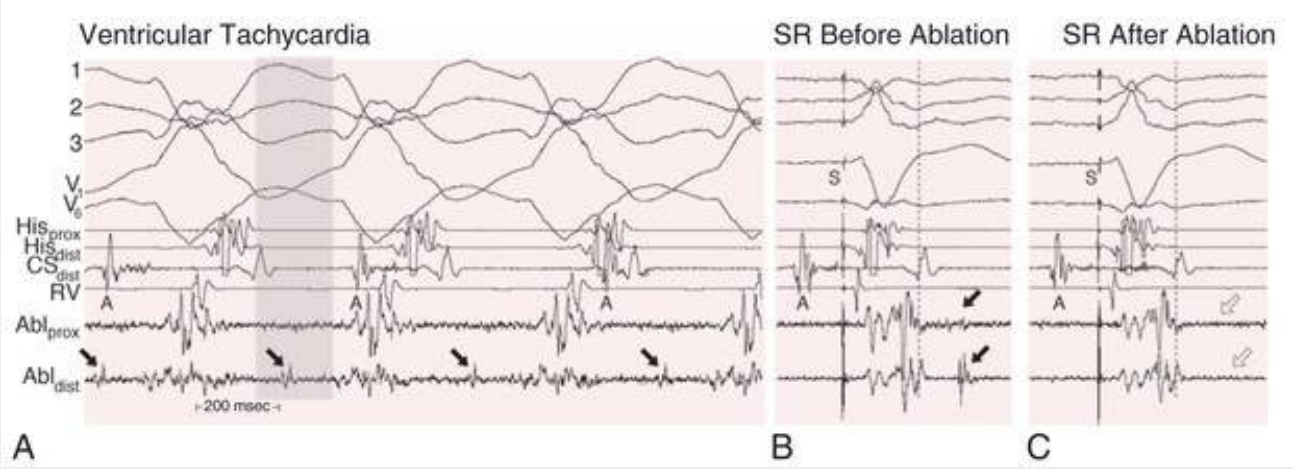

FIGURE 36.18 Mid-diastolic potentials during ventricular tachycardia correlating with late potentials in sinus rhythm (*SR*). In **A,** VT is shown; diastole (from the end of one QRS complex to the beginning of the next) is shaded in *gray*. In the Abl_{dist} recording, a small, sharp signal is seen in mid-diastole that corresponds to a protected corridor of propagation. **B,** After termination of VT with pacing, recording at the same location shows a delayed ("late") potential in SR with tracked ventricular pacing (*black arrows*; the *dashed line* denotes the end of the QRS complex). **C,** Ablation here eliminated the late potential (*white arrows*), as well as inducible VT. *A,* Atrial recording; *S,* stimulus artifact.

In patients without structural heart disease, only a single VT is usually present, and catheter ablation of that VT is most often curative. In patients with extensive structural heart disease, multiple VTs are usually present. Most of these patients already have, or soon will have, an ICD; ablation can be used to decrease the frequency of ICD therapies but is generally not intended to cure the patient of all ventricular arrhythmias. Catheter ablation of a single VT in such patients may be only palliative and may not eliminate the need for further AAD or device therapy, but can improve quality of life by decreasing ICD shocks. The genesis of multiple tachycardia morphologies is not clear, although in some cases they are merely different manifestations of one circuit (e.g., different directions of wavefront propagation or exit to the ventricle as a whole), and ablation of one may prevent recurrence of others. The presence of multiple VT morphologies contributes to the difficulties in mapping and ablation of VT in these patients, because pacing techniques used to validate recordings at potential sites of ablation may result in a change in morphology to another VT that may not arise in the same region.

After ablation of VT, ventricular stimulation is repeated to assess efficacy. In some cases, rapid polymorphic VT or VF is initiated. The clinical significance of these arrhythmias is unclear, but some evidence has suggested that they have a low likelihood of spontaneous occurrence during follow-up.

As noted earlier, most cases of polymorphic VT and VF are not currently amenable to standard ablation methods because of hemodynamic instability and beat-to-beat changes in activation sequence. However, some cases appear to have a focal source (similar to the focal sources of AF), and if the focus can be identified and ablated, further arrhythmia episodes can be prevented. In such cases, repeated episodes of arrhythmia have constant electrocardiographic features of the initiating beat or beats, thus suggesting a consistent source, which may be in either ventricle. The electrogram at sites of successful ablation often has very sharp presystolic potentials reminiscent of Purkinje potentials, with a 50- to 100-millisecond delay until onset of the QRS (**Fig. 36.19**).[30] In some cases of VF, "rotors" (sites of rapid circulation within a small region) have been reported, ablation of which has prevented recurrences (similar to the case with AF). This work is promising but preliminary.

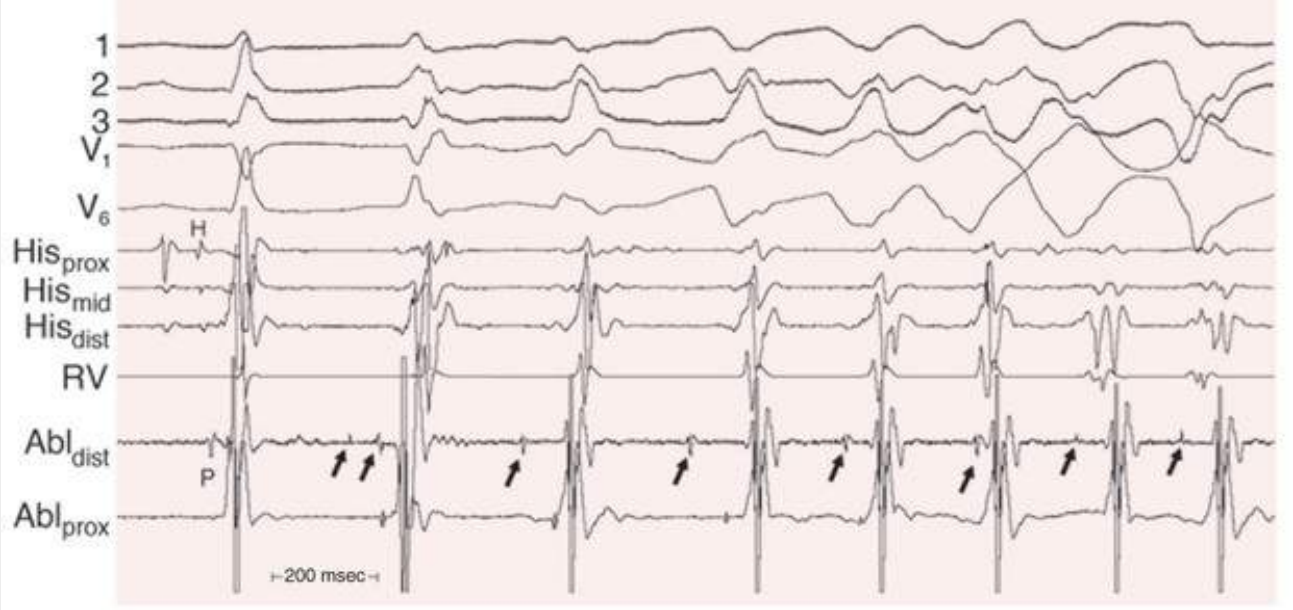

FIGURE 36.19 "Focal ventricular fibrillation." Recordings are shown from a patient with multiple episodes of VF in a day. A sinus rhythm complex, during which a Purkinje potential (*P*) is recorded from the ablation (*Abl*) electrode, is followed by a premature complex from this site that is preceded by sharp Purkinje spikes (*arrows*) that continue to precede subsequent complexes of polymorphic VT that degenerated to VF. Ablation at this site eliminated recurrent episodes of VF.

Indications

Patients considered for RF catheter ablation of VT in the absence of structural heart disease are those with symptomatic, sustained monomorphic VT when the tachycardia is drug resistant, when the patient is drug intolerant, or when the patient does not desire long-term drug therapy. Patients with structural heart disease who are candidates for ablation include those with bundle branch reentrant VT and those with sustained monomorphic VT and an ICD who are receiving multiple shocks not manageable by reprogramming or concomitant drug therapy. In some patients (usually without structural heart disease, but also in patients with diseased ventricles), nonsustained VT or even severely symptomatic PVCs warrant RF catheter ablation. In some of these patients, in whom the ventricular ectopy occurs frequently, significant left ventricular systolic dysfunction has occurred (presumably similar to tachycardia-related cardiomyopathy). After successful ablation, ventricular function may improve significantly or even normalize.

Results

In patients with structurally normal hearts, the success rate of VT or PVC ablation is approximately 85%.[31] In patients with postinfarction VT, more than 70% no longer have recurrences of VT after the ablation procedure despite inducibility of rapid VT or VF; only approximately 30% of patients will have no inducible ventricular arrhythmia of any type and no spontaneous recurrences. As noted earlier, most of these patients already have, or will have, an ICD as backup. Significant complications occur in up to 3%, including vascular damage, heart block, worsening of heart failure, cardiac tamponade, stroke, and valve damage. Death is rare but can occur in patients with severe CAD and/or systolic dysfunction.

New Mapping and Ablation Technologies

Multielectrode Mapping Systems.

Some of the limitations of ablation are related to inadequate mapping. These problems include having only isolated premature complexes during the EPS instead of sustained tachycardias (in idiopathic AT and VT), nonsustained episodes of VT, poor hemodynamic tolerance of VT, and multiple VT morphologies. Standard mapping techniques sample single sites sequentially and are poorly suited to these situations. New mapping systems are available that enable sampling of many sites simultaneously and incorporate sophisticated computer algorithms for analysis and display of global maps. These mapping systems use various technologies ranging from multiple electrodes situated on each of several splines of a basket catheter (**see Fig. 34.16**), to the use of low-intensity electrical or magnetic fields to localize the tip of the catheter in the heart and record and plot activation times on a contour map of the chamber, to the use of complex mathematics to compute "virtual" electrograms recorded from a mesh electrode situated in the middle of a chamber cavity or on the body surface. Some of these systems are capable of generating activation maps of an entire chamber by using only one cardiac complex, an obvious advantage in patients with only rare premature complexes, nonsustained arrhythmias, or poor hemodynamic tolerance of sustained arrhythmias.

Epicardial Catheter Mapping.

Although most VTs can be ablated from the endocardium, occasional cases are resistant to this therapy. In many of these cases, epicardial ablation may be successful. It is often needed in VT attributable to cardiomyopathy but less frequently in postinfarction patients and those without structural heart disease.

For gaining access to the pericardial space for epicardial mapping and ablation, a long spinal anesthesia needle is introduced from a subxiphoid approach under fluoroscopic guidance. As the pericardium is approached, a small amount of radiocontrast agent is injected. If the tip of the needle is still outside the pericardium, the dye stays where it is injected; when the pericardial space has been entered, the dye disperses and outlines the heart. A guidewire is introduced through the needle and a standard vascular introducer sheath exchanged over the wire. The pericardial space is then accessible for a mapping/ablation catheter, and standard mapping techniques can then be applied. When a site is selected for possible ablation, coronary arteriography is usually warranted to avoid delivery of RF energy near a coronary artery. This is less important in cases of postinfarction VT because the VT substrate is typically in a region of previous transmural infarction. For left ventricular sites, high-output pacing should be performed to assess proximity to the left phrenic nerve; if captured, another ablation site may be sought at which phrenic capture is absent, or a balloon catheter can be placed in the pericardial space (or air or fluid instilled) to physically displace and thus protect the nerve from damage during ablation. Epicardial mapping can be used for patients who have previously undergone cardiac surgery, although adhesions may obliterate portions of the pericardial space; on occasion, a small subxiphoid incision is needed for better access and visualization of the space. The most frequent complication of epicardial mapping is pericarditis related to the ablation; cardiac tamponade is rare.

Chemical Ablation.

Chemical ablation of an area of myocardium can be used for treatment of VT refractory to drug and standard catheter ablation. Using this specialized technique, an angioplasty catheter is maneuvered into an arterial (or venous) branch in the region of the VT (determined by mapping). After verifying the correct vessel by injecting iced saline into it and observing transient slowing or termination of VT, the angioplasty balloon is inflated (to prevent spillage of alcohol) and 100% ethanol is injected into the vessel. This generally terminates VT and kills the cells responsible for its continuation. Recurrences of tachycardia several days after apparently successful ablation are possible. Excessive myocardial

necrosis is the major complication, and alcohol ablation should be considered only when other ablative approaches fail or cannot be done.

Several other mapping/imaging techniques have been developed recently, including integration of a previously obtained computed tomography or magnetic resonance study into computerized mapping systems and use of intracardiac ultrasound to construct a facsimile of the intracardiac anatomy in any chamber during ablation procedures, to guide placement of anatomic ablation and reduce fluoroscopic exposure. Other techniques include use of algorithms to select complex fractionated atrial electrograms for ablation in patients with AF and algorithms to assess the fidelity of pace maps with native tachycardia complexes. Cryoablation, high-frequency focused ultrasound, and delivery of RF energy between two catheters on opposite sides of a ventricular wall, or through a needle electrode inserted into myocardium, have had some success in select patients.

Surgical Therapy for Tachyarrhythmias

The objectives of a surgical approach to treatment of a tachycardia are to excise, isolate, or interrupt tissue in the heart critical for initiation, maintenance, or propagation of the tachycardia while preserving or even improving myocardial function. In addition to a direct surgical approach to the arrhythmia, indirect approaches such as aneurysmectomy, coronary artery bypass grafting, and relief of valvular regurgitation or stenosis can be useful in select patients by improving cardiac hemodynamics and myocardial blood supply. *Cardiac sympathectomy* (stellate ganglionectomy) alters adrenergic influences on the heart and has been effective in some patients, particularly those who have recurrent VT with long-QT syndrome despite beta blockade, and catecholaminergic polymorphic VT.

Supraventricular Tachycardias

Surgical procedures exist for patients (adults and children) with AT, atrial flutter and fibrillation, AV node reentry, and AV reentry (**Fig. 36.20**). RF catheter ablation adequately treats most of these patients and thus has replaced direct surgical intervention, except for the occasional patient in whom RF catheter ablation fails or who is undergoing concomitant cardiovascular surgery. In some cases, a prior attempt at RF catheter ablation complicates surgery by obliterating the normal tissue planes that exist in the AV groove of the heart or by rendering tissues friable. On occasion, patients with ATs have multiple foci that require surgical intervention. Several surgical procedures have been developed to treat AF and are reviewed in **Chapter 38**.

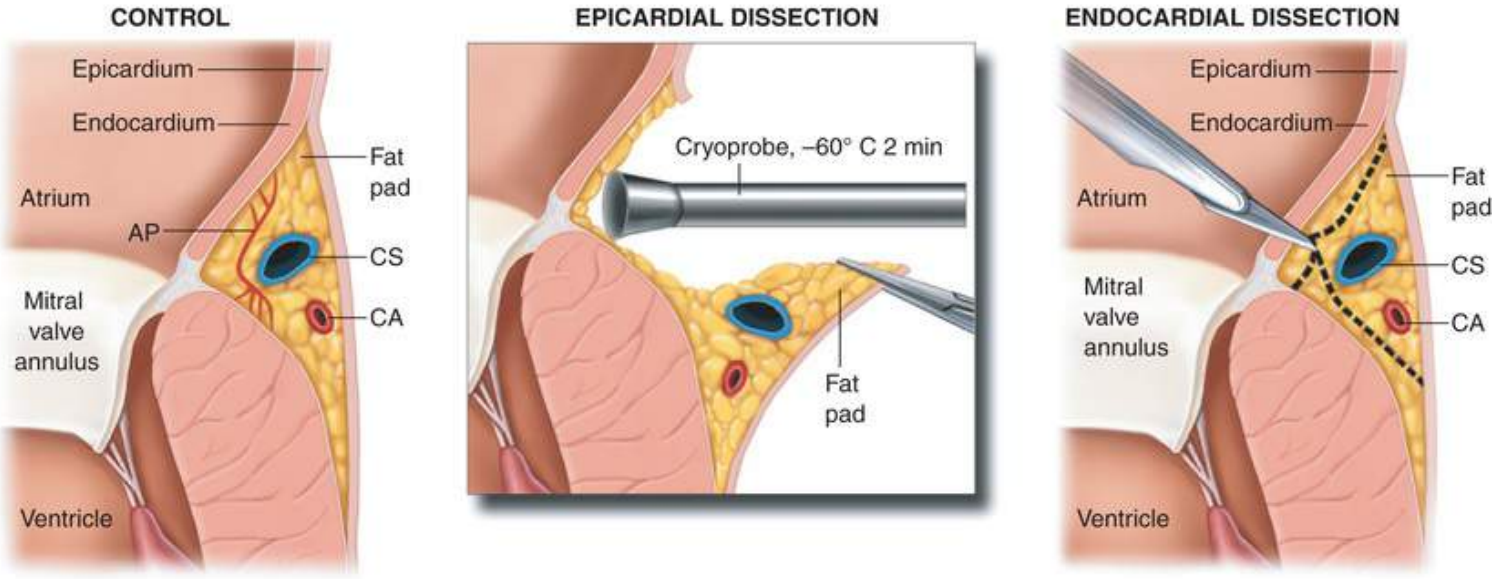

FIGURE 36.20 Schematic diagram showing the two approaches for surgical interruption of an accessory pathway. **Left,** Left AV groove and its vascular contents the coronary sinus (*CS*) and circumflex coronary artery (*CA*). Multiple accessory pathways (*AP*) course through the fat pad. **Middle,** Approach for epicardial dissection. **Right,** Endocardial dissection. Both approaches clear out the fat pad and interrupt any accessory pathways. (From Zipes DP. Cardiac electrophysiology: promises and contributions. J Am Coll Cardiol 1989;13:1329. Reprinted by permission of the American College of Cardiology.)

Ventricular Tachycardia

In contrast to patients with supraventricular arrhythmias, candidates for surgical therapy for ventricular arrhythmias often have severe left ventricular dysfunction, generally the result of CAD. The cause of the underlying heart disease influences the type of surgery performed. Candidates are patients with drug-resistant, symptomatic, recurrent ventricular tachyarrhythmias who ideally have a segmental wall motion abnormality (scar or aneurysm) with preserved residual left ventricular function, have not benefited from previous attempts at catheter ablation, or are not candidates for catheter ablation because of hemodynamic instability during VT or the presence of left ventricular thrombi (precluding endocardial catheter ablation).

Idiopathic VT/PVCs and Nonischemic Cardiomyopathy

Patients with VT or PVCs in the absence of structural heart disease or with nonischemic cardiomyopathy who have undergone unsuccessful drug and catheter ablation therapy for their arrhythmias are candidates for surgical therapy.

The procedure is usually performed through a limited thoracotomy, exposing only the area of the ventricles believed responsible for the arrhythmia. In idiopathic VT/PVC cases, this is often at the basal aspect of the anterior left ventricle, an area where catheter ablation is difficult because of thick epicardial fat and proximity to major coronary arteries. After exposing the area of the ventricular epicardial surface of interest, mapping is done to confirm the source of the arrhythmia, after which cryoablation is usually performed. This typically results in cessation of the arrhythmia. Extensive ablation is often needed in patients with nonischemic cardiomyopathy, in whom epicardial and intramural

scarring in the basal left and right ventricles is a common substrate for ventricular arrhythmias.

Ischemic Heart Disease

In almost all patients who have VT associated with ischemic heart disease, the arrhythmia, regardless of its configuration on the surface ECG, arises in the left ventricle or on the left ventricular side of the interventricular septum. The electrocardiographic contour of the VT can change from a right bundle branch block to a left bundle branch block pattern without a change in the site of earliest diastolic activation, thus suggesting that the location of the circuit within the left ventricle remains the same, often near the septum, but that its exit pathway is altered.

Indirect surgical approaches, including cardiothoracic sympathectomy, coronary artery revascularization, and ventricular aneurysm or infarct resection with or without coronary artery bypass grafting, have been successful in no more than 20% to 30% of VT cases. Coronary artery bypass grafting as a primary therapeutic approach has generally been successful only in patients who experience rapid VT because of severe ischemia, as well as in patients with ischemia-related VF, but it can sometimes be useful in patients with coronary disease resuscitated from sudden death who have no inducible arrhythmias at EPS. These patients generally show a clear relationship between episodes of ventricular arrhythmia and immediately antecedent severe ischemia and have no evidence of infarction or minimal wall motion abnormalities but have preserved overall left ventricular function. Patients with sustained monomorphic VT or only polymorphic VT rarely have their arrhythmias affected by coronary bypass surgery, although it can reduce the frequency of the arrhythmic episodes in some patients and prevent new ischemic events.

Surgical Techniques.

In general, two types of direct surgical procedures are used, resection and ablation (**Fig. 36.21**). The first direct surgical approach to VT was encircling endocardial ventriculotomy, which entails performing a transmural ventriculotomy to isolate areas of endocardial fibrosis that were recognized visually; this procedure is rarely used now. Another procedure, subendocardial resection, is based on data indicating that arrhythmias after MI arise mostly at the subendocardial borders between normal and infarcted tissue. Subendocardial resection involves peeling off a 1- to 3-mm-thick layer of endocardium, often near the rim of an aneurysm, that has been demonstrated by mapping procedures to contain sites of mid-diastolic activation recorded during VT. Tachycardias arising from near the base of the papillary muscles are treated with a cryoprobe cooled to −70°C. Cryoablation can also be used to isolate areas of the ventricle that cannot be resected and is often combined with resection. Lasers have also been used with good success, but the equipment is expensive and cumbersome.

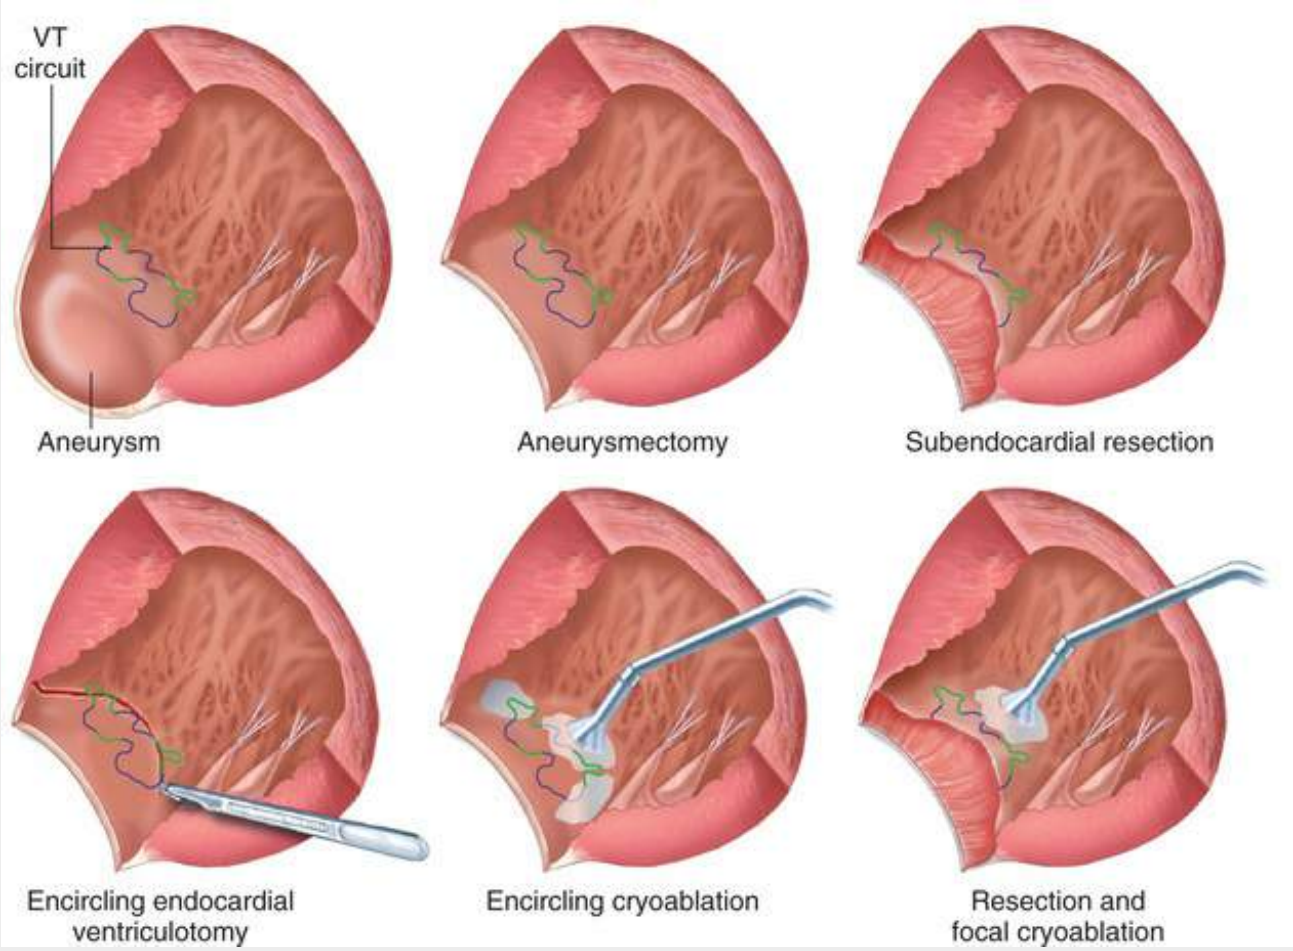

FIGURE 36.21 Schematic diagram showing surgical procedures for the treatment of postinfarction ventricular tachycardia with a left ventricular aneurysm. A damaged left ventricle is depicted as opened along the lateral wall and showing the septum and papillary muscles. The tachycardia circuit **(upper left)** takes a meandering course near the point where the aneurysm meets normal myocardium and at times is superficial (*purple lines*) and at other times is coursing deeper (*green lines*). Simple aneurysmectomy that leaves a portion of the aneurysm for suturing often misses the circuit and thus does not cure the arrhythmia. By subendocardial resection, a layer of endocardium and subjacent tissue is removed, including at least some of the tachycardia circuit. Such resection results in elimination of the tachycardia. Encircling endocardial ventriculotomy attempts to isolate the circuit electrically without removal of tissue, but it probably actually works by incising portions of the circuit. Cryoablation can be used to encircle the infarct zone, alone or in combination with resection of damaged tissue too deep in the wall to be resected safely.

Results

For ventricular tachyarrhythmias, operative mortality ranges from 5% to 10%. Success, defined as the absence of recurrence of spontaneous ventricular arrhythmias, is achieved in 59% to 98% of patients. In experienced centers, operative mortality can be as low as 5% in stable patients undergoing elective procedures, with 85% to 95% of survivors being free of inducible or spontaneous ventricular tachyarrhythmias. Long-term recurrence rates range from 2% to 15% and correlate with results of the patient's postoperative electrophysiologic stimulation study. Operative survival is strongly influenced by the degree of left ventricular dysfunction.

Electrophysiologic Studies

Preoperative Electrophysiologic Study.

In patients for whom direct surgical therapy for VT is planned, a preoperative EPS is usually warranted. This study involves initiation of the VT and electrophysiologic mapping to localize the area to be resected, as is done with catheter ablation. Preoperative catheter mapping is contraindicated in patients with known left ventricular thrombi that might be dislodged by the mapping catheter.

Intraoperative Ventricular Mapping.
Electrophysiologic mapping is also performed at surgery, with the surgeon using a handheld probe or an electrode array coupled with computer techniques that instantaneously provide an overall activation map, cycle by cycle. The sequence of activation during VT can be plotted and the area of earliest activation determined. Resection or cryoablation of tissue from which these recordings are made usually cures the VT, thus indicating that they represent a critical portion of the reentrant circuit. When the earliest recordable endocardial electrical activity occurs less than 30 milliseconds before onset of the QRS complex, the critical portions of the circuit may be in the interventricular septum or near the epicardium of the free wall. In some patients, intramural mapping using a plunge needle electrode can be useful. Most centers have used a strategy of "sequential" subendocardial resection in which VT is initiated, mapped, and ablated (resected or cryoablated) while the heart is warm and beating, and stimulation is repeated immediately. If VT can still be initiated, mapping and resection are also repeated until VT can no longer be initiated. Reentry around an inferior scar, with a critical diastolic pathway confined to an isthmus of ventricular muscle between the scar and mitral valve annulus, can be cured by cryoablation of this isthmus. Cure rates in this situation exceed 93%.

Supraventricular Arrhythmias

Jeffrey E. Olgin, Douglas P. Zipes

Normal Sinus Rhythm

Impulse formation beginning in the sinus node at rates between 60 and 100 beats/min defines normal sinus rhythm. Faster heart rates at rest and during exercise occur in infants and children than in adults. The P wave is upright in electrocardiographic leads I, II, and aVF and negative in lead aVR, with a vector in the frontal plane of between 0 and +90 degrees. The P vector is directed anteriorly and slightly leftward in the horizontal plane and can therefore be negative in leads V_1 and V_2 but positive in V_3 to V_6. The PR interval exceeds 120 milliseconds and can vary slightly with the rate. A change in morphology of the P wave can occur if the pacemaker site (site of impulse origin) shifts. The rate of sinus rhythm varies significantly and depends on many factors, including age, sex, and physical activity.

The sinus rate responds readily to autonomic stimuli. Steady vagal (parasympathetic) stimulation decreases the spontaneous sinus rate and predominates over steady sympathetic stimulation, which increases the spontaneous sinus rate.

Rates less than 60 beats/min are considered to be bradycardia, and rates higher than 100 beats/min, tachycardia. As described in **Chapter 34**, the normal sequence of electrical activation of the heart is from the sinus node through the atria to the atrioventricular (AV) node and His-Purkinje system and to the ventricular myocardium. Specific tachyarrhythmias and bradyarrhythmias presented as disorders of this electrophysiologic hierarchy and their characteristics are summarized in **Table 37.1**.

TABLE 37.1

Characteristics of Arrhythmias*

TYPE OF ARRHYTHMIA	P WAVES			QRS COMPLEXES			VENTRICULAR RESPONSE TO CAROTID SINUS MASSAGE AND ADENOSINE	PHYSICAL EXAMINATION			ACU TREA
	Rate (beats/min)	Rhythm	Contour	Rate (beats/min)	Rhythm	Contour		Intensity of S_1	Splitting of S_2	A Waves	
Sinus rhythm	60-100	Regular†	Normal	60-100	Regular	Normal	Gradual slowing and return to former rate	Constant	Normal	Normal	None

*In an effort to summarize these arrhythmias in tabular form, generalizations have to be made. For example, the response to carotid sinus massage may be slightly different from what is listed. Acute therapy to terminate a tachycardia may be different from chronic therapy to prevent recurrence. Some of the exceptions are indicated in the footnotes; the reader is referred to text for a complete discussion.

†P waves initiated by sinus node discharge may not be precisely regular because of sinus arrhythmia.

‡Frequently, carotid sinus massage fails to slow a sinus tachycardia.

§Any independent atrial arrhythmia may exit or the atria may be captured retrogradely.

‖Constant if the atria are captured retrogradely.

¶Atrial rhythm and rate may vary, depending on whether sinus bradycardia, sinus tachycardia, or another abnormality is the atrial mechanism.

**Regular or constant if block is unchanging.

AA, Antiarrhythmic drug (procainamide, quinidine, propafenone, flecainide, sotalol, dofetilide, dronedarone, amiodarone); *BB,* beta blocker (e.g., propranolol, metoprolol); *CSM,* carotid sinus massage; *DC,* direct-current; *ICD,* implantable cardioverter-defibrillator; *NDCCB,* nondihydropyridine calcium channel blocker (e.g., diltiazem, verapamil); *PPM,* permanent pacemaker; *CRT,* cardiac resynchronization therapy.

Tachyarrhythmias

Tachyarrhythmias are broadly characterized as *supraventricular tachycardia* (SVT),[1] defined as a tachycardia in which the driving circuit or focus originates, at least in part, in tissue above the level of the ventricle (i.e., sinus node, atria, AV node, or His bundle). Atrial fibrillation is discussed in **Chapter 38**.

Ventricular tachycardia (VT) is defined as a tachycardia in which the driving circuit or focus originates solely in ventricular tissue (including valves and root of the great arteries) or Purkinje fibers (**see Chapter 39**). Because of differences in prognosis and management, distinction between SVT and VT is critical early in the acute management of a tachyarrhythmia.[2] In general, with the exception of the idiopathic form, VT often carries a much poorer prognosis, usually implies the presence of significant heart disease, results in more profound hemodynamic compromise, and therefore requires immediate attention and measures to revert to sinus rhythm. SVT is not usually lethal and often does not result in hemodynamic collapse; therefore more conservative measures can be applied initially to convert to sinus rhythm.[1,3]

Distinction between SVT and VT can generally be made on the basis of the electrocardiogram (ECG) obtained during tachycardia (**see Chapter 35**). It is important to obtain a 12-lead ECG during tachycardia if possible and to obtain 12-lead (or at least multilead) rhythm strips during any intervention aimed at termination of the tachycardia, because examining the termination (and initiation) can help identify the specific arrhythmia. If the QRS is narrow (duration <120 msec, often referred to as *narrow-complex tachycardias*), the ventricle is usually being activated through the normal His-Purkinje system, and thus the origin of the tachycardia is supraventricular[4] (**Fig. 37.1**). A wide QRS (duration >120 msec) during tachycardia suggests VT, although in some common scenarios, SVT can produce a wide QRS complex. Therefore a more descriptive term, *wide-complex tachycardia* (WCT), is often used when the precise arrhythmia mechanism cannot be determined. For example, SVT with a concurrent bundle branch block (BBB) or intraventricular conduction defect can produce WCTs despite a supraventricular origin, as can preexcited tachycardias (tachycardias in which the ventricle is activated in whole or in part over an accessory pathway). Therefore, although a narrow-complex tachycardia almost always makes the diagnosis of SVT, a WCT can be supraventricular or ventricular. Fusion or capture beats and AV dissociation are diagnostic of VT but are often not present or are difficult to detect. Criteria and algorithms have been developed to determine whether a WCT is more likely to be SVT or VT (**Table 37.2; see Chapter 39**). The general principles behind these algorithms rest on the assumption that the closer the QRS morphology is to a typical BBB pattern, the more likely it is an SVT and assumes that the septum is still rapidly activated in a WCT caused by SVT.

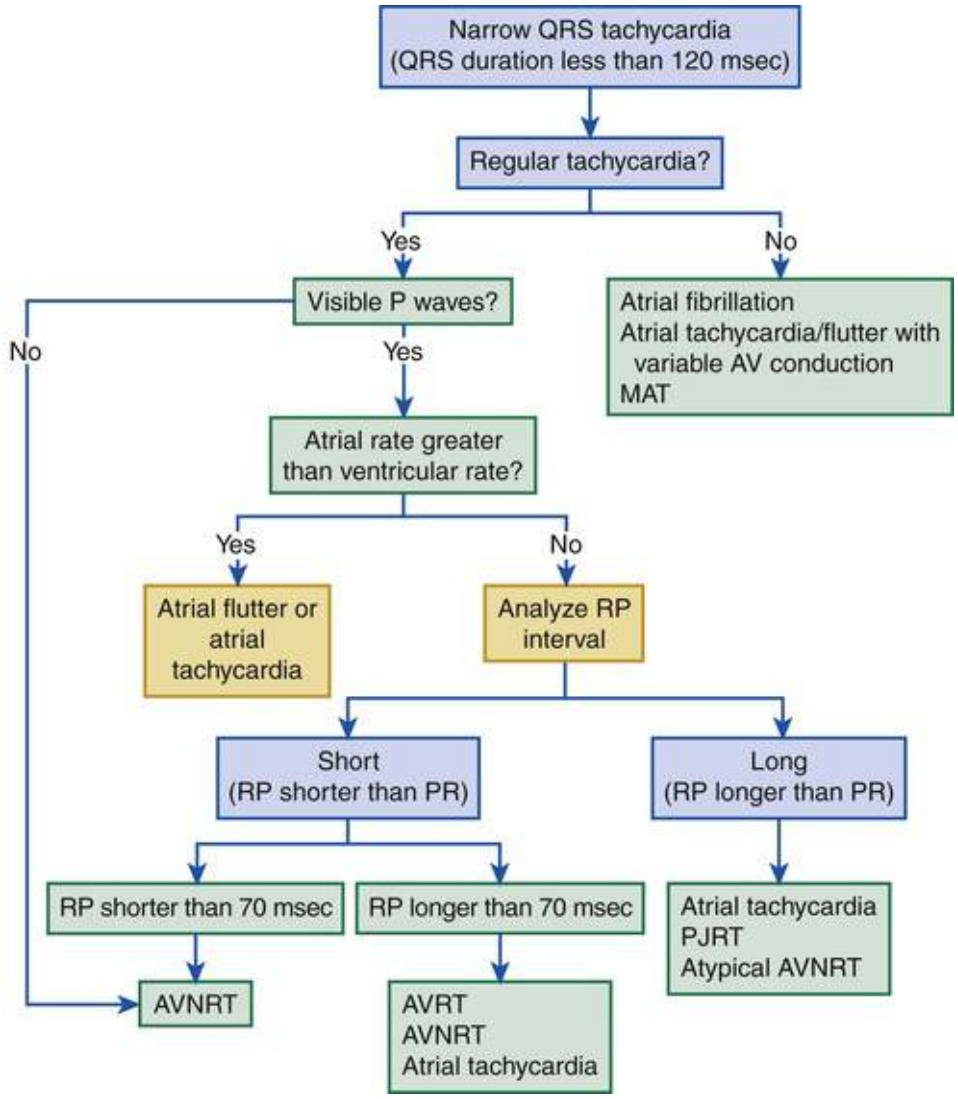

FIGURE 37.1 Algorithm for the diagnosis of a narrow-QRS tachycardia. *AVRT,* Atrioventricular reentrant tachycardia; *AVNRT,* atrioventricular nodal reentrant tachycardia; *MAT,* multifocal atrial tachycardia; *PJRT,* permanent form of AV junctional reciprocating tachycardia. Supraventricular Tachycardias

Sinus Tachycardia

Electrocardiographic Recognition

During sinus tachycardia the sinus rate is 100 to 180 beats/min, although it can be higher with extreme exertion and in young individuals (**Fig. 37.2**). The maximum heart rate achieved during strenuous physical activity varies widely but decreases with age. Sinus tachycardia generally has a gradual onset and termination. The P-P interval can vary slightly from cycle to cycle, especially at slower rates, when the normal contour can develop a larger amplitude and become peaked. P waves appear before each QRS complex with a stable PR interval unless concomitant AV block ensues.

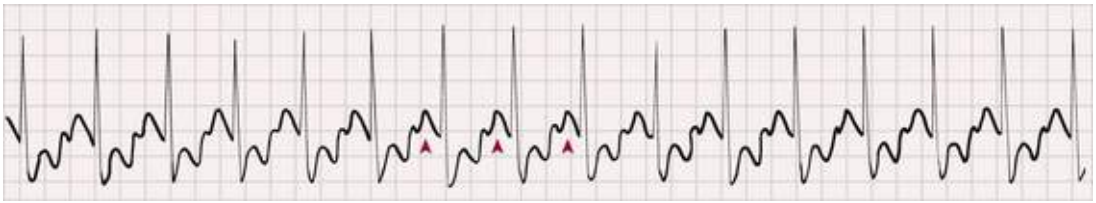

FIGURE 37.2 Sinus tachycardia (150 beats/min) in a patient during acute myocardial ischemia; note the ST-segment depression. P waves are indicated by *arrowheads*.

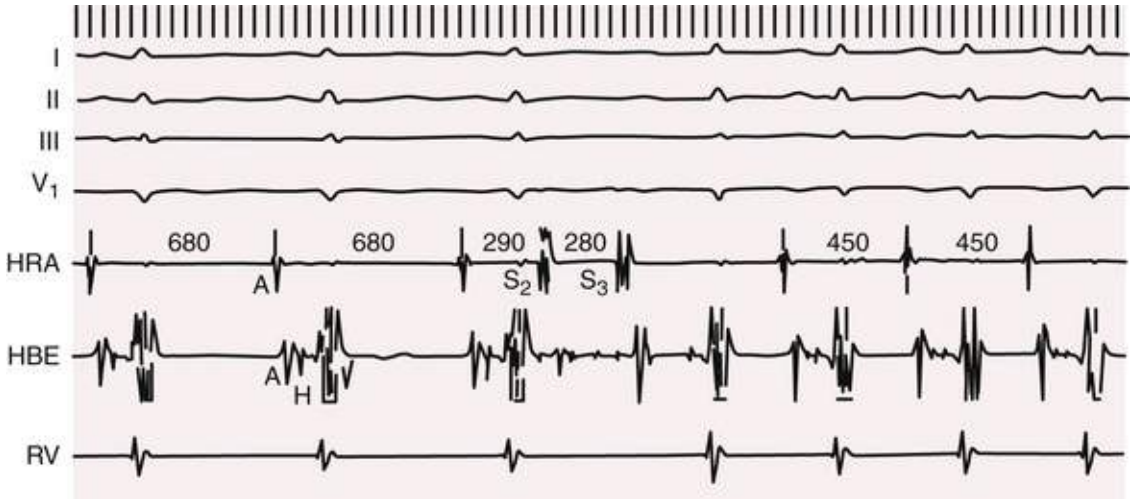
Accelerated phase 4 diastolic depolarization of sinus nodal cells (**see Chapter 34**) generally causes sinus tachycardia, usually from elevated adrenergic tone or withdrawal of parasympathetic tone. Carotid sinus massage and Valsalva or other vagal maneuvers gradually slow sinus tachycardia, which then accelerates to its previous rate on cessation of the enhanced vagal tone. More rapid sinus rates can fail to slow in response to a vagal maneuver, particularly those driven by high adrenergic tone.

Clinical Features

Sinus tachycardia is common in infancy and early childhood and is the normal reaction to various physiologic or pathophysiologic stresses, such as fever, hypotension, thyrotoxicosis, anemia, anxiety, exertion, hypovolemia, pulmonary emboli, myocardial ischemia, congestive heart failure, and shock. Atropine, catecholamines, and thyroid medications, as well as alcohol, nicotine, caffeine, and amphetamines or other stimulants, can produce sinus tachycardia. Persistent sinus tachycardia can be a manifestation of heart failure.

In patients with structural heart disease, sinus tachycardia can result in reduced cardiac output or angina or can precipitate another arrhythmia, in part related to the abbreviated ventricular filling time and compromised coronary blood flow. Sinus tachycardia can cause inappropriate defibrillator discharge in patients with an implantable cardioverter-defibrillator (ICD; **see Chapter 41**). *Chronic inappropriate sinus tachycardia* (also known as the syndrome of inappropriate sinus tachycardia) has been described in otherwise healthy persons, possibly secondary to increased automaticity of the sinus node or an automatic atrial focus near the sinus node.[5] The abnormality can result from a defect in sympathetic or vagal nerve control of sinoatrial (SA) automaticity or from an abnormality of the intrinsic heart rate. In *postural orthostatic tachycardia syndrome* (POTS), a related syndrome consisting of orthostatic hypotension and sinus tachycardia, the cause of the orthostatic decrease in blood pressure is not hypovolemia or drugs. Both syndromes can result from autonomic neuropathy, either peripheral, as in diabetic patients, or central, from spinal cord injury. Sinus node reentry (**eFig. 37.1**) is an atrial tachycardia originating from tissue near the sinus node and thus has a P wave morphology similar to sinus rhythm (see later, Focal Atrial Tachycardias).



EFIGURE 37.1 Sinus node reentry. After three spontaneous sinus-initiated beats, premature stimulation of the high right atrium (S_2, S_3) initiates a sustained tachycardia at a cycle length of 450 milliseconds that has the identical high-low atrial activation sequence characteristic of sinus node discharge. This is sinus node reentry. Leads I, II, III, and V_1 are scalar leads. *H,* His electrogram; *HBE,* His bundle electrogram; *HRA,* high right atrial electrogram; *RV,* right ventricular electrogram. Numbers are milliseconds.

Management

Management focuses on the cause of the sinus tachycardia. In the hospital setting the cause is usually obvious (e.g., hemorrhage, sepsis, agitation), whereas in the outpatient arena it may be more elusive. The most common reversible causes include hyperthyroidism, anemia, infection or inflammation, and hypovolemia. Diabetic neuropathy is also common but not reversible. Elimination of tobacco, alcohol, caffeine, or other stimulants, such as the sympathomimetic agents in nose drops and cold medications, may be helpful. Beta blockers and nondihydropyridine calcium channel blockers (verapamil and diltiazem), fluid replacement in a hypovolemic patient, or fever reduction in a febrile patient can help slow the sinus nodal discharge rate. Treatment of inappropriate sinus tachycardia requires beta blockers or calcium channel blockers, alone or in combination. In severe cases, sinus node radiofrequency (RF) or surgical ablation may be indicated; however, these approaches are usually only temporarily palliative (**see Chapter 36**). A specific blocker of the pacemaker current (I_f), ivabradine, has been useful in some patients with inappropriate or refractory sinus tachycardia.

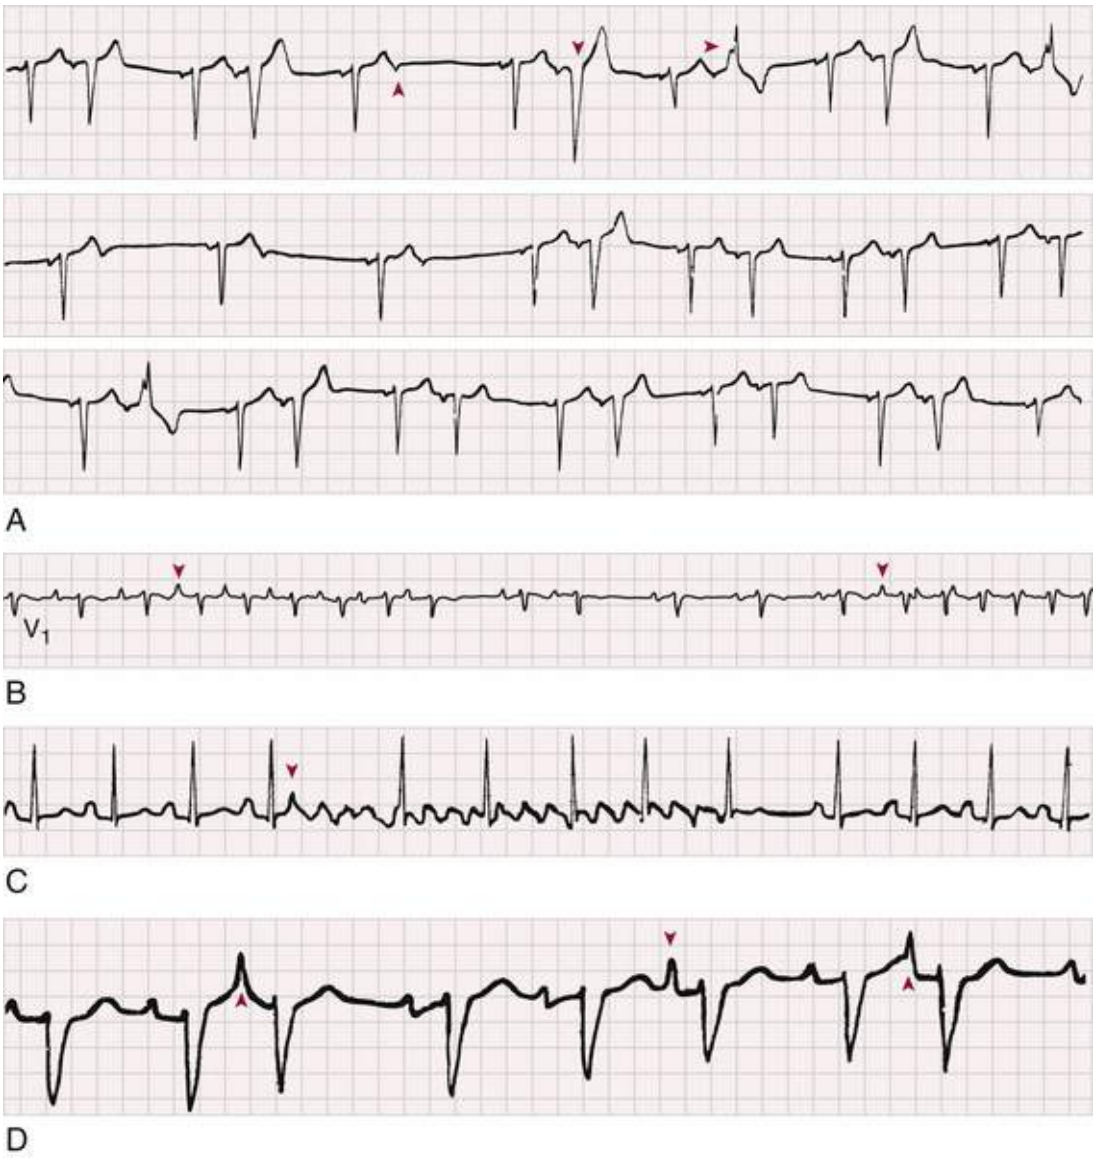
Premature Atrial Complexes

Premature complexes are among the most common causes of an irregular pulse and palpitations. They can originate from any area in the heart—most frequently from the ventricles, less often from the atria and the AV junctional area, and rarely from the sinus node. Premature complexes are common in normal hearts and increase in frequency with age.

Electrocardiographic Recognition

Premature atrial complexes (PACs) are diagnosed electrocardiographically (**Fig. 37.3**) by the presence of a premature P wave with a PR interval exceeding 120 milliseconds (except in Wolff-Parkinson-White [WPW] syndrome, when the PR interval is generally shorter than 120 msec). The contour of a premature P wave can resemble that of a normal sinus P wave, although it generally differs. Variations in the basic sinus rate can make the diagnosis of prematurity difficult, but differences in the contour of the P waves are

usually apparent and indicate a different focus of origin. PACs early in diastole may become blocked (nonconducted PAC; **Fig. 37.3A**) or conduct with a prolonged PR interval. The RP interval is usually inversely related to the PR interval; thus a long PR interval follows a short RP interval produced by an early PAC occurring close to the preceding QRS complex. PACs occurring early in the cardiac cycle can be difficult to discern because of superimposed T waves. Careful examination of tracings from several leads may be necessary before the PAC is recognized as a slight deformity of the T wave. Frequently, such PACs are blocked before reaching the ventricle and can be misinterpreted as a sinus pause or sinus exit block (**see Fig. 37.3A**).



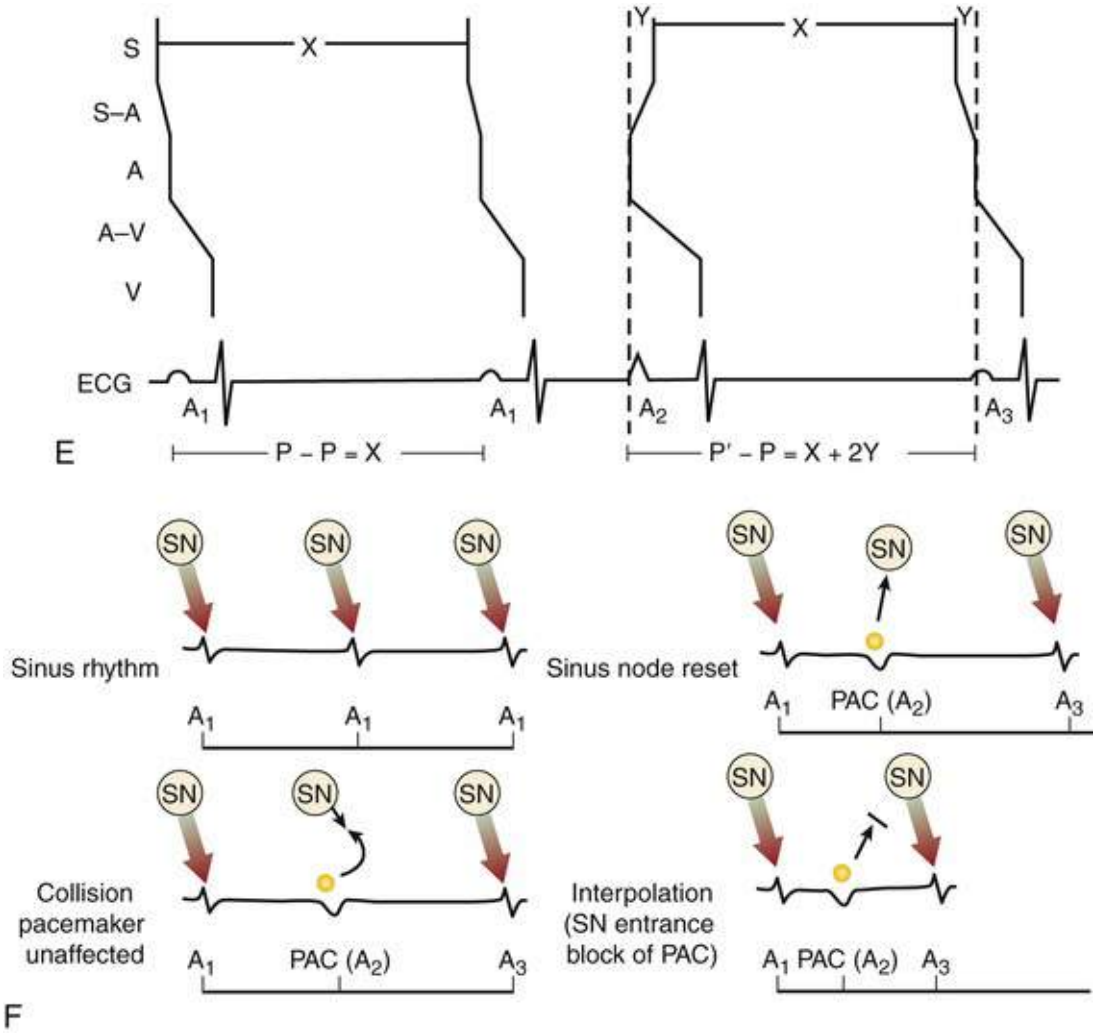


FIGURE 37.3 **A,** Premature atrial complexes (PACs) that block conduction entirely or conduct with a functional right or functional left bundle branch block. Depending on the preceding cycle length and coupling interval of the PAC, the PAC blocks conduction entirely in the AV node (*arrowhead* ↑) or conducts with a functional left bundle branch block (*arrowhead* ↓) or functional right bundle branch block (*arrowhead* →). **B,** A PAC on the left (*arrowhead*) initiates AV nodal reentry that is caused by reentry anterogradely and retrogradely over two slow AV nodal pathways, with a retrograde P wave produced midway in the cardiac cycle. On the right, a PAC (*arrowhead*) initiates AV nodal reentry as a result of anterograde conduction over the slow pathway and retrograde conduction over the fast pathway (**see Fig. 37.8A**), which produces a retrograde P wave in the terminal portion of the QRS complex that simulates an r′ wave. **C, D,** A PAC (*arrowhead* ↓) initiating a short run of atrial flutter **(C)** and a PAC (*arrowhead* ↑) depressing return of the next sinus nodal discharge **(D).** A slightly later PAC (*arrowhead* ↓) in **D** does not depress sinus nodal automaticity. **B-D,** Monitor leads. **E,** Ladder diagram of the effects of a PAC. The sinus interval (A_1-A_1) equals X. The third P wave represents a PAC (A_2) that reaches and discharges the SA node, which causes the next sinus cycle to begin at that time. Therefore the P-P (A_2-A_3) interval equals X + 2Y milliseconds, assuming no depression of SA nodal automaticity. **F,** Diagram of the interactions of a PAC (*yellow circles* indicate origin; QRS complexes omitted) with the sinus node (*SN*) depending on the degree of prematurity. The **top** represents spontaneous sinus rhythm. The **bottom** is a late coupled PAC that collides with the exiting sinus impulse and therefore does not affect (or reset) the sinus pacemaker. The next sinus impulse (S_3) occurs at exactly twice the sinus interval. An early coupled PAC in the next diagram is able to penetrate the SN and resets the pacemaker, thereby resulting in resetting of the SN (as depicted in **E**). An even earlier coupled PAC in the lower part of the figure reaches refractory tissue around the SN and is thus unable to penetrate it (SN entrance block); therefore, it does not affect SN discharge. The next spontaneous sinus beat (S_3) arrives exactly at the sinus interval. (***E,*** Modified from Zipes DP, Fisch C. Premature atrial contraction. Arch Intern Med 1971;128:453.)

Several factors determine the length of the pause that follows any premature complex or series of

premature complexes. If the PAC occurs when the sinus node and perinodal tissue are not refractory, the impulse can be conducted into the sinus node, can discharge it prematurely, and can cause the next sinus cycle to begin from that time. The interval between the two normal P waves flanking a PAC that has reset the timing of the basic sinus rhythm is less than twice the normal P-P interval, and the pause after the PAC is said to be *noncompensatory* (**Fig. 37.3E, F**). Reset (noncompensatory pause) occurs when the A_1-A_2 interval plus the A_2-A_3 interval is less than two times the A_1-A_1 interval and the A_2-A_3 interval is greater than the A_1-A_1 interval. The interval between the PAC (A_2) and the following sinus-initiated P wave (A_3) exceeds one sinus cycle but is less than fully compensatory (see later), because the A_2-A_3 interval is lengthened by the time that it takes the ectopic atrial impulse to be conducted to the sinus node and depolarize it and then for the sinus impulse to return to the atrium. These factors lengthen the return cycle, that is, the interval between the PAC (A_2) and the following sinus-initiated P wave (A_3) (**see Fig. 37.3E, F**). Premature discharge of the sinus node by an early PAC can temporarily depress sinus nodal automatic activity and cause the sinus node to beat more slowly initially (**Fig. 37.3D**). Often when this happens, the interval between the A_3 and the next sinus-initiated P wave exceeds the A_1-A_1 interval.

Less frequently, the PAC encounters a refractory sinus node or perinodal tissue (**see Fig. 37.3F**), in which case the timing of the basic sinus rhythm is not altered because the sinus node is not reset by the PAC and the interval between the two normal sinus-initiated P waves flanking the PAC is twice the normal P-P interval. The interval that follows this PAC is said to be a *full compensatory pause*, that is, of sufficient duration that the P-P interval bounding the PAC is twice the normal P-P interval. However, sinus arrhythmia can lengthen or shorten this pause. Rarely, an interpolated PAC can occur. In this case the pause after the PAC is very short, and the interval bounded by the normal sinus-initiated P waves on each side of the PAC is equal to one normal P-P cycle length or slightly longer. The interpolated PAC fails to affect the sinus nodal pacemaker, and the sinus impulse that follows the PAC is conducted to the ventricles, often with a slightly lengthened PR interval. An interpolated PAC or premature ventricular complex (PVC) of any type represents the only type of premature systole that does not actually replace the normally conducted beat. PACs can originate in the sinus node and are identified by premature P waves that have a contour identical to that of the normal sinus P wave.

On occasion, when the AV node has had sufficient time to repolarize and conduct without delay, the supraventricular QRS complex initiated by the PAC can be aberrant in configuration, because the His-Purkinje system or ventricular muscle has not completely repolarized and conducts with a functional delay or block (**see Fig. 37.3A**). The refractory period of cardiac fibers is directly related to cycle length. (In an adult, the effective AV nodal refractory period is prolonged at shorter cycle lengths.) A slow heart rate (long cycle length) produces a longer His-Purkinje refractory period than does a faster heart rate. As a consequence, a PAC that follows a long R-R interval (long refractory period) can result in a functional BBB (aberrant ventricular conduction). Because the right bundle branch at long cycles has a longer refractory period than the left bundle branch does, aberration with a right bundle branch block (RBBB) pattern at slow rates occurs more commonly than aberration with a left bundle branch block (LBBB) pattern. At shorter cycles, the refractory period of the left bundle branch exceeds that of the right bundle branch, and an LBBB pattern may be more likely to occur.

Clinical Features

PACs can occur in various situations, such as during infection, inflammation, or myocardial ischemia, or can be provoked by various medications, tension states, tobacco, alcohol, or caffeine. PACs can precipitate or presage the occurrence of sustained supraventricular tachyarrhythmias (**Fig. 37.3B, C**) and,

rarely, ventricular tachyarrhythmias. Frequently, PACs occur without any reversible causes and increase in frequency with aging. In general, PACs have a benign prognosis. Most patients do not have significant symptoms with PACs; however, those who do have symptoms most often feel the pauses that occur after the PAC.

Management

PACs generally do not require therapy. In symptomatic patients or when the PACs precipitate tachycardias, treatment with a beta blocker or a calcium antagonist can be attempted. In drug-refractory, highly symptomatic cases, ablation of the PAC focus can be effective when a single focus can be identified.

Atrial Fibrillation

See Chapter 38.

Atrial Tachycardias

Automatic, triggered, and reentrant causes of atrial tachycardia (AT) have been distinguished experimentally. In most cases, clear identification of the mechanism cannot be made clinically because the clinical and electrophysiologic features can overlap, especially when the reentrant circuit is small (i.e., microreentry). For example, adrenergic stimulation can initiate automatic and triggered ATs, and burst pacing can initiate triggered and microreentrant ATs. Therefore, because it determines the approach to mapping and management, ATs are more broadly characterized clinically as being *focal* (originating from a small area of the atrium with atrial excitation emanating centrifugally from this focus) or *macroreentrant* (a relatively large reentrant circuit using conduction barriers to create the circuit).[6] Atrial flutter is the most common type of macroreentrant AT.

Atrial Flutter and Other Macroreentrant Atrial Tachycardias

Atrial flutter is the prototypic macroreentrant atrial rhythm. The typical atrial flutter is a reentrant rhythm in the right atrium that is constrained anteriorly by the tricuspid annulus and posteriorly by the crista terminalis and eustachian ridge. The flutter can circulate in a counterclockwise direction around the tricuspid annulus in the frontal plane (*counterclockwise* flutter) or in a clockwise direction (*clockwise* or *reverse* flutter). Both are typical flutters because they use the cavotricuspid isthmus. Because both these forms use the same circuit and are constrained by the same anatomic structures, their rates and flutter wave morphology on the surface ECG are consistent and predictable (see later). Rarely, intra-isthmus flutter can occur when the reentrant circuit is isolated to the cavotricuspid isthmus rather than rotating around the entire tricuspid annulus; this typically occurs after ablation in this region (usually done as treatment of typical flutter). Other forms of atrial flutter are now recognized as distinct types and include atrial macroreentry caused by incisional scars[7] from previous atrial surgery, previous atrial ablation, mitral annular flutter,[8] idiopathic fibrosis in areas of the atrium, or other anatomic or functional barriers to conduction in the atria. Because the barriers that constrain these flutters are variable, the electrocardiographic pattern of these atrial flutters can vary. Sometimes, flutter wave morphology changes during the same episode of flutter, which indicates multiple circuits or nonfixed conduction barriers.

Electrocardiographic Recognition

The atrial rate during typical atrial flutter is usually 250 to 350 beats/min, although it is occasionally slower, particularly when the patient is treated with antiarrhythmic drugs (AADs), which can reduce the rate to about 200 beats/min. If such slowing occurs, the ventricles can respond in a 1 : 1 fashion to the slower atrial rate.

In typical atrial flutter, the ECG reveals identically recurring, regular, sawtooth flutter waves (**see Fig. 37.3C**), and evidence of continual electrical activity (lack of an isoelectric interval between flutter waves), often best visualized in leads II, III, aVF, or V_1 (**Fig. 37.4**).[9] During 2 : 1 or 1 : 1 conduction, transient slowing of the ventricular response with carotid sinus massage or adenosine is necessary to visualize the flutter waves. The flutter waves for the most common form, counterclockwise typical atrial flutter, are inverted (negative) in these leads because of a counterclockwise reentrant pathway, and sometimes they are upright (positive) when the reentrant loop is clockwise (**see Fig. 37.4**). When the flutter waves are upright from clockwise rotation, they are often notched. If the AV conduction ratio remains constant, the ventricular rhythm will be regular; if the ratio of conducted beats varies (generally the result of a Wenckebach AV block), the ventricular rhythm will be irregular, although this is rare. Various degrees of penetration into the AV junction by flutter impulses can also influence AV conduction. The ratio of flutter waves to conducted ventricular complexes is most often an even number (e.g., 2 : 1, 4 : 1).

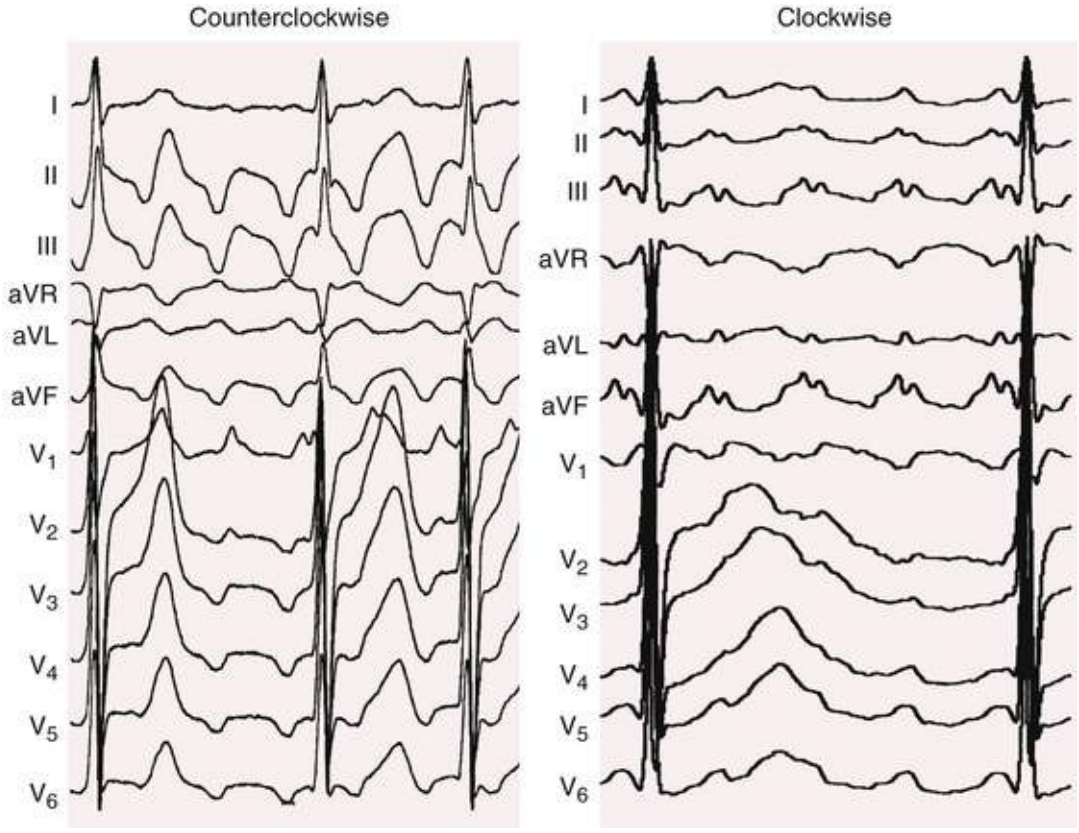

FIGURE 37.4 Twelve-lead ECG showing counterclockwise and clockwise atrial flutter. In counterclockwise atrial flutter, the flutter waves are negative in leads II, III, aVF, and V_6 and upright in V_1. In clockwise atrial flutter, the flutter waves are upright in leads II, III, and aVF and often notched.

As mentioned earlier, because the circuits for atypical flutter (not involving the cavotricuspid isthmus) can be variable, the electrocardiographic features of these macroreentrant ATs are highly variable, without consistent rates or flutter wave contours (**see eFig. 37.2**). However, these tachycardias frequently

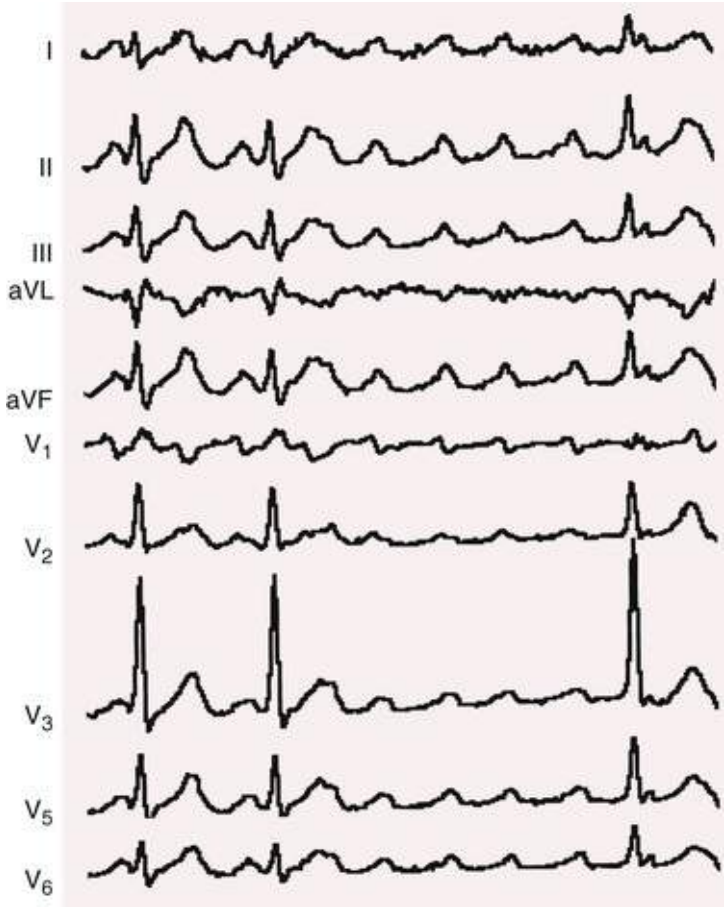
have a flutter rate similar to that of typical flutter (250 to 350 beats/min). **Table 37.3** shows common electrocardiographic findings with the different types of macroreentrant atrial flutter. After extensive left atrial ablation for atrial fibrillation, the electrocardiographic pattern of even typical flutter can change because of the altered left atrial activation caused by altered conduction secondary to ablation. In addition, unusual forms of atrial flutter can occur around ablation lines.

TABLE 37.3

Characteristics of Different Types of Atrial Flutter and Distinguishing Features on Scalar Electrocardiography

TYPE	REENTRANT CIRCUIT	ECG PATTERN	LEAD V_1/V_6
Typical counterclockwise	Tricuspid annulus dependent on the CTI	Sawtooth flutter wave; negative in II, III, and aVF	Positive V_1 Negative V_6
Typical clockwise	Tricuspid annulus dependent on the CTI	"Inverse sawtooth"; positive and often notched in II, III, and aVF	Broad and negative in V_1 (often notched) Positive in V_6
Lower loop reentry	CTI	Usually similar to typical counterclockwise CTI flutter except subtle loss of terminal positive deflection in leads II, III, and aVF	Usually similar to typical counterclockwise
Upper loop reentry	Superior vena cava and upper crista terminalis	Similar to typical clockwise flutter	Similar to typical clockwise flutter
Right atrial free wall	Around areas of scar in lateral or posterior right atrium (caused by previous atrial surgery or spontaneously)	Variable	Typically negative or biphasic with terminal negative deflection in V_1
Septal atrial flutter	Atrial septum, typically after previous surgery	Variable	Usually biphasic or isoelectric in V_1
Mitral annular flutter	Around mitral annulus, often slow zone of block around PV interval; frequently occurs in setting of left atrial surgery or ablation	Variable; I, III, and aVF, often positive but low amplitude	Usually positive in V_1 (or rarely isoelectric) and often broad
Post–atrial fibrillation ablation/maze flutter	Variable; circuit involves previous ablations or scar in left atrium	Variable	Variable

CTI, Cavotricuspid isthmus.



EFIGURE 37.2 Macroreentrant atrial tachycardia in a patient who underwent repair of an atrial septal defect 10 years earlier. This tachycardia uses a reentrant circuit established by the atriotomy on the lateral atrial wall. Ablation to extend the scar to the tricuspid annulus eliminated this tachycardia.

Clinical Features

Atrial flutter is less common than atrial fibrillation. It can result from atrial dilation caused by septal defects, pulmonary emboli, mitral or tricuspid valve stenosis or regurgitation, heart failure, previous extensive atrial ablation, and aging,[10] but it can also occur without underlying heart disease. Toxic and metabolic conditions that affect the heart, such as thyrotoxicosis, alcoholism, and pericarditis, can cause atrial flutter. When it follows surgical repair of congenital heart disease, most patients can have both typical flutter and atypical flutter involving the atriotomy, often occurring years after the surgery.

Carotid sinus massage usually decreases the ventricular rate in stepwise multiples; the ventricular rate returns in reverse manner to the former rate when carotid massage stops. Physical examination can reveal rapid flutter waves in the jugular venous pulse. The first heart sound will have a constant intensity if the relationship of flutter waves to conducted QRS complexes remains constant. Sounds caused by atrial contraction can occasionally be auscultated.

Management

Cardioversion is usually the initial treatment of choice for atrial flutter because it promptly and effectively restores sinus rhythm (**see Chapter 36**). Cardioversion can be accomplished with synchronous direct current (DC), which often requires relatively low energy (approximately 50 J). If the electrical shock results in atrial fibrillation (AF), a second shock at a higher energy level is used to restore sinus rhythm, or depending on clinical circumstances, the AF can be left untreated and can revert to atrial flutter or sinus rhythm. The short-acting AAD ibutilide can also be given intravenously to convert

atrial flutter. Ibutilide appears to successfully cardiovert approximately 60% to 90% of episodes of atrial flutter. However, because this medication prolongs the QT interval, torsades de pointes is a potential complication during and shortly after the infusion. Other medications, such as procainamide or amiodarone, can be given to convert atrial flutter chemically, but they are generally less effective than ibutilide. Rapid atrial pacing with an esophageal or right atrial catheter can effectively terminate typical and some forms of atypical atrial flutter in most patients. Because catheter ablation is highly effective for typical flutter and because of the high relapse rate after cardioversion, catheter ablation is the preferred approach for stable patients who do not require immediate cardioversion. Although the risk for thromboembolism may be lower than for AF, patients with atrial flutter do have a risk for thromboembolism immediately after conversion to sinus rhythm. In general, indications for anticoagulation in patients with atrial flutter are similar to those in patients with AF.

Atrial flutter is usually more difficult to rate-control than AF. To slow the ventricular response, verapamil, given as an initial bolus of 2.5 to 10 mg intravenously (may repeat with an additional 5 to 10 mg after 15 to 30 minutes), or diltiazem, 0.25 mg/kg, can be tried (**see Chapter 36**). Adenosine produces a transient AV block and can be used to reveal flutter waves if diagnosis is in doubt. Adenosine will not generally terminate atrial flutter and can provoke AF. Esmolol, a beta-adrenergic blocker with a 9-minute elimination half-life, or other intravenous (IV) beta blockers can be used to slow the ventricular rate. If calcium channel blockers and beta blockers in combination are insufficient, digoxin can be added. The dose of digitalis necessary to slow the ventricular response varies and at times can result in toxic levels because it is often difficult to slow the ventricular rate during atrial flutter. IV amiodarone can slow the ventricular rate as effectively as digoxin.

If the atrial flutter persists or recurs, class IA, IC, or III drugs can be tried, to restore sinus rhythm and prevent recurrences. Side effects, especially proarrhythmic responses, must be carefully considered (**see Chapter 36**). Treatment of the underlying disorder, such as thyrotoxicosis, is sometimes necessary to effect conversion to sinus rhythm. In many cases, atrial flutter can continue (or even become more persistent) while taking AADs, and the flutter rate will slow. Class IA or IC drugs should not be used unless the ventricular rate during atrial flutter has been slowed with a calcium antagonist or beta blocker. Because class I drugs can slow the flutter rate, AV conduction can be facilitated sufficiently to result in a 1 : 1 ventricular response to the atrial flutter (**Fig. 37.5**).

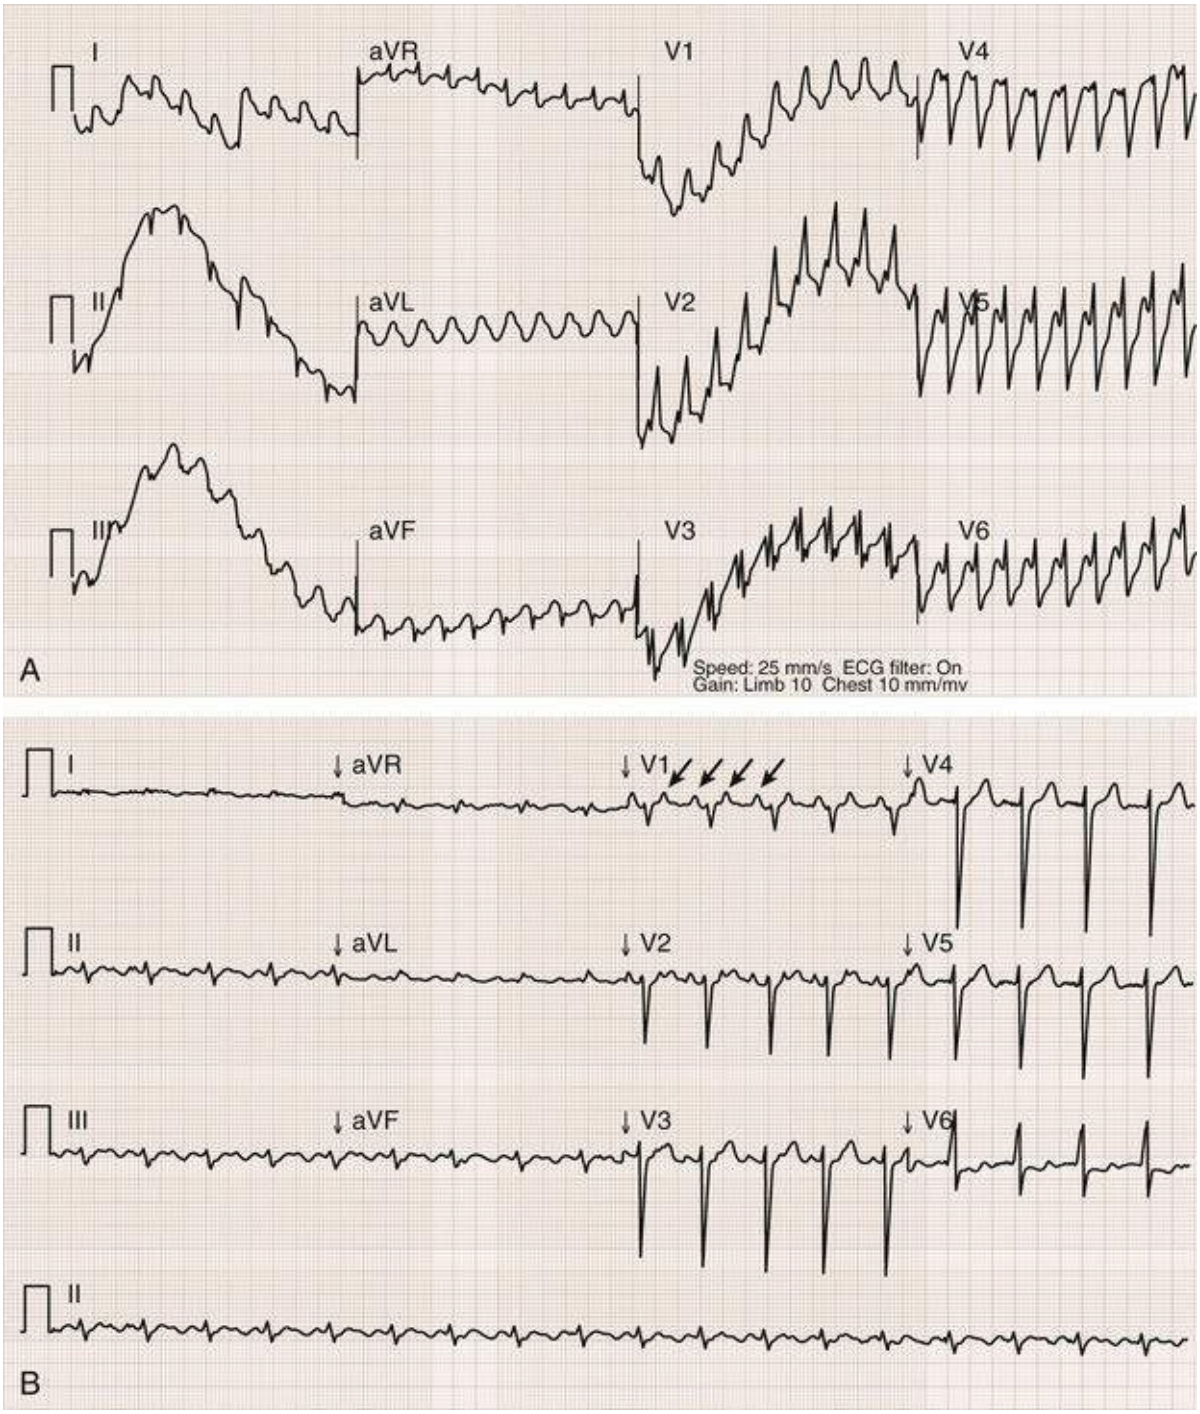


FIGURE 37.5 Atrial flutter with 1 : 1 conduction and QRS widening caused by flecainide. **A,** Atrial flutter occurs with 1 : 1 conduction and a widened QRS because of slowing of the atrial flutter rate as a result of flecainide and acceleration of conduction through the AV node, which leads to a rapid ventricular response. This rapid ventricular response results in a widened QRS complex because of the use dependence of sodium channel blocking by flecainide. **B,** After administration of AV nodal–blocking agents (in this case, metoprolol), 2 : 1 conduction occurs, the ventricular rate is slowed, and the QRS duration shortens. In addition, the flutter waves are now apparent on the ECG (*arrows*).

Prevention of recurrent atrial flutter is frequently difficult to achieve medically but should be approached as outlined for AF (**see Chapters 36 and 38**). Catheter ablation should be considered in patients with symptomatic or recurrent atrial flutter. Catheter ablation of typical flutter (counterclockwise and clockwise) is a highly effective cure and has a long-term success rate of 90% to 100%.[11] Because ablation of atrial flutter is so effective and poses little risk, it can be offered as an alternative to drug therapy. Ablation of other forms of macroreentrant AT is also effective,[7] although success rates are somewhat lower and more variable. Because of the risk for emboli in patients with atrial flutter, and because many patients with atrial flutter also have AF, anticoagulation is usually warranted.

Focal Atrial Tachycardias

Electrocardiographic Recognition

Focal atrial tachycardias generally have atrial rates of 150 to 200 beats/min, with a P wave contour different from that of the sinus P wave (**Fig. 37.6**). However, ATs with foci near the sinus node can have P wave contours very similar to those in sinus rhythm. At onset the rate can increase over the initial several complexes. Frequently, ATs occur in short, recurrent bursts with spontaneous terminations or can become incessant. However, more incessant forms of AT do occur. P waves are generally found in the second half of the tachycardia cycle (long RP–short PR tachycardia). If the atrial rate is not excessive and AV conduction is not depressed, each P wave can conduct to the ventricles. If the atrial rate increases and AV conduction becomes impaired, a Wenckebach (Mobitz type I) second-degree AV block can ensue (**see Chapter 40**), sometimes called *atrial tachycardia with block*. When digitalis causes the AT with block, other manifestations of digitalis excess are present, such as PVCs. In almost half the cases of AT with block, the atrial rate is irregular. Characteristic isoelectric intervals between P waves, in contrast to atrial flutter, are usually present in all leads. However, at rapid atrial rates, distinction between AT with block and atrial flutter can be difficult. Analysis of P wave configuration during tachycardia indicates that a positive or biphasic P wave in V_1 predicts a left atrial focus, whereas a negative P wave in V_1 predicts a right atrial focus.

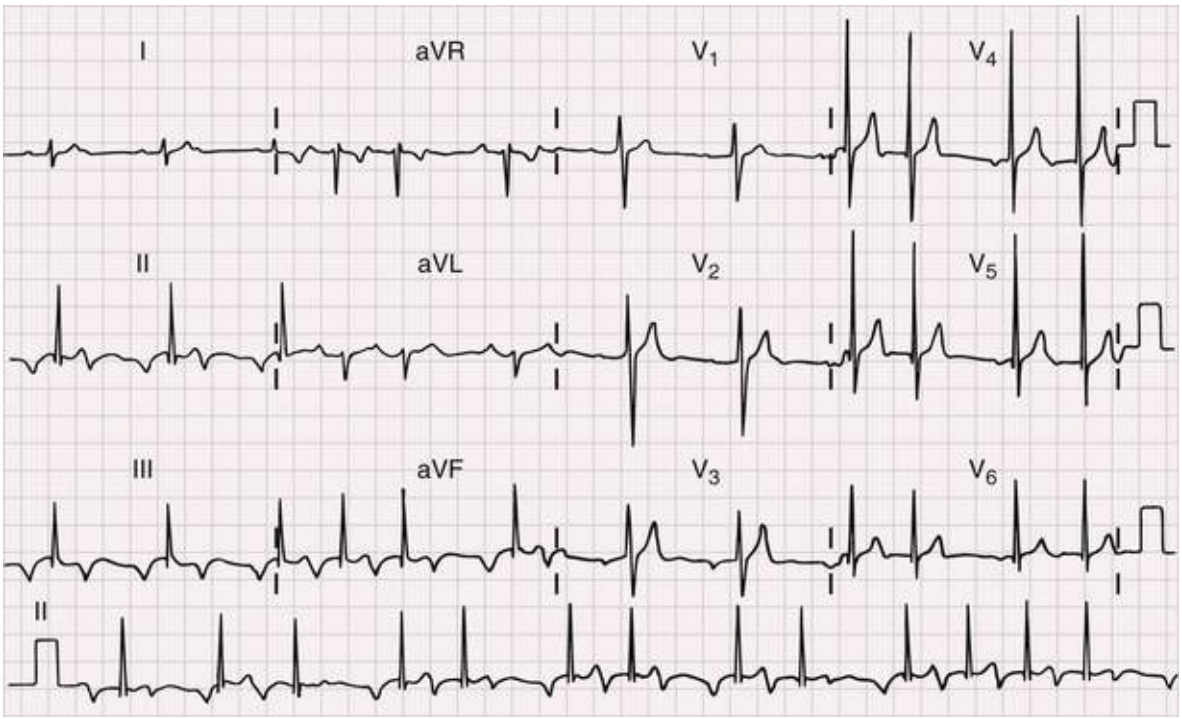

FIGURE 37.6 Atrial tachycardia. This 12-lead ECG and rhythm strip (*bottom*) demonstrate AT at a cycle length of approximately 520 milliseconds. Conduction varies between 3 : 2 and 2 : 1. Note the negative P waves in leads II, III, and aVF and, when consecutive P waves are conducted, that the RP interval exceeds the PR interval. Note also that the tachycardia persists despite the development of an AV block, an important finding that excludes participation of an AV accessory pathway and sharply differentiates this AT from the one shown in **Fig. 37.21**.

Clinical Features

Atrial tachycardia occurs often in patients with significant structural heart disease such as coronary artery

disease, with or without myocardial infarction, heart failure, and cor pulmonale, as well as in patients without structural heart disease. It can also occur with digitalis intoxication, often precipitated by potassium depletion. The signs, symptoms, and prognosis are usually related to the underlying cardiovascular status and the rate of the tachycardia. When symptoms are incessant, tachycardia-induced cardiomyopathy can result, partially or totally reversible with tachycardia elimination.[12] In some patients, exercise or stress can provoke the tachycardia; in others the tachycardia can be positional. Stimulants such as caffeine, chocolate, and ephedrine can also provoke episodes.

Physical findings during a variable rhythm include variable intensity of the first heart sound and systolic blood pressure as a result of the varying AV block and PR interval. An excessive number of *a* waves can be seen in the jugular venous pulse. Carotid sinus massage or administration of adenosine increases the degree of AV block and slows the ventricular rate in stepwise fashion without terminating the tachycardia, as in atrial flutter. Massage should be performed cautiously in patients with digitalis toxicity because serious ventricular arrhythmias can result. On occasion, carotid sinus massage or adenosine can terminate some forms of AT.

Management

Depending on the clinical situation, a beta blocker or a calcium channel blocker can be administered to slow the ventricular rate; if AT is still present, class IA, IC, or III drugs can be added. Catheter ablation procedures are generally effective in eliminating the AT, depending on the mechanism and underlying heart disease.[6] Ablation should be considered in those who fail drug therapy and can be considered as a first-line alternative in patients without underlying heart disease. The most important factor for successful ablation is the ability to induce the tachycardia during the procedure, usually with programmed stimulation and the use of catecholaminergic agents such as isoproterenol. Inducibility can be variable, depending on the mechanism of the AT. ATs can occasionally recur at a different site after successful ablation. If AT develops in a patient taking digitalis, the drug should initially be assumed to be responsible and its use stopped. Administration of digitalis antibodies should be considered in unstable patients.

Chaotic Atrial Tachycardia.

Chaotic (sometimes called *multifocal*) AT is characterized by atrial rates between 100 and 130 beats/min along with marked variation in P wave morphology and totally irregular P-P intervals (**Fig. 37.7**). In general, at least three P wave contours are noted, with most P waves being conducted to the ventricles, although often with variable PR intervals. This tachycardia occurs frequently in older patients with chronic obstructive pulmonary disease and congestive heart failure and may eventually develop into AF. Digitalis appears to be an unusual cause, and theophylline administration has been implicated. Chaotic AT can occur in childhood.

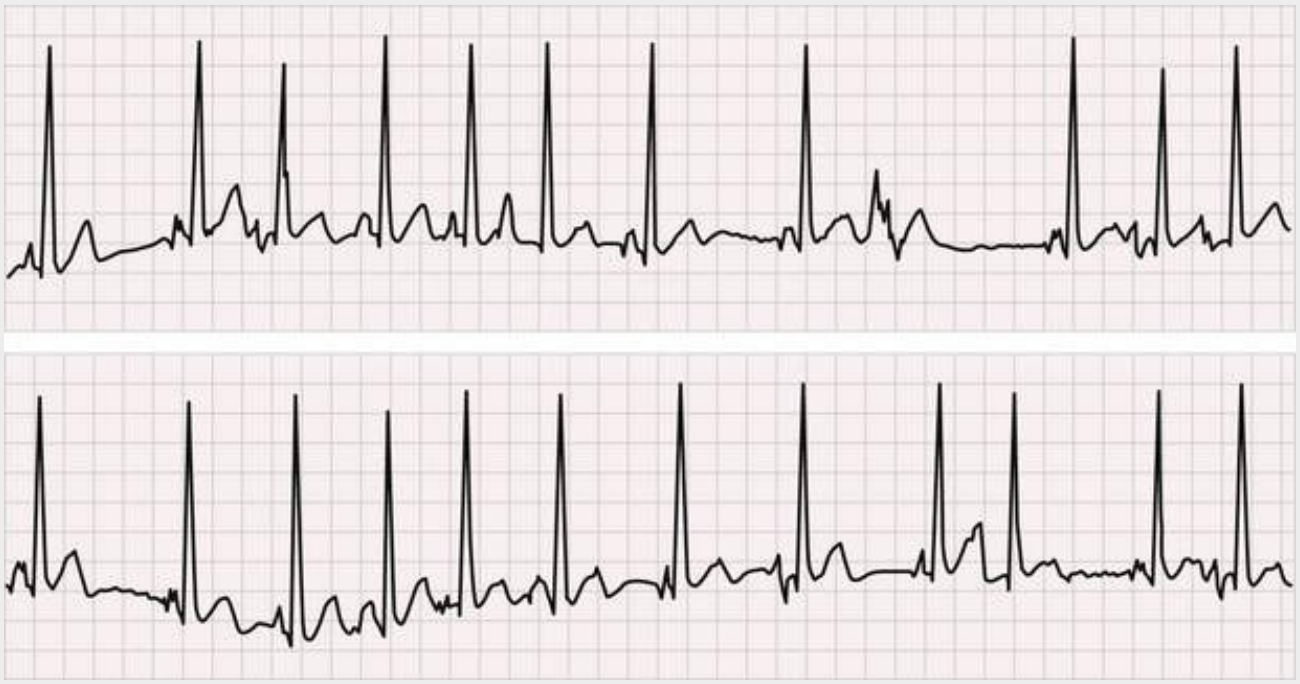

FIGURE 37.7 Chaotic (multifocal) atrial tachycardia. PACs occur at varying cycle lengths and with different contours.

Management.
Management is directed primarily toward the underlying disease. AADs are frequently ineffective in slowing either the rate of the AT or the ventricular response. Beta adrenoceptor blockers should be avoided in patients with bronchospastic pulmonary disease but can be effective if tolerated. Verapamil and amiodarone have been useful. Potassium and magnesium replacement may suppress the tachycardia. Ablation may be effective in some cases.

Tachycardias Involving the Atrioventricular Junction

Confusion exists about the nomenclature of tachycardias characterized by a supraventricular QRS complex, a regular R-R interval, and no evidence of ventricular preexcitation. Because various electrophysiologic mechanisms can account for these tachycardias (**Fig. 37.8**), the nonspecific term *paroxysmal supraventricular tachycardia* has been proposed to encompass the entire group. This term may be inappropriate, however, because some tachycardias in patients with accessory pathways (see later) are no more supraventricular than they are ventricular in origin, since they may require participation of both the atria and the ventricles in the reentrant pathway and may exhibit a QRS complex of normal contour and duration only because anterograde conduction occurs over the normal AV node–His bundle pathways (**Fig. 37.8C**). If conduction over the reentrant pathway reverses direction and travels in an "antidromic" direction (i.e., to the ventricles over the accessory pathway and to the atria over the AV node–His bundle), the QRS complex exhibits a prolonged duration, although the tachycardia is basically the same. The term *reciprocating tachycardia* has been offered as a substitute for paroxysmal SVT, but use of such a term presumes the mechanism of the tachycardia to be "reentrant," which is probably the case for most but not all SVTs. Thus, no universally acceptable nomenclature exists, but rather descriptive labels for specific arrhythmias, as used throughout this chapter.

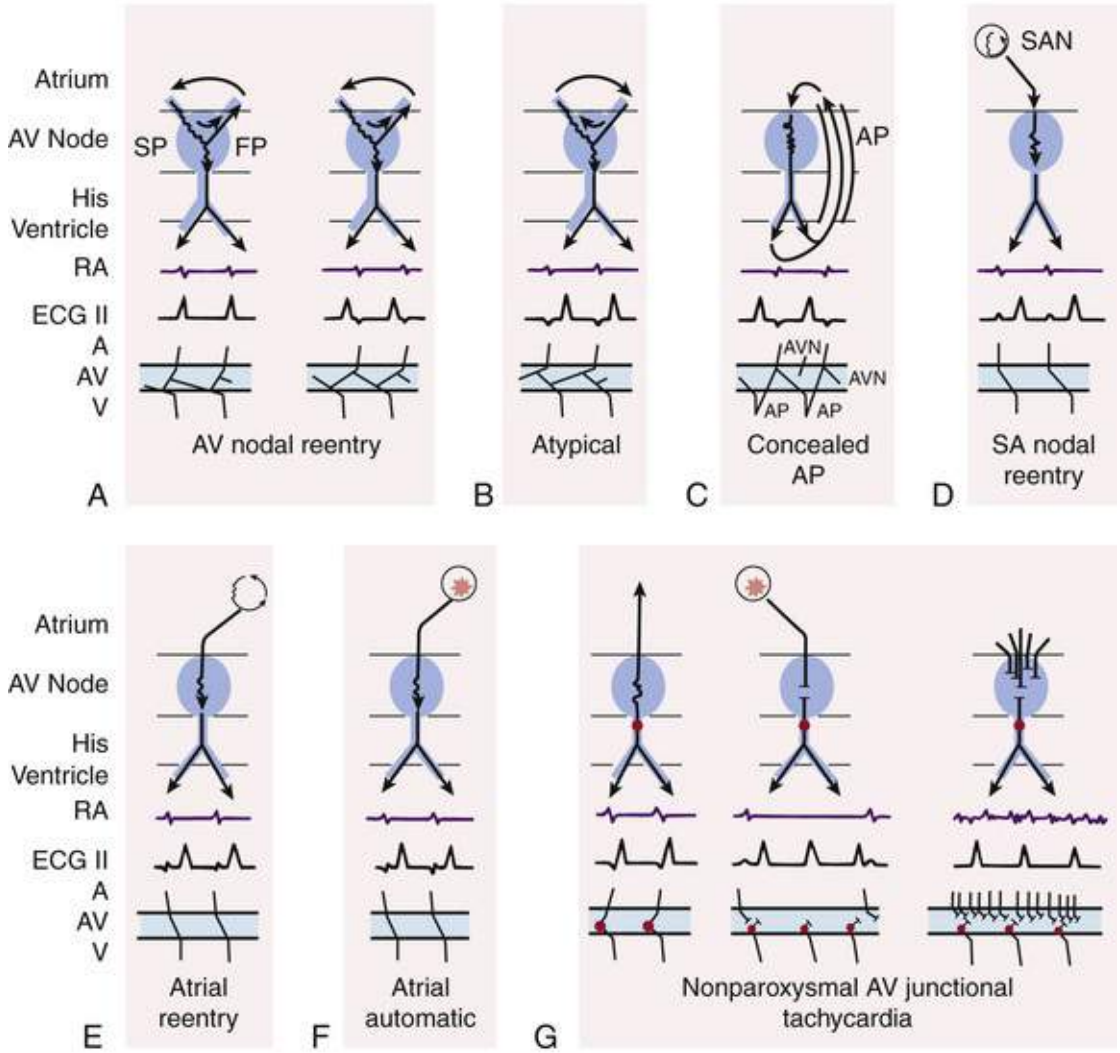

FIGURE 37.8 Diagrammatic representation of various tachycardias. In the *upper* portion of each example, a schematic of the presumed anatomic pathways is shown; in the *lower* half the ECG and explanatory ladder diagram are depicted. **A,** AV nodal reentry. In the **left** example, reentrant excitation is drawn with retrograde atrial activity occurring simultaneously with ventricular activity as a result of anterograde conduction over the slow AV nodal pathway (*SP*) and retrograde conduction over the fast AV nodal pathway (*FP*). In the **right** example, atrial activity occurs slightly later than ventricular activity because of retrograde conduction delay. **B,** Atypical AV nodal reentry caused by anterograde conduction over a fast AV nodal pathway and retrograde conduction over a slow AV nodal pathway. **C,** Concealed accessory pathway (*AP*). Reciprocating tachycardia is caused by anterograde conduction over the AV node (*AVN*) and retrograde conduction over the accessory pathway. Retrograde P waves occur after the QRS complex. **D,** Sinus nodal reentry. The tachycardia is caused by reentry within the sinus node, which then conducts the impulse to the rest of the heart. *SAN,* Sinoatrial node. **E,** Atrial reentry. Tachycardia is caused by reentry within the atrium, which then conducts the impulse to the rest of the heart. **F,** Automatic atrial tachycardia (the *star* indicates the origin). Tachycardia is caused by automatic discharge in the atrium, which then conducts the impulse to the rest of the heart; it is difficult to distinguish from atrial reentry. **G,** Various manifestations of nonparoxysmal AV junctional tachycardia are depicted with retrograde atrial capture, AV dissociation with the sinus node in control of the atria, and AV dissociation with atrial fibrillation. The *star* indicates sinus node discharge. *Red circles* indicate the site of junctional discharge.

Atrioventricular Nodal Reentrant Tachycardia

Electrocardiographic Recognition

Reentrant tachycardia involving the AV node is characterized by a tachycardia with a QRS complex of supraventricular origin, sudden onset and termination generally at rates 150 to 250 beats/min (usually 180 to 200 beats/min in adults), and a regular rhythm. Infrequently, the rate may be as low as 110 beats/min;

occasionally, especially in children, it may exceed 250 beats/min. Unless functional aberrant ventricular conduction or a previous conduction defect exists, the QRS complex is normal in contour and duration. P waves are generally buried in the QRS complex. Frequently, the P wave occurs just before or just after the end of the QRS complex and causes a subtle alteration that results in a pseudo-S or pseudo-r′, which may be recognized only on comparison with the QRS complex in normal sinus rhythm (**Fig. 37.9**). When seen, P waves are generally directed superiorly and are relatively narrow. AV nodal reentry begins abruptly, usually after a PAC that conducts with a prolonged PR interval (**see Figs. 37.3B and 37.8A**). The R-R interval can shorten over the course of the first few beats at the onset or lengthen during the last few beats preceding termination of the AT. Variation in cycle length, particularly at the onset of tachycardia or just before termination, is usually caused by variation in anterograde AV nodal conduction time. Cycle length or QRS alternans can occur, generally when the rate is very fast. Carotid sinus massage can slow the AT slightly before its termination or, if termination does not occur, can produce only slight slowing of the tachycardia.

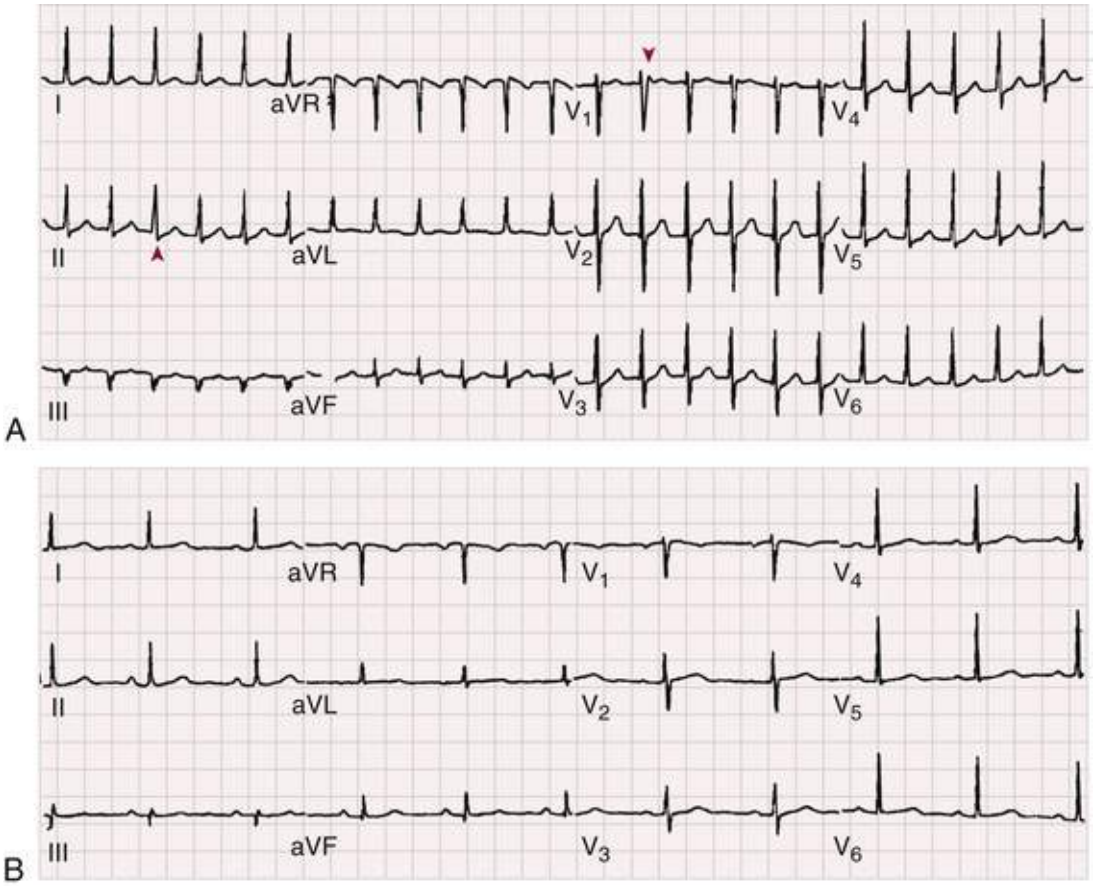

FIGURE 37.9 Twelve-lead ECG of AV nodal reentrant tachycardia (AVNRT). **A,** During tachycardia, a pseudo-r′ is seen in lead V_1 (*arrowhead*), and pseudo-S waves (*arrowhead*) are seen in leads II, III, and aVF. **B,** These waves become more obvious when compared with the QRS complexes during sinus rhythm.

Electrophysiologic Features

An atrial complex that conducts with a critical prolongation of AV nodal conduction time generally precipitates AV nodal reentry (**Figs. 37.10 and 37.11**). Premature ventricular stimulation can also induce AV nodal reentry in about one third of patients. Data from the results of RF catheter ablation and mapping support the presence of differential atrial input into the AV node, the fast and slow pathways, to explain

this tachycardia (**see Chapters 34 and 36**). In **Fig. 37.8A and B**, the atria are shown as a necessary link between the fast and slow pathways. Whether these pathways are discrete pathways (perhaps caused by anisotropy) or are functional in nature is not known. In most examples the retrograde P wave occurs at the onset of the QRS complex, which clearly excludes the possibility of an accessory pathway. If an accessory pathway in the ventricle were part of the tachycardia circuit, the ventricles would have to be activated anterogradely before the accessory pathway could be activated retrogradely and depolarize the atria, thus placing the retrograde P wave no earlier than 30 milliseconds after onset of the QRS and typically during the ST segment.

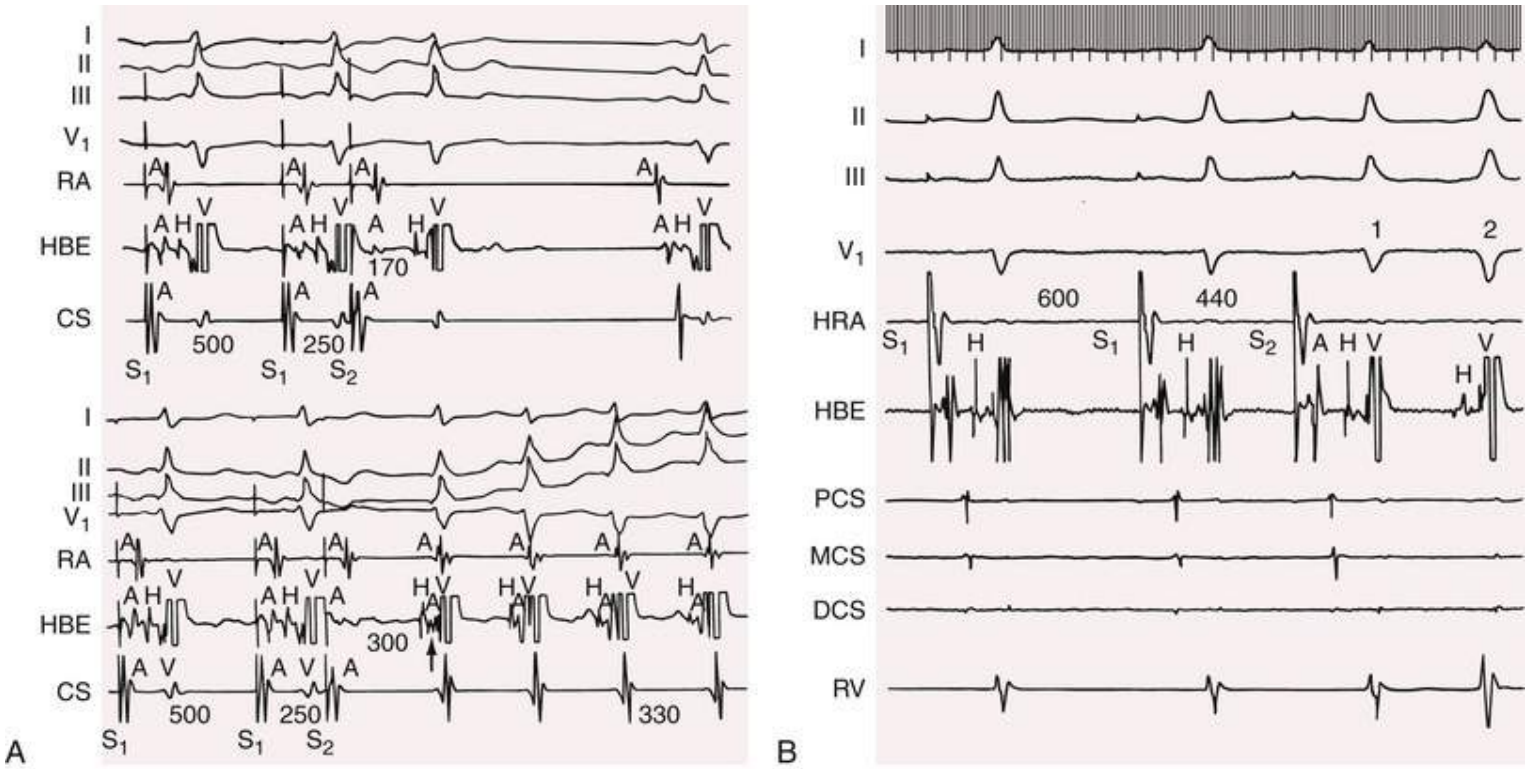

FIGURE 37.10 **A,** Initiation of AVNRT in a patient with dual AV nodal pathways. The upper and lower panels show the last two paced beats of a train of stimuli delivered to the coronary sinus at a pacing cycle length of 500 milliseconds. The results of premature atrial stimulation at an S_1-S_2 interval of 250 milliseconds on two occasions are shown. **Upper panel,** S_2 was conducted to the ventricle with an A-H interval of 170 milliseconds and was then followed by a sinus beat. **Lower panel,** S_2 was conducted with an A-H interval of 300 milliseconds and initiated AV nodal reentry. Note that the retrograde atrial activity occurs (*arrow*) before the onset of ventricular septal depolarization and is superimposed on the QRS complex. Retrograde atrial activity begins first in the low right atrium (HBE lead) and then progresses to the high right atrium (RA) and coronary sinus (CS) recordings. **B,** Two QRS complexes in response to a single atrial premature complex. After a basic train of S_1 stimuli at 600 milliseconds, an S_2 at 440 milliseconds is introduced. The first QRS complex in response to S_2 occurs after a short A-H interval (95 msec) caused by anterograde conduction over the fast AV nodal pathway. The first QRS complex is labeled 1 (in lead V_1). The second QRS complex in response to the S_2 stimulus (labeled 2) follows a long A-H interval (430 msec) caused by anterograde conduction over the slow AV nodal pathway. *DCS,* Distal coronary sinus; *HRA,* high right atrium; *MCS,* mid coronary sinus; *PCS,* proximal coronary sinus; *RV,* right ventricle.

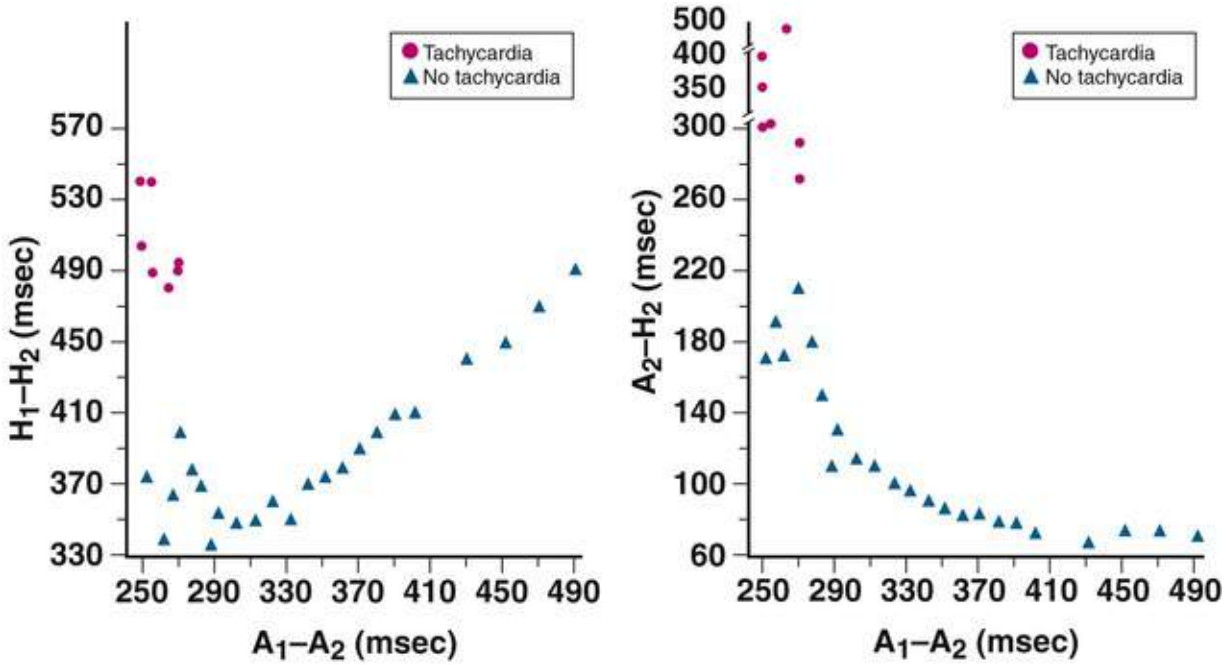

FIGURE 37.11 H_1-H_2 intervals **(left)** and A_2-H_2 intervals **(right)** at various A_1-A_2 intervals with a discontinuous AV nodal curve. At a critical A_1-A_2 interval, the H_1-H_2 and A_2-H_2 intervals increase markedly. At the break in the curves, AVNRT is initiated.

Atrial activation begins at the end of or just after the QRS complex in approximately 30% of cases and gives rise to a discrete P wave on the scalar ECG (often appearing as a nubbin of an R in V_1; **see Fig. 37.8A**). In most patients, P waves are not seen because they are buried within the inscription of the QRS complex. In the most common variety of AV nodal reentrant tachycardia (AVNRT), the ventriculoatrial (VA) interval is less than 50% of the R-R interval (a short-RP tachycardia). These VA intervals are longer in patients with tachycardia related to accessory pathways, as well as in those with atypical forms of AV nodal reentry (**see Fig. 37.8B**).

Slow and Fast Pathways.

In most patients, anterograde conduction to the ventricle occurs over the slow pathway and retrograde conduction occurs over the fast pathway, so-called typical AVNRT (**see Fig. 37.8A, B,** and **Chapter 34**). To initiate tachycardia, an atrial complex blocks anterogradely in the fast pathway (because it typically has a longer refractory period relative to the slow pathway), travels to the ventricle over the slow pathway, and returns to the atrium over the previously blocked fast pathway (slow-fast form). The proximal and distal final pathways for this *circus movement* appear to be located within the AV node, so as currently conceived, the circus movement occurs over the two atrial approaches and the AV node. The reentrant loop for typical AV nodal reentry is the anterograde slow AV nodal pathway to the final distal common pathway (probably the distal AV node), to the retrograde fast AV nodal pathway, and then to the atrial myocardium. In atypical AV nodal reentry, the reentry occurs in the opposite direction. Less often, the reentry pathway can be over two slow pathways or over a slow and intermediate pathway, the so-called slow-slow AV nodal reentry (**see Fig. 37.3B**). Conduction time in the anterograde slow pathway is a major determinant of the cycle length of the tachycardia.

Dual–Atrioventricular Nodal Pathway Concept.

Evidence supporting the dual-pathway concept is derived from several observations, the most compelling of which is that RF catheter ablation of the slow or the fast pathway eliminates AV nodal reentry without

eliminating AV nodal conduction. Additionally, in these patients a plot of the A_1-A_2 pathway versus the A_2-H_2 or the H_1-H_2 interval shows a discontinuous curve (**see Fig. 37.11**), because at a crucial A_1-A_2 interval the impulse is suddenly blocked in the fast pathway and is conducted with delay over the slow pathway, with sudden prolongation of the A_2-H_2 (or H_1-H_2) interval. In general, the A-H interval increases at least 50 milliseconds, with only a 10-millisecond decrease in the coupling interval of the PAC. Less frequently, dual pathways can be manifested by different PR or A-H intervals during sinus rhythm or at identical paced rates or by a sudden jump in the A-H interval during atrial pacing at a constant cycle length. Virtually irrefutable proof of dual AV nodal pathways is the simultaneous propagation in opposite directions of two AV nodal wavefronts without collision (**see Chapter 34**), or the production of two QRS complexes from one P wave (**see Fig. 37.10B**) or two P waves from one QRS complex.

Some patients with AV nodal reentry may not have discontinuous refractory period curves, and some patients who do not have AV nodal reentry can exhibit discontinuous refractory curves. In the latter patients, dual AV nodal pathways can be a benign finding. Many of these patients also exhibit discontinuous curves retrogradely. Triple AV nodal pathways can be demonstrated in occasional patients.

In less than 5% to 10% of patients with AV nodal reentry, anterograde conduction proceeds over the fast pathway and retrograde conduction over the slow pathway (termed the *unusual* or *atypical* form of fast-slow AV nodal reentry), with production of a long VA interval and a relatively short AV interval (generally an AV/VA ratio <0.75; **see Fig. 37.8B**). The least common form (slow-slow) exhibits a retrograde P wave midway in the cardiac cycle. Finally, it is possible to have tachycardias that use the anterograde slow or fast pathways and conduct retrogradely over an accessory pathway (see later).

Because in some instances either the atria or the ventricles are not needed to maintain AV nodal reentry, spontaneous AV block can occur, particularly at the onset of the arrhythmia, in the AV node distal to the reentry circuit, between the AV node and bundle of His, within the bundle of His, or distal to it (**see Chapter 34**). Most often, when a block appears, it is below the bundle of His, rarely in the upper common final pathway between the reentry circuit in the AV node and the atrium, and results in dissociation of the atria from the tachycardia. Termination of the tachycardia generally results from a block in the anterogradely conducting slow pathway (weak link), so a retrograde atrial response is not followed by a His or ventricular response. A functional BBB during AVNRT does not modify the tachycardia significantly.

Retrograde Atrial Activation.

The sequence of retrograde atrial activation is normal (also called *concentric*) during AV nodal reentrant SVT, which means that the earliest site of atrial activation during retrograde conduction over the fast pathway is recorded in the His bundle electrogram, followed by electrograms recorded from the os of the coronary sinus and then spreading to depolarize the rest of the right and left atria. During retrograde conduction over the slow pathway in the atypical type of AV nodal reentry, atrial activation recorded in the proximal coronary sinus precedes atrial activation recorded in the low right atrium, which suggests that the slow and fast pathways can enter the atria at slightly different positions.

Clinical Features

AV nodal reentry frequently occurs in patients without structural heart disease, often in the late teens or 20s; however, there is a second peak in incidence in the 40s and 50s. There is a higher incidence in women, and adult onset tends to be younger in women. Symptoms frequently accompany the AT and range from feelings of palpitations, nervousness, and anxiety to angina, heart failure, syncope, or shock,

depending on the duration and rate of the tachycardia and the presence of structural heart disease. Tachycardia can cause syncope because of the rapid ventricular rate, reduced cardiac output, and cerebral circulation or because of asystole when the tachycardia terminates as a result of tachycardia-induced depression of sinus node automaticity. The prognosis for patients without heart disease is usually good.

Management

Acute Attack.

Management of AVNRT depends on the underlying heart disease, how well the tachycardia is tolerated, and the natural history of previous attacks in the individual patient. For some patients, rest may be all that is required to abort an occasional attack. Vagal maneuvers, including carotid sinus massage, the Valsalva and Müller maneuvers, gagging, and occasionally exposure of the face to ice water, serve as the first line of therapy. These maneuvers can slow the tachycardia rate slightly, which may then speed up to the original rate after cessation of the attempt, or can terminate it. If vagal maneuvers fail, adenosine, 6 to 12 mg administered rapidly intravenously, is the initial drug of choice and successfully terminates (within 1 minute) the tachycardia in about 90% of cases (**see Chapter 36**). Verapamil, 5 to 10 mg intravenously, or diltiazem, 0.25 to 0.35 mg/kg intravenously, terminates AV nodal reentry successfully in about 2 minutes in approximately 90% of cases when simple vagal maneuvers and adenosine fail. Beta receptor blockers can be effective but are not generally used as first-line therapy because adenosine, verapamil, and diltiazem are more effective and faster acting. Calcium antagonists, beta adrenoceptor blockers, and adenosine normally depress conduction in the anterogradely conducting slow AV nodal pathway, whereas class IA and IC drugs (not usually required) depress conduction in the retrogradely conducting fast pathway (**Table 37.4**). DC cardioversion should generally be attempted before use of these latter agents, which are more often administered to prevent recurrence.

TABLE 37.4

Drugs That Slow Conduction in and Prolong Refractoriness of the Accessory Pathway and Atrioventricular Node

AFFECTED TISSUE	DRUGS
Accessory pathway	Class IA
AV node	Class II
	Class IV
	Adenosine
	Digitalis
Both	Class IC
	Class III (amiodarone)

Rarely, if AVNRT results in hemodynamic compromise and is refractory to adenosine, DC cardioversion may be indicated. DC shock in patients who have received excessive amounts of digitalis can be dangerous and can result in serious postshock ventricular arrhythmias (**see Chapter 36**). DC shock, synchronized to the QRS complex to avoid precipitation of ventricular fibrillation (VF), successfully terminates AV nodal reentry with energy in the range of 10 to 50 J; higher energy may be required in some cases. If DC shock is contraindicated or if pacing wires are already in place (postoperatively, or if the patient has a permanent pacemaker), competitive atrial or ventricular pacing can restore sinus rhythm.

Pressor drugs can terminate AV nodal reentry by inducing reflex vagal stimulation mediated by baroreceptors in the carotid sinus and aorta when systolic blood pressure is acutely elevated to levels of

approximately 180 mm Hg. Pressors are rarely needed, however, unless the patient is also hypotensive.

Prevention of Recurrences.

Initially, the clinician must decide whether the frequency and severity of the attacks warrant long-term therapy. If the attacks are infrequent, well tolerated, and short and either terminate spontaneously or are easily terminated by the patient, no prophylactic therapy may be necessary. Longer and more frequent attacks can be treated with drugs, although ablation is an effective first-line alternative. In patients with syncope or near-syncope, ablation should be considered as first-line therapy. A long-acting calcium antagonist or a long-acting beta adrenoceptor blocker is a reasonable initial choice for drug therapy. The clinical situation and potential contraindications, such as beta blockers in an asthmatic patient, usually dictate the selection.

Radiofrequency Ablation.

RF ablation achieves long-term cure in more than 95%, with a low incidence of complications, and should be considered early in the management of patients with symptomatic recurrent episodes of AV nodal reentry, especially for patients who do not want to take drugs, who are drug intolerant, or in whom drugs are ineffective.

Accessory Atrioventricular Pathways

Accessory pathways are fibers that connect the atrium or AV node to the ventricle outside the normal AV nodal–His-Purkinje conduction system. These pathways can conduct impulses in the forward (anterograde from the atrium to the ventricle) or reverse (retrograde from the ventricle to the atrium) direction and are potential substrates for reentrant tachycardias (AV reciprocating tachycardia).[13] When the pathway is capable of anterograde conduction, the ventricle can be depolarized in part by the accessory pathway (outside the normal His-Purkinje system) and produces a QRS complex that is preexcited (i.e., with a delta wave; see later). When ventricular preexcitation is present and the symptoms are compatible with tachycardia, the patient is said to have WPW *syndrome*. In some cases the pathways are able to conduct only in the retrograde direction; thus they do not produce any ventricular preexcitation and are said to be "concealed."

Reentry Over a Concealed (Retrograde-Only) Accessory Pathway

Electrocardiographic Recognition

The presence of an accessory pathway that conducts unidirectionally from the ventricle to the atrium but not in the reverse direction is not apparent by analysis of the ECG during sinus rhythm because the ventricle is not preexcited (**Fig. 37.12**). Therefore, electrocardiographic manifestations of WPW syndrome are absent, and the accessory pathway is "concealed." Because the mechanism responsible for most ATs in patients with WPW syndrome is macroreentry caused by anterograde conduction over the AV node–His bundle pathway and retrograde conduction over an accessory pathway, the accessory pathway, even if it conducts only retrogradely, can still participate in the reentrant circuit and cause an AV reciprocating tachycardia. On electrocardiographic examination, a tachycardia resulting from this mechanism can be suspected when the QRS complex is normal and the retrograde P wave occurs after completion of the QRS complex, in the ST segment, or early in the T wave (**see Fig. 37.8C**). Sometimes the P wave is not clearly visible and can result in depression of the ST segment; when this is seen during

AT, the mechanism of the arrhythmia is most often reentry involving an accessory pathway (AV reentrant tachycardia). In addition, in this setting the ST depression that occurs only during the AT (resolves with termination of the tachycardia) does not indicate ischemia in the absence of other evidence of ischemia (chest pain, enzyme elevation, known coronary disease).

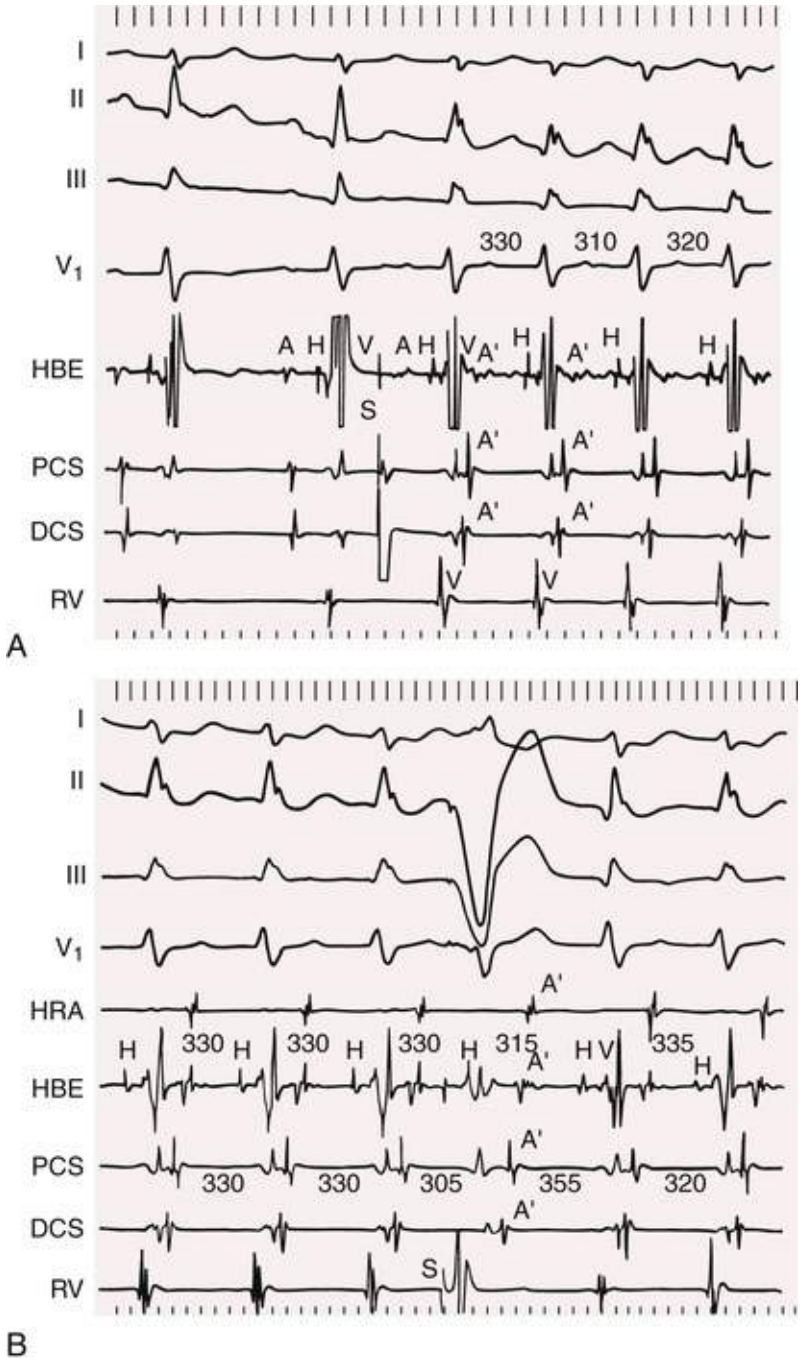

FIGURE 37.12 Atrial preexcitation during AV reciprocating tachycardia in a patient with a concealed accessory pathway. No evidence of accessory pathway conduction is present in the two sinus-initiated beats shown in **A.** A premature stimulus in the coronary sinus (*S*) precipitates SVT at a cycle length of approximately 330 milliseconds. The retrograde atrial activation sequence begins first in the distal coronary sinus (A′, DCS), followed by activation recorded in the proximal coronary sinus (PCS), low right atrium (HBE), and then the high right atrium (not shown). The QRS complex is normal and identical to the sinus-initiated QRS complex. (The terminal portion is slightly deformed by superimposition of the retrograde atrial recording.) Note that the RP interval is short and the PR interval is long. The shortest VA interval exceeds 65 milliseconds, consistent with conduction over a retrogradely conducting AV pathway. **B,** Premature ventricular stimulation at a time when the His bundle is still refractory from anterograde activation during tachycardia shortens the A-A interval from 330 to 305 milliseconds without a change in the retrograde atrial activation sequence. (Note that no change occurs in the H-H interval when the RV stimulus [*S*] is delivered. H-H intervals are in milliseconds in the HBE lead.) Thus the ventricular stimulus, despite His bundle refractoriness, still reaches the atrium and produces an identical retrograde atrial activation sequence. The only way that this finding can be explained is by conduction over a retrogradely conducting accessory pathway. Therefore the patient has a concealed accessory pathway with WPW syndrome. *HRA,* High right atrium; *RV,* right ventricle.

The P wave follows the QRS complex during tachycardia because the ventricle must be activated before the propagating impulse can enter the accessory pathway and excite the atria retrogradely.

Therefore the retrograde P wave must occur after ventricular excitation, in contrast to AV nodal reentry, in which the atria are usually excited during ventricular activation (**see Fig. 37.8A**). Also, the contour of the retrograde P wave can differ from that of the usual retrograde P wave because the atria may be activated eccentrically, that is, in a manner other than the normal retrograde activation sequence, which starts at the low right atrial septum, as in AV nodal reentry. This eccentric activation occurs because the concealed accessory pathway in most cases is left sided (i.e., inserts into the left atrium), which makes the left atrium the first site of retrograde atrial activation and causes the retrograde P wave to be negative in lead I (**see Fig. 37.12**).

Finally, because the tachycardia circuit involves the ventricles, if a functional BBB occurs in the same ventricle in which the accessory pathway is located, the VA interval and cycle length of the tachycardia can become longer (**Fig. 37.13**). This important change ensues because the BBB lengthens the reentrant circuit. For example, the normal activation sequence for a reciprocating tachycardia circuit with a left-sided accessory pathway but without a functional BBB progresses from the atrium to the AV node–His bundle, to the right and left ventricles, to the accessory pathway, and then to the atrium. However, during a functional LBBB, the tachycardia circuit travels from the atrium to the AV node–His bundle, to the right ventricle, to the septum, to the left ventricle, to the accessory pathway, and then back to the atrium. This increase in the VA interval provides definitive proof that the ventricle and accessory pathway are part of the reentry circuit. The additional time required for the impulse to travel across the septum from the right to the left ventricle before reaching the accessory pathway and atrium lengthens the VA interval, which consequently lengthens the cycle of the tachycardia by an equal amount, assuming that no other changes in conduction times occur within the circuit. Thus, lengthening of the tachycardia cycle by more than 30 milliseconds during an ipsilateral functional BBB is diagnostic of a free wall accessory pathway if the lengthening can be shown to be caused by VA prolongation only and not by prolongation of the H-V interval (which can develop with the appearance of a BBB). In an occasional patient, the increase in cycle length because of prolongation of VA conduction can be nullified by a simultaneous decrease in the PR (A-H) interval.

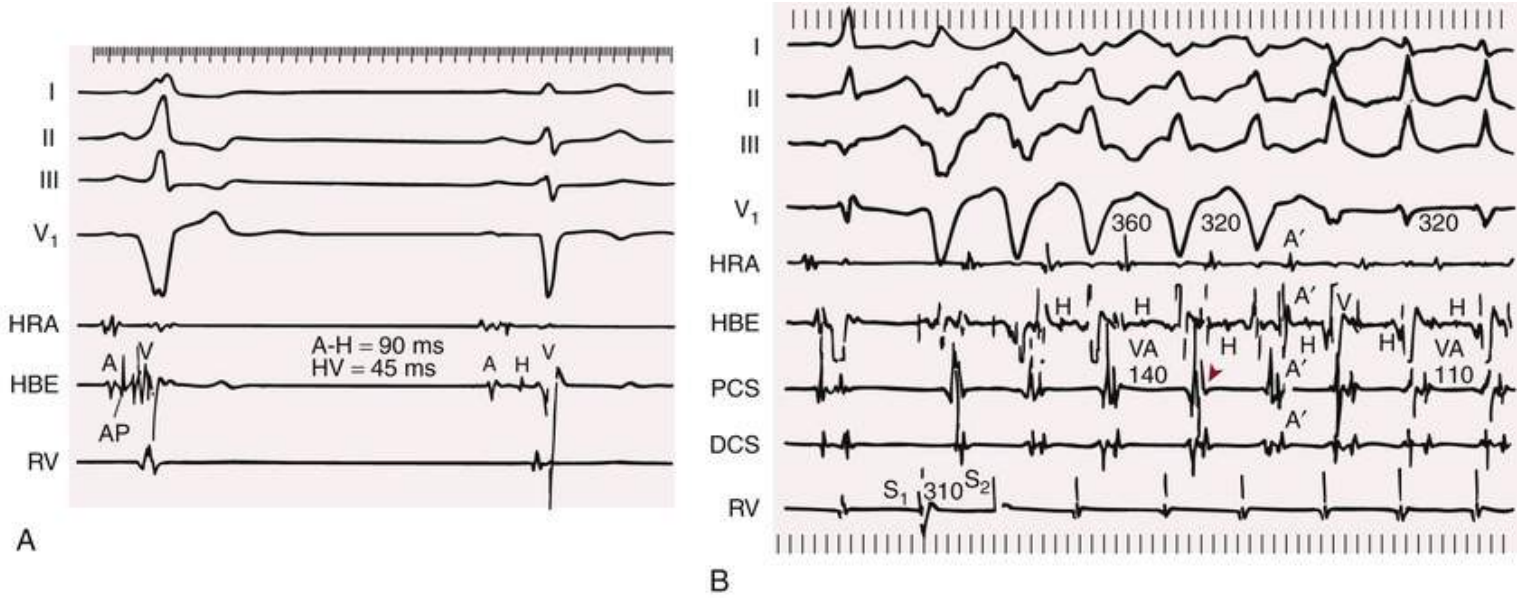

FIGURE 37.13 **A,** Recording of depolarization of an accessory pathway (*AP*) with a catheter electrode. The first QRS complex illustrates conduction over the AP. On the scalar ECG, a short PR interval and delta wave (best seen in leads I and V_1) are apparent. His bundle activation is buried within the ventricular complex. In the following complex, conduction has been blocked over the AP, and a normal QRS complex results. His bundle activation clearly precedes the onset of ventricular depolarization by 45 milliseconds. The A-H interval for this complex is 90 milliseconds. **B,** Influence of a functional ipsilateral bundle branch block on the VA interval during AV reciprocating tachycardia. Partial preexcitation can be noted in the sinus-initiated complex (first complex). Two premature ventricular stimuli (S_1, S_2) initiate a sustained SVT that persists with a left bundle branch block for several complexes before finally reverting to normal. The retrograde atrial activation sequence is recorded first in the proximal coronary sinus lead (*arrowhead,* PCS), then in the distal coronary sinus lead (DCS) and low right atrium (HBE), and then high in the right atrium (HRA). During the functional bundle branch block, the VA interval in the PCS lead is 140 milliseconds, which shortens to 110 milliseconds when the QRS complex reverts to normal. Such behavior is characteristic of a left-sided accessory pathway with prolongation of the reentrant pathway by the functional left bundle branch block. (***A,*** From Prystowsky EN, Browne KF, Zipes DP. Intracardiac recording by catheter electrode of accessory pathway depolarization. J Am Coll Cardiol 1983;1:468.)

The presence of an ipsilateral BBB can facilitate reentry and cause an incessant AV reentrant tachycardia. A functional BBB in the ventricle contralateral to the accessory pathway does not lengthen the tachycardia cycle if the H-V interval does not lengthen.

Septal Accessory Pathway

An exception to these observations occurs in patients with a concealed septal accessory pathway. First, retrograde atrial activation is normal (concentric) because it occurs retrogradely up the septum. Second, the VA interval and cycle length of the tachycardia increase 25 milliseconds or less with the development of an ipsilateral functional BBB.

Vagal maneuvers, by acting predominantly on the AV node, produce a response on AV reentry similar to AV nodal reentry, and the tachycardia can transiently slow and sometimes terminate. In general, termination occurs in the anterograde direction, so the last retrograde P wave fails to conduct to the ventricle.

Electrophysiologic Features

Electrophysiologic criteria supporting the diagnosis of tachycardia involving reentry over a concealed accessory pathway include the fact that initiation of tachycardia depends on a critical degree of AV delay (necessary to allow time for the accessory pathway to recover excitability so that it can conduct

retrogradely), but the delay can be in the AV node or His-Purkinje system; that is, a critical degree of A-H delay is not necessary (as it is in AV nodal reentry). On occasion, a tachycardia can start with little or no measurable lengthening of AV nodal or His-Purkinje conduction time. The AV nodal refractory period curve is smooth, in contrast to the discontinuous curve found in many patients with AV nodal reentry. Dual AV nodal pathways can occasionally be noted as a concomitant but unrelated finding.

Diagnosis of Accessory Pathways

Diagnosis can be made by demonstrating that during ventricular pacing, premature ventricular stimulation activates the atria before retrograde depolarization of the His bundle, thus indicating that the impulse reached the atria before it depolarized the His bundle and therefore must have traveled a different pathway. Also, if the ventricles can be stimulated prematurely during tachycardia at a time when the His bundle is refractory, and the impulse still conducts to the atrium, the retrograde propagation traveled to the atrium over a pathway other than the bundle of His (**see Fig. 37.12B**). If the PVC depolarizes the atria without lengthening the VA interval and with the same retrograde atrial activation sequence, one assumes that the stimulation site (i.e., ventricle) is within the reentrant circuit, without intervening His-Purkinje or AV nodal tissue that might increase the VA interval and therefore the A-A interval. In addition, if a PVC delivered when the His bundle is refractory terminates the tachycardia without activating the atria retrogradely, it must have invaded and blocked conduction in an accessory pathway and is therefore diagnostic of an accessory pathway participating in the reentrant circuit.

The VA interval (a measurement of conduction over the accessory pathway) is generally constant over a wide range of ventricular-paced rates and coupling intervals of PVCs, as well as during the tachycardia in the absence of aberration. Similar short VA intervals can be observed in some patients during AV nodal reentry, but if the VA conduction time or RP interval is the same during tachycardia and ventricular pacing at comparable rates, an accessory pathway is almost certainly present. The VA interval is usually less than 50% of the R-R interval. The tachycardia can easily be initiated after premature ventricular stimulation that conducts retrogradely in the accessory pathway but blocks conduction in the AV node or His bundle. Atria and ventricles are required components of the macroreentrant circuit; therefore, continuation of the tachycardia in the presence of an AV or VA block excludes an accessory AV pathway as part of the reentrant circuit.

Clinical Features

Concealed accessory pathways are estimated to be present in approximately 30% of patients with apparent SVT referred for electrophysiologic evaluation. Most of these accessory pathways are located between the left ventricle and left atrium or in the posteroseptal area, less often between the right ventricle and right atrium. It is important to be aware of a concealed accessory pathway as a possible cause of apparently routine SVT because the therapeutic response may at times not follow the usual guidelines. Tachycardia rates tend to be somewhat faster than those occurring in AV nodal reentry (200 beats/min), but great overlap exists between the two groups.

Syncope can occur because the rapid ventricular rate fails to provide adequate cerebral circulation or because the tachyarrhythmia depresses the sinus pacemaker and causes a period of asystole when the tachyarrhythmia terminates. Physical examination reveals an unvarying, regular ventricular rhythm, with constant intensity of the first heart sound and blood pressure. Jugular venous pressure can be elevated (large A wave), but the waveform generally remains constant.

Management

The therapeutic approach to termination of this form of tachycardia acutely is as outlined for AV nodal reentry because the AV node is a critical part of the circuit here as well. It is necessary to achieve block of a single impulse from the atrium to the ventricle or from the ventricle to the atrium. In general, the most successful method is to produce a transient AV nodal block; therefore, vagal maneuvers and IV administration of adenosine, verapamil, or diltiazem and beta blockers are acceptable choices. RF catheter ablation and AADs that prolong the activation time or refractory period in the accessory pathway need to be considered for chronic prophylactic therapy, similar to that discussed for reciprocating tachycardias associated with preexcitation syndrome. RF catheter ablation is curative, has low risk, and should be considered early for symptomatic patients (**see Chapter 36**). The presence of AF in patients with a concealed accessory pathway should not be a greater therapeutic challenge than in patients who do not have such a pathway, because anterograde AV conduction occurs only over the AV node and not over an accessory pathway. IV administration of verapamil is not contraindicated. However, in some circumstances, such as catecholamine stimulation, anterograde conduction can occur in the apparently concealed accessory pathway.

Preexcitation Syndrome

Electrocardiographic Recognition

Preexcitation, or the WPW abnormality on the ECG, occurs when the atrial impulse activates the entire ventricle or some part of it, or the ventricular impulse activates the entire atrium or some part of it, earlier than would be expected if the impulse traveled only by way of the normal specialized conduction system (**Fig. 37.14**). This premature activation is caused by muscle connections of working myocardial fibers that exist outside the specialized conducting tissue and connect the atrium and ventricle while bypassing AV nodal conduction delay. Termed *accessory atrioventricular pathways* or *connections*, they are responsible for the most common variety of preexcitation. The term *syndrome* is attached to this disorder when tachyarrhythmias occur as a result of the accessory pathway. Three basic features typify the electrocardiographic abnormalities in patients with the usual form of WPW conduction caused by an AV connection: (1) PR interval less than 120 milliseconds during sinus rhythm; (2) QRS complex duration exceeding 120 milliseconds with a slurred, slowly rising onset of the QRS in some leads (delta wave) and usually a normal terminal QRS portion; and (3) secondary ST-T wave changes that are generally directed in an opposite direction to the major delta and QRS vectors. Analysis of the scalar ECG can be used to localize the accessory pathway (**see Fig. 37.14D**).

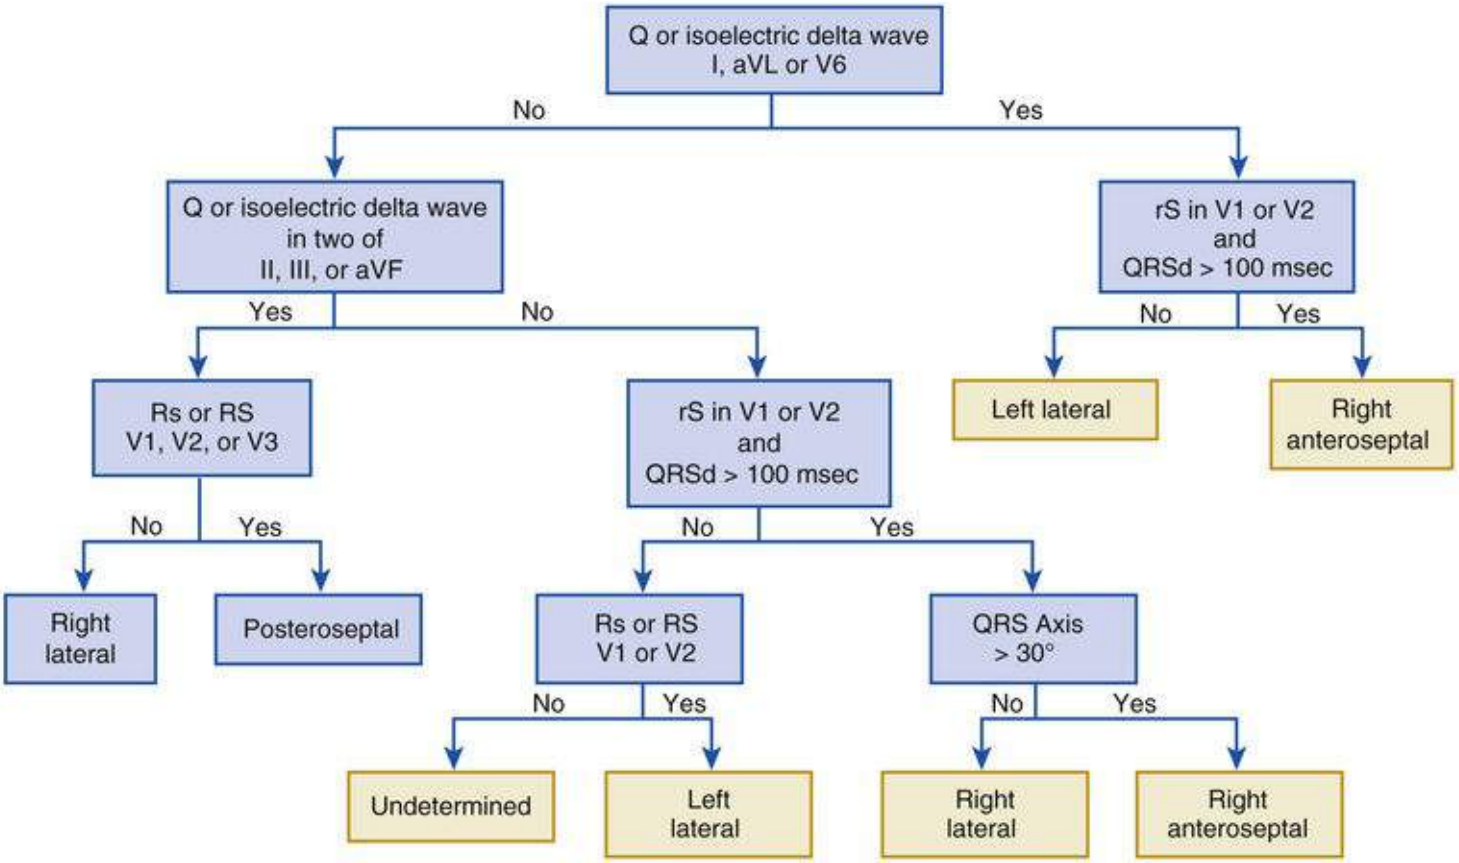

FIGURE 37.14 **A,** Right anteroseptal accessory pathway. The 12-lead ECG characteristically exhibits a normal to inferior axis. The delta wave is upright in leads I, II, and aVF; isoelectric or negative in aVL; and negative in aVR. There is an rS in V_1 and V_2. **B,** Right posteroseptal accessory pathway. Negative delta waves in leads II, III, and aVF, upright in I and aVL, localize this pathway to the posteroseptal region. The negative delta wave in V_1 with sharp transition to an upright delta wave in V_2 pinpoints it to the right posteroseptal area. Atrial fibrillation is present. **C,** Left lateral accessory pathway. A positive delta wave in the anterior precordial leads and in leads II, III, and aVF, positive or isoelectric in leads I and aVL, and isoelectric or negative in leads V_5 and V_6 are typical of a left lateral accessory pathway. Also notice the relatively small amount of preexcitation typical of left lateral accessory pathways during sinus rhythm, which is caused by the sinus impulse taking longer to travel through the entire right and left atria to the accessory pathway than it does from the sinus node to the AV node. **D,** Right free wall accessory pathway. The predominantly negative delta wave in V_1 and the axis more leftward than in **A** indicate the presence of a right free wall accessory pathway. **E,** Stepwise algorithm to determine the general location of accessory pathways on a 12-lead ECG with preexcitation. The algorithm assumes that some preexcitation is present and uses the delta wave polarity (determined as the first 20 msec after the onset of the delta wave on the ECG) and QRS morphology. *QRSd,* QRS duration. (**E,** From Fox DJ, Klein GJ, Skanes AC, et al. How to identify the location of an accessory pathway by the 12-lead ECG. Heart Rhythm 2008;5:1763.)

In WPW syndrome, the most common tachycardia is characterized by a normal QRS, a regular rhythm, ventricular rates of 150 to 250 beats/min (generally faster than AV nodal reentry), and sudden onset and termination, in most respects behaving like the tachycardia described for conduction over a concealed pathway (see earlier). The major difference between the two is the capacity for anterograde conduction over the accessory pathway during atrial flutter or AF (see later).

Variants.

Various other anatomic substrates exist and provide the basis for different electrocardiographic manifestations of several variations of preexcitation syndrome (**Table 37.5 and Fig. 37.15**). Fibers from the atrium to the His bundle bypassing the physiologic delay of the AV node are called *atriohisian tracts* (**Fig. 37.15B**) and are associated with a short PR interval and a normal QRS complex. Although demonstrated anatomically (see later), the electrophysiologic significance of these tracts in the genesis of tachycardias with a short PR interval and a normal QRS complex (so-called Lown-Ganong-Levine [LGL] syndrome) remains to be established. Indeed, evidence does not support the presence of a specific LGL syndrome consisting of a short PR interval, normal QRS complex, and tachycardias related to an atriohisian bypass tract.

TABLE 37.5

Accessory Pathway Variants

PATHWAY TYPE	PR	QRS	TACHYCARDIA	COMMENTS
Atriohisian	Short	Normal	Unlikely	
Atriofascicular	Normal	Preexcitation (LBBB, superior axis)	Antidromic AVRT	Preexcitation with fast atrial rates or atrial extrastimuli
Nodofascicular	Normal	Preexcitation (LBBB, superior axis)	Antidromic AVRT; AVNRT with bystander activation of the AP	Preexcitation with fast atrial rates or atrial extrastimuli
Fasciculoventricular	Normal	Anomalous (short H-V interval)	None	

AP, Accessory pathway; *AVRT,* atrioventricular reentrant (reciprocating) tachycardia; *AVNRT;* AV nodal reentrant (reciprocating) tachycardia; *LBBB,* left bundle branch block.

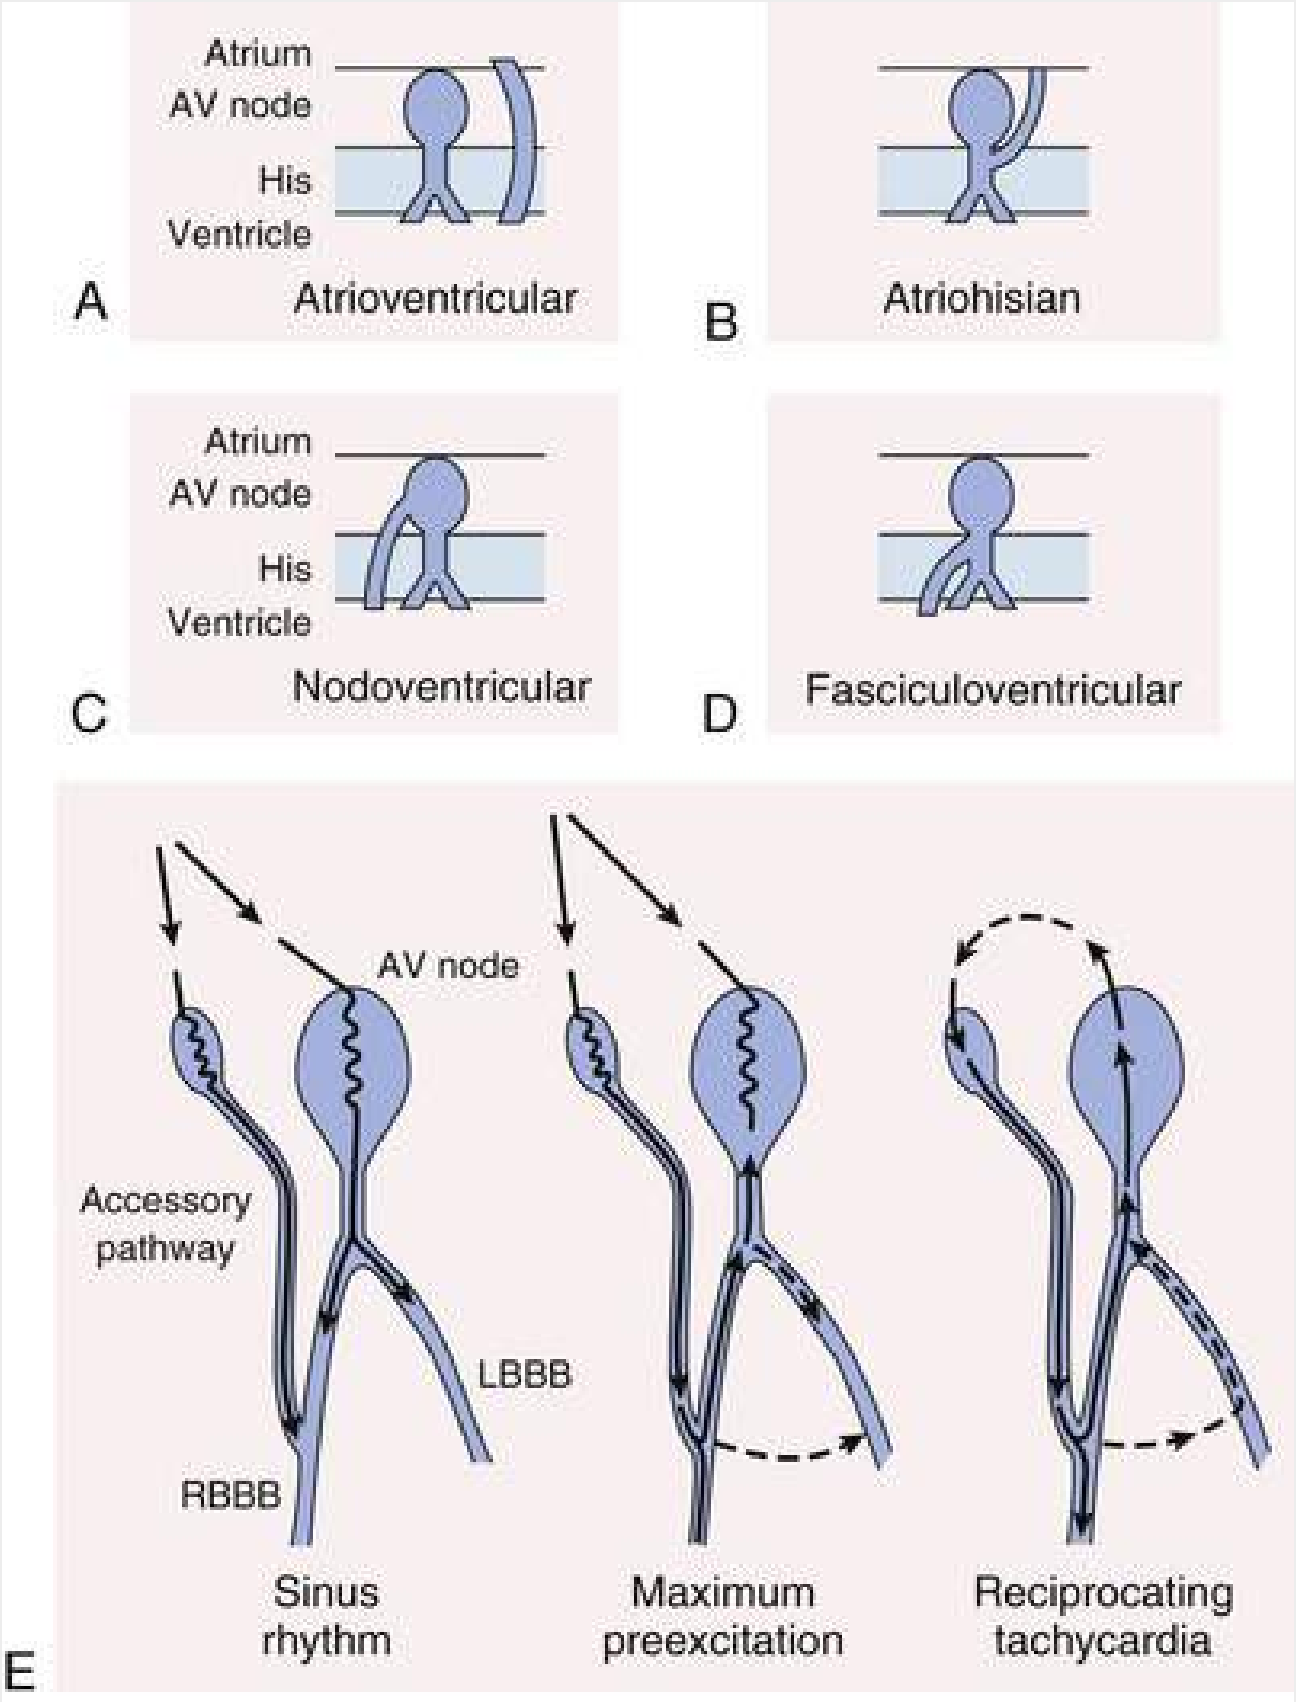

FIGURE 37.15 Schematic representation of accessory pathways. **A,** The "usual" AV accessory pathway giving rise to most clinical manifestations of tachycardia associated with WPW syndrome. **B,** The very uncommon atriohisian accessory pathway. If LGL syndrome is present, it would have this type of anatomy, which has been demonstrated histopathologically on occasion. **C,** Nodoventricular pathways, original concept, in which anterograde conduction travels down the accessory pathway with retrograde conduction in the bundle branch–His bundle–AV node (see later). **D,** Fasciculoventricular connections, which are not thought to play an important role in the genesis of tachycardias. **E,** Current concept of the nodofascicular accessory pathway, in which the accessory pathway is an AV communication with AV node–like properties. Sinus rhythm results in a fusion QRS complex, as in the usual form of WPW syndrome shown in **A.** Maximum preexcitation results in ventricular activation over the accessory pathway, and the His bundle is activated retrogradely. During reciprocating tachycardia, anterograde conduction occurs over the

accessory pathway and retrograde conduction over the normal pathway. *LBBB,* Left bundle branch block; *RBBB,* right bundle branch block. (**E,** From Benditt DG, Milstein S. Nodoventricular accessory connection: a misnomer or a structural/functional spectrum? J Cardiovasc Electrophysiol 1990;1:231.)

Another variant of accessory pathway conduction is that caused by atriofascicular or nodofascicular accessory pathways. These fibers result in a unique AV conduction pattern, sometimes referred to as Mahaim conduction, characterized by the development of ventricular preexcitation (widened QRS and short H-V interval) with a progressive increase in the AV interval in response to atrial overdrive pacing, unlike the behavior of the usual accessory pathway in which preexcitation occurs with short AV intervals (**Fig. 37.16**). Because the accessory pathways responsible for this conduction pattern usually insert into the right bundle branch, preexcitation generally results in an LBBB pattern. This phenomenon can be caused by fibers passing from the AV node to the ventricle, called *nodoventricular fibers* (or *nodofascicular* if the insertion is into the right bundle branch rather than into ventricular muscle; **see Fig. 37.15C**). For nodoventricular connections, the PR interval can be normal or short, and the QRS complex is a fusion beat. This pattern of preexcitation can also result from atriofascicular accessory pathways. These fibers almost always represent a duplication of the AV node and the distal conducting system and are located in the right ventricular free wall. The apical end lies close to the lateral tricuspid annulus and conducts slowly, with AV node–like properties. After a long course, the distal portion of these fibers, which conducts rapidly, inserts into the distal right bundle branch or the apical region of the right ventricle. No preexcitation is generally apparent during sinus rhythm, but it can be exposed by premature or rapid right atrial stimulation. The usual absence of retrograde conduction in these pathways produces only an antidromic AV reentry tachycardia (“preexcited” tachycardia) characterized by anterograde conduction over the accessory pathway and retrograde conduction over the right bundle branch–His bundle–AV node, thus making the atrium a necessary part of the circuit. The preexcited tachycardia has an LBBB pattern, long AV interval (because of the long conduction time over the accessory pathway), and short VA interval. An RBBB can be proarrhythmic by increasing the length of the tachycardia circuit (VA interval is prolonged because of a delay in retrograde activation of His bundle), and the tachycardia can become incessant.

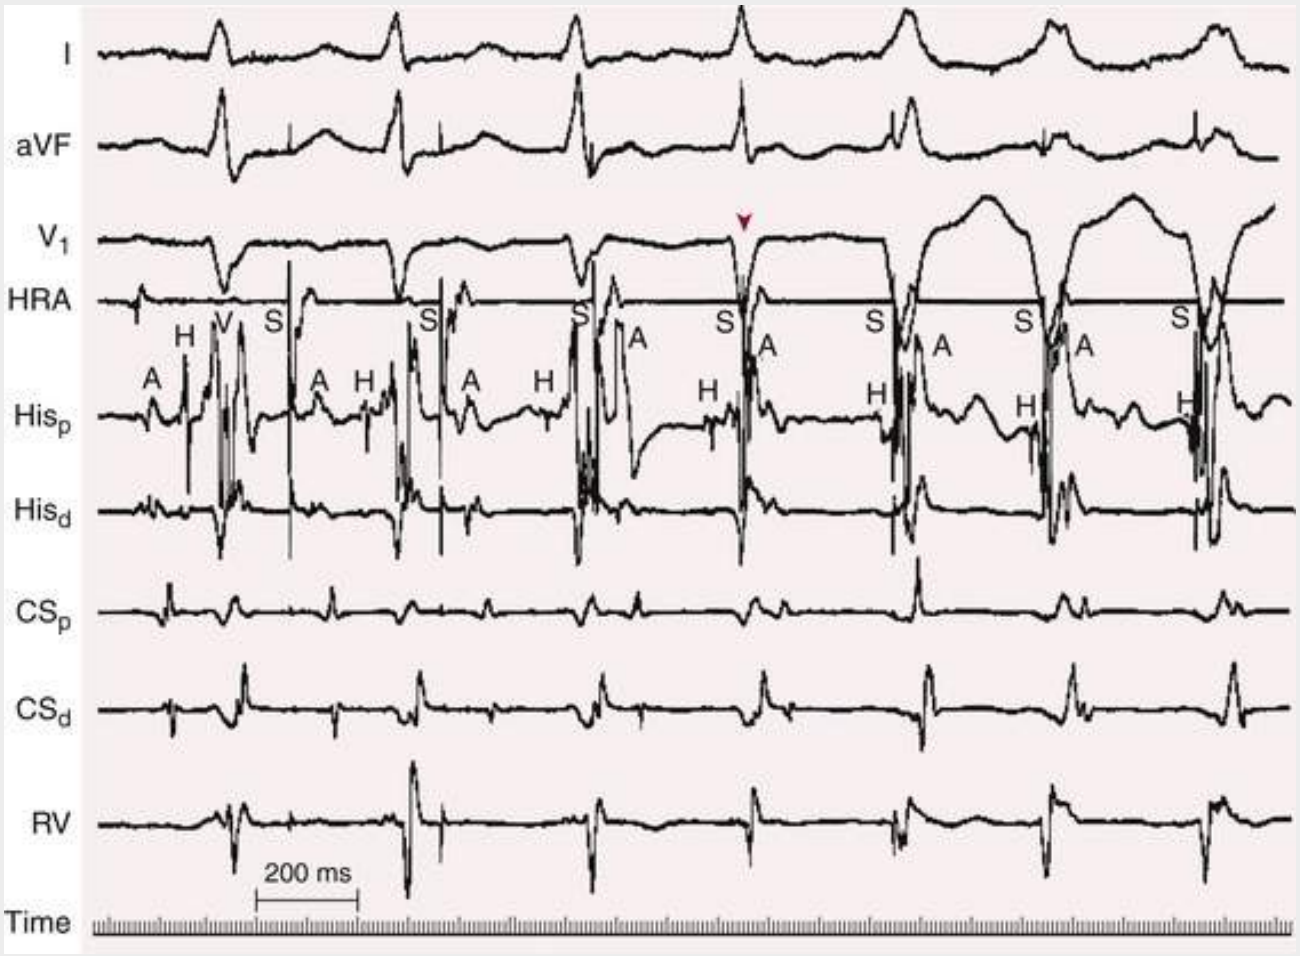

FIGURE 37.16 Development of preexcitation over an atriofascicular accessory pathway. During atrial pacing (*S*) on the left side of the figure, conduction occurs down the AV node, as evidenced by a normal-appearing QRS complex and a normal H-V interval. The stimulus marked by the *arrowhead* conducts the impulse down an atriofascicular fiber, which results in a preexcited QRS, as evidenced by a widened QRS and short H-V interval. *CS,* Coronary sinus; *HRA,* high right atrium; *RV,* right ventricle.

In patients with an atriohisian tract, the QRS complex would theoretically remain normal and the short A-H interval would be fixed or would show negligible increase during atrial pacing at more rapid rates. This response is uncommon. Rapid atrial pacing in patients who have nodoventricular or nodofascicular connections shortens the H-V interval and widens the QRS complex, with production of an LBBB contour, but in contrast to the situation in patients who have an AV connection (**Fig. 37.17**), the AV interval also lengthens. In patients with fasciculoventricular connections, the H-V interval remains short and the QRS complex unchanged and anomalous during rapid atrial pacing.

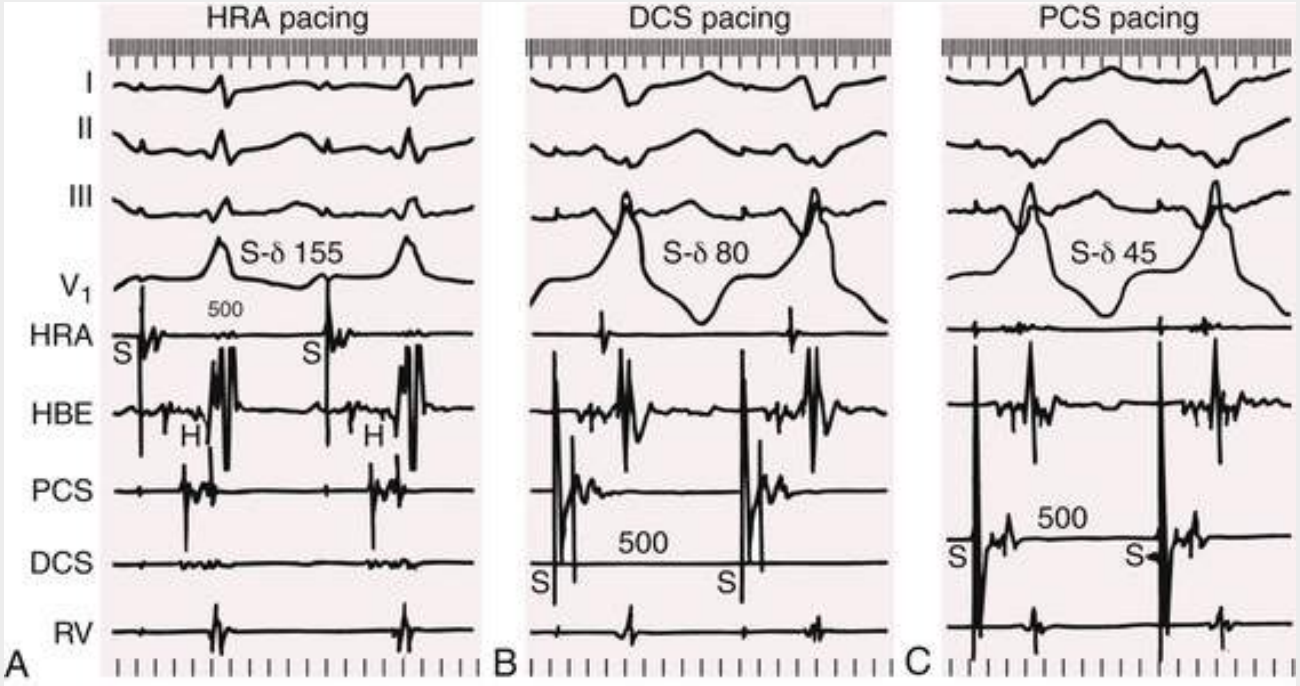

FIGURE 37.17 Atrial pacing at different atrial sites illustrating different conduction over the accessory pathway. **A,** High right atrial (HRA) pacing at a cycle length of 500 milliseconds produces anomalous activation of the ventricle (note the upright QRS complex in V_1) and a stimulus-delta interval of 155 milliseconds (*S-δ 155*). This interval indicates that the time from the onset of the stimulus to the beginning of the QRS complex is relatively long because the stimulus is delivered at a fairly large distance from the accessory pathway. Note that His bundle activation (*H*) occurs at about the onset of the QRS complex. **B,** Atrial pacing occurs through the distal coronary sinus electrode (DCS). At the same pacing cycle length, DCS pacing results in more anomalous ventricular activation and a shorter stimulus-delta interval (80 msec). His bundle activation is now buried within the inscription of the ventricular electrogram in the low right atrium (His bundle electrogram [HBE] lead). **C,** Pacing from the proximal coronary sinus electrode (PCS) results in the shortest stimulus-delta interval (45 msec); such an interval indicates that the pacing stimulus is being delivered very close to the atrial insertion of the accessory pathway, which in this case is located in the left posteroseptal region of the AV groove. *RV,* Right ventricle.

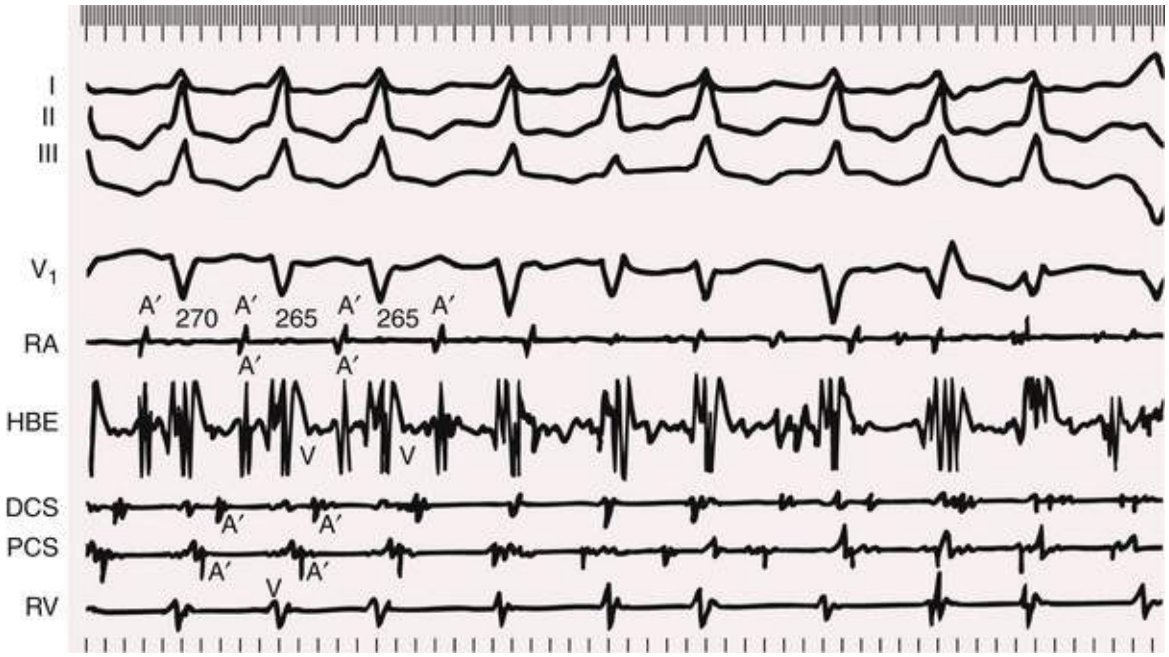
Electrophysiologic Features of Preexcitation

If the accessory pathway is capable of anterograde conduction, two parallel routes of AV conduction are possible, one subject to physiologic delay over the AV node and the other passing directly without delay from the atrium to the ventricle (**see Figs. 37.13 and 37.15 through 37.22; eFig. 37.3**). This direct route of conduction produces the typical QRS complex, which is a fusion beat as a result of depolarization of the ventricle, in part by the wavefront traveling over the accessory pathway and in part by the wavefront traveling over the normal AV node–His bundle route. The delta wave represents ventricular activation from input over the accessory pathway. The extent of the contribution to ventricular depolarization by the wavefronts over each route depends on their relative activation times. If AV nodal conduction delay occurs because of a rapid atrial pacing rate or a PAC, for example, more of the ventricle becomes activated over the accessory pathway and the QRS complex becomes more anomalous in contour. Total activation of the ventricle over the accessory pathway can occur if the AV nodal conduction delay is sufficiently long. In contrast, if the accessory pathway is relatively far from the sinus node (e.g., a left lateral accessory pathway), or if the AV nodal conduction time is relatively short, more of the ventricle can be activated by conduction over the normal pathway (**see Fig. 37.17**). The normal fusion beat during sinus rhythm has a short H-V interval, or His bundle activation actually begins after the onset of ventricular depolarization because part of the atrial impulse bypasses the AV node and activates the ventricle early, at a time when the atrial impulse traveling the normal route just reaches the His bundle.

This finding of a short or negative H-V interval occurs only during conduction over an accessory pathway or from retrograde His activation during a complex originating in the ventricle, such as VT.



EFIGURE 37.3 Atrioventricular reciprocating tachycardia (AVRT) disorganizing into atrial fibrillation (AF). During sustained AVRT at a cycle length of approximately 265 milliseconds, the retrograde atrial activation sequence began first in the right paraseptal region (not shown in this example; location proved at surgery) and was then recorded in the proximal coronary sinus (*PCS*) electrogram, followed by atrial activity in the distal coronary sinus (*DCS*), in the low right atrium recorded in the His bundle lead, and then in the high right atrium. Spontaneously, the atrial activation sequence becomes irregular (after the last A′) and AF begins. Note that the last QRS complex reflects conduction over the accessory pathway. Such a transformation occurred repeatedly in this patient and was associated with quickening of the ventricular rate. AF did not recur after surgical interruption of the accessory pathway. *HBE,* His bundle electrogram; *RA,* right atrium; *RV,* right ventricle.

Pacing the atrium at rapid rates, at premature intervals, or from a site close to the atrial insertion of the accessory pathway accentuates the anomalous activation of the ventricles and shortens the H-V interval even more (His activation may become buried in the ventricular electrogram, as shown in **Fig. 37.17B**). The position of the accessory pathway can be determined by careful analysis of the spatial direction of the delta wave on the 12-lead ECG in maximally preexcited beats (**see Fig. 37.14**). T wave abnormalities can occur after the disappearance of preexcitation, with orientation of the T wave according to the site of preexcitation (T wave memory).

Accessory Pathway Conduction

Even though the accessory pathway conducts more rapidly than the AV node (conduction velocity is faster in the accessory pathway), the accessory pathway usually has a longer refractory period during long cycle lengths (e.g., sinus rhythm); that is, it takes longer for the accessory pathway than the AV node to recover excitability. Consequently, a PAC can occur sufficiently early to block conduction anterogradely in the accessory pathway and conduct to the ventricle only over the normal AV node–His bundle (**Fig. 37.18A, B**). The resultant H-V interval and QRS complex become normal. Such an event can initiate the most common type of reciprocating tachycardia, one characterized by anterograde conduction over the normal pathway and retrograde conduction over the accessory pathway (*orthodromic* AV reciprocating tachycardia). The accessory pathway, which blocks conduction in an anterograde direction, recovers

excitability in time to be activated after the QRS complex in a retrograde direction, thereby completing the reentrant loop.

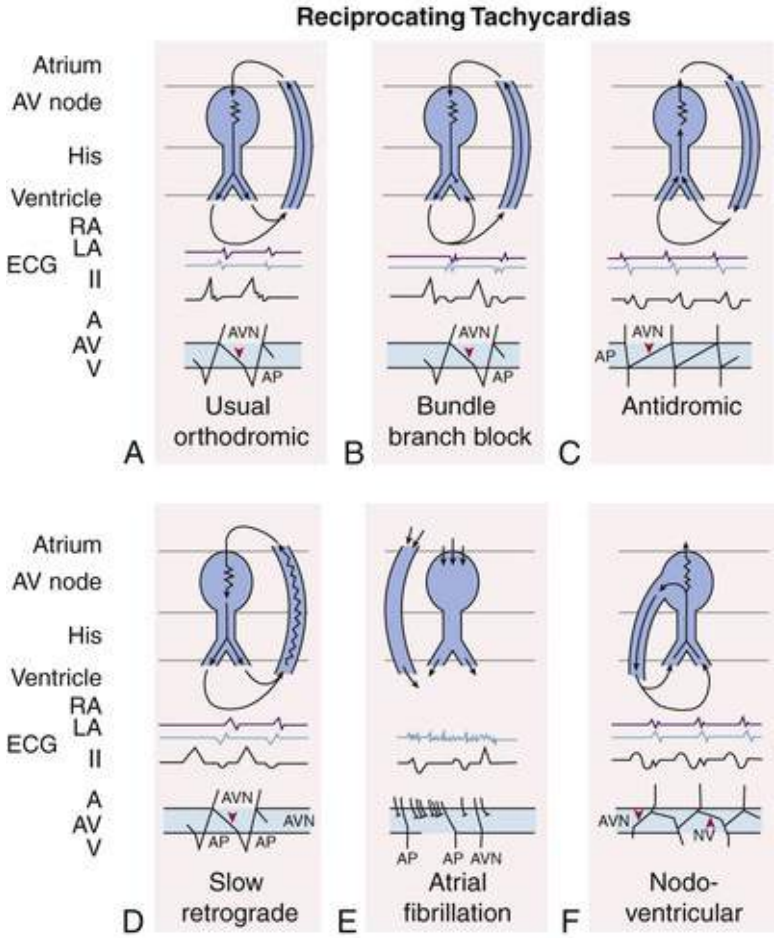


FIGURE 37.18 Schematic diagram of tachycardias associated with accessory pathways. **A,** Orthodromic tachycardia with anterograde conduction (*arrowhead*) over the AV node–His bundle route and retrograde conduction over the accessory pathway (left sided for this example, as depicted by left atrial activation preceding right atrial activation). **B,** Orthodromic tachycardia and ipsilateral functional bundle branch block. **C,** Antidromic tachycardia with anterograde conduction over the accessory pathway and retrograde conduction (*arrowhead*) over the AV node–His bundle. **D,** Orthodromic tachycardia with a slowly conducting accessory pathway (*arrowhead*). **E,** Atrial fibrillation with the accessory pathway as a bystander. **F,** Anterograde conduction over a portion of the AV node and a nodoventricular (*NV*) pathway and retrograde conduction over the AV node (*arrowheads*). *AP,* Accessory pathway; *AVN,* atrioventricular node; *LA,* left atrium; *RA,* right atrium.

Much less often, patients can have tachycardias called *antidromic* tachycardias, during which anterograde conduction occurs over the accessory pathway and retrograde conduction over the AV node. The resultant QRS complex is abnormal because of total ventricular activation over the accessory pathway (**Fig. 37.18C and Fig. 37.19**). In both tachycardias the accessory pathway is an obligatory part of the reentrant circuit.

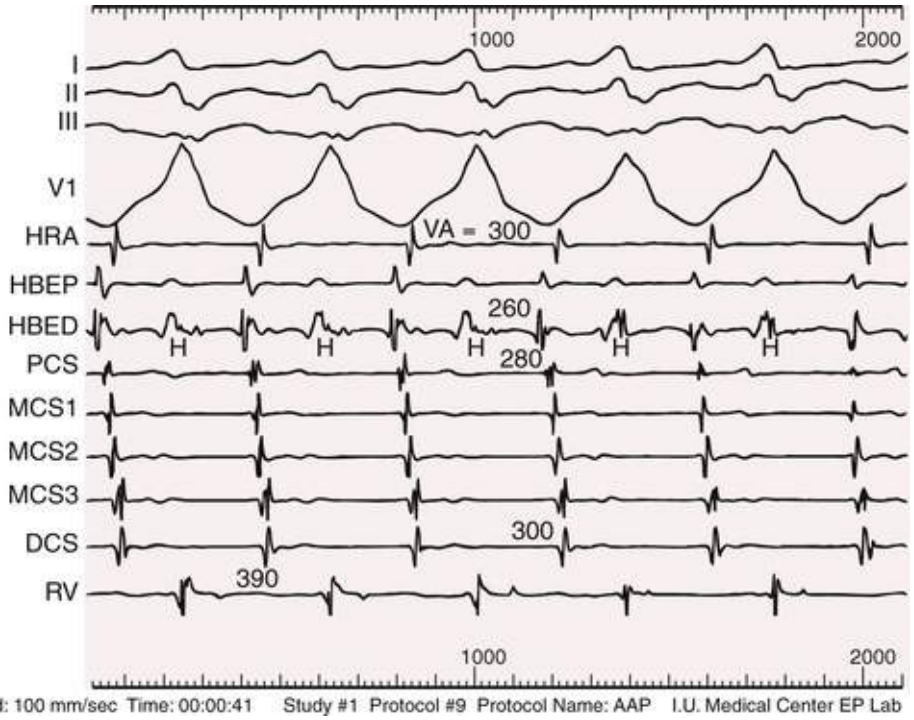

FIGURE 37.19 Antidromic AV reciprocating tachycardia. The tachycardia in this example is caused by anterograde conduction over the accessory pathway (note the abnormal QRS complex of a left posterior accessory pathway) and a normal retrograde atrial activation sequence (beginning first in the HBED lead), which is caused by retrograde conduction over the AV node. The tachycardia cycle length is 390 milliseconds, with a VA interval of 300 milliseconds measured in the high right atrial lead, 260 milliseconds in the distal His lead, and 280 milliseconds in the proximal coronary sinus lead. I, II, III, and V_1 are scalar leads. *DCS,* Distal coronary sinus lead; *HBEP* and *HBED* leads, His bundle electrogram, proximal and distal; *HRA,* high right atrial electrogram; *MCS1* to *MCS3,* midcoronary sinus leads; *PCS,* proximal coronary sinus; *RV,* right ventricular electrogram.

A small percentage of patients have multiple accessory pathways, often suggested by various clues on the ECG, and on occasion, tachycardia can be caused by a reentrant loop conducting anterogradely over one accessory pathway and retrogradely over the other. From 15% to 20% of patients may exhibit AV nodal echoes or AV nodal reentry after interruption of the accessory pathway.

Permanent Form of Atrioventricular Junctional Reciprocating Tachycardia

An incessant form of SVT has been recognized that generally occurs with a long RP interval that exceeds the PR interval (**Figs. 37.20 and 37.21**). Usually, a posteroseptal accessory pathway (most often right ventricle but other locations as well) that conducts very slowly, possibly because of a long and tortuous route, appears to be responsible. Tachycardia is maintained by anterograde AV nodal conduction and retrograde conduction over the accessory pathway (**see Fig. 37.18D**). Although anterograde conduction over this pathway has been demonstrated, the long anterograde conduction time over the accessory pathway usually prevents the electrocardiographic manifestations of accessory pathway conduction during sinus rhythm. Therefore, during sinus rhythm, the QRS duration is prolonged from conduction over this accessory pathway only when conduction times through the AV node–His bundle exceed those in the accessory pathway.

FIGURE 37.20 Termination of the permanent form of AV junctional reciprocating tachycardia (PJRT). In the left portion of this example, PJRT is present. The atrial activation sequence is indistinguishable from atypical AV nodal reentry and atrial tachycardia originating in the low right atrium. The response to premature stimulation identifies the tachycardia as PJRT. Premature ventricular stimulation (*arrowhead*) occurs at a time when the His bundle is refractory from depolarization during the tachycardia (second labeled *H*). Therefore premature ventricular stimulation cannot enter the AV node. Furthermore, premature ventricular stimulation does not reach the atrium. Premature ventricular stimulation, however, terminates the tachycardia. This detail can be explained only by the PVC invading and blocking in a retrogradely conducting accessory pathway. I, II, III, and V_1 are scalar electrocardiographic leads. *DCS,* Distal coronary sinus electrogram; *HBEP, HBED,* His bundle electrogram, proximal and distal; *HRA,* high right atrial electrogram; *MCS1, MCS2,* midcoronary sinus electrograms; *PCS,* proximal coronary sinus electrogram; *RV,* right ventricular electrogram.

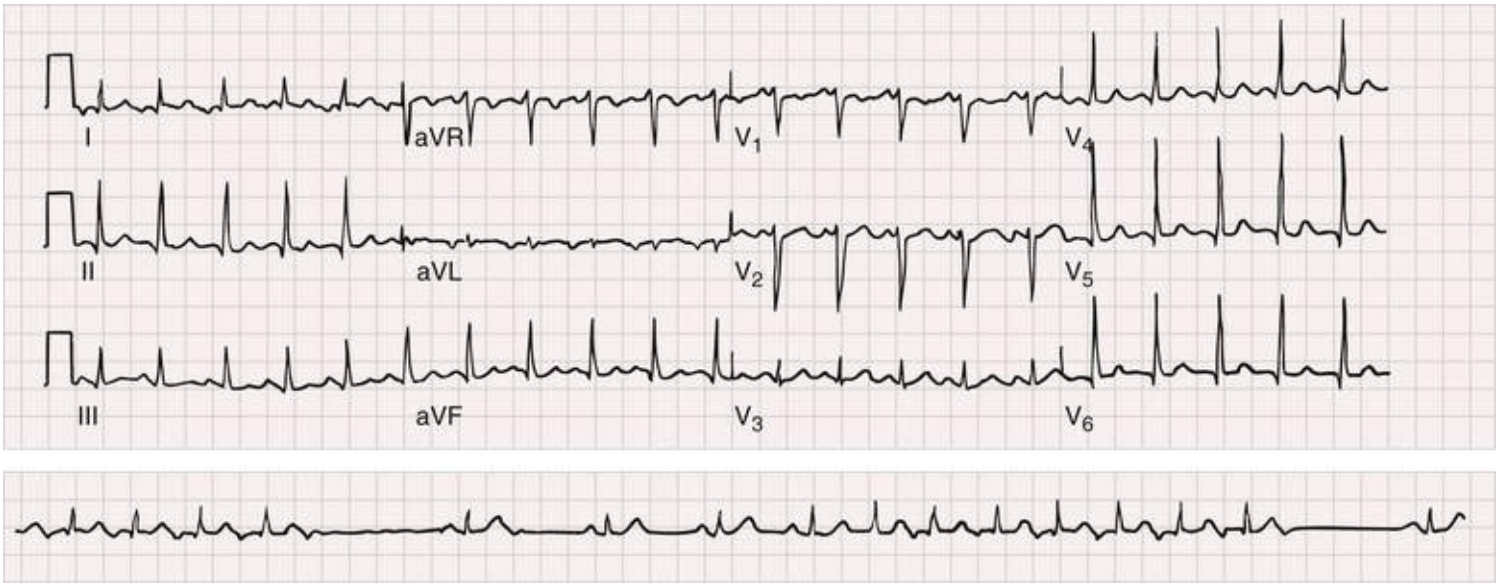

FIGURE 37.21 Permanent form of junctional reciprocating tachycardia (PJRT) in a patient with a left-sided accessory pathway. The 12-lead ECG demonstrates a long RP interval–short PR interval tachycardia, which in contrast to the usual form of PJRT, exhibits negative P waves in leads I and aVL. The rhythm strips below (lead I) indicate that whenever a nonconducted P wave occurs, the tachycardia always terminates, only to begin again after several sinus beats. This pattern is in marked contrast to that in **Fig. 37.6**, in which the tachycardia continues despite nonconducted P waves.

Recognition of Accessory Pathways

When retrograde atrial activation during tachycardia occurs over an accessory pathway that connects the left atrium to the left ventricle, the earliest retrograde activity is recorded from a left atrial electrode usually positioned in the coronary sinus (**see Fig. 37.12**). When retrograde atrial activation during tachycardia occurs over an accessory pathway that connects the right ventricle to the right atrium, the earliest retrograde atrial activity is generally recorded from a lateral right atrial electrode. Participation of a septal accessory pathway creates the earliest retrograde atrial activation in the low right portion of the atrium situated near the septum, anterior or posterior, depending on the insertion site. These mapping techniques provide an accurate assessment of the position of the accessory pathway, which can be anywhere in the AV groove except in the intervalvular trigone between the mitral valve and the aortic valve annuli. Recording electrical activity directly from the accessory pathway obviously provides precise localization.

It may be difficult to distinguish AV nodal reentry from participation of a septal accessory connection by use of the retrograde sequence of atrial activation because activation sequences during both tachycardias are similar. Other approaches to demonstrate retrograde atrial activation over the accessory pathway must be tried and can be accomplished by inducing PVCs during tachycardia to determine whether retrograde atrial excitation can occur from the ventricle at a time when the His bundle is refractory. VA conduction cannot occur over the normal conduction system because the His bundle is refractory, so an accessory pathway must be present for the atria to become excited. No patient with a reciprocating tachycardia from an accessory AV pathway has a VA interval less than 70 milliseconds—this is measured from the onset of ventricular depolarization to the onset of the earliest atrial activity recorded on an esophageal lead—or a VA interval less than 95 milliseconds when it is measured to the high right part of the atrium. In contrast, in most patients with reentry in the AV node, intervals from the onset of ventricular activity to the earliest onset of atrial activity recorded in the esophageal lead are less than 70 milliseconds.

Other Forms of Tachycardia in Patients with Wolff-Parkinson-White Syndrome

Patients can have other types of tachycardia during which the accessory pathway is a bystander, that is, uninvolved in the mechanism responsible for the tachycardia, such as AV nodal reentry or an AT that conducts to the ventricle over the accessory pathway. In patients with atrial flutter or AF, the accessory pathway is not a requisite part of the mechanism responsible for tachycardia, and the flutter or fibrillation occurs in the atrium unrelated to the accessory pathway (**see Fig. 37.18E**). Propagation to the ventricle during atrial flutter or AF can therefore occur over the normal AV node–His bundle or accessory pathway. Patients with WPW syndrome and AF almost always have inducible reciprocating tachycardias as well, which can develop into AF (**eFig. 37.3**). In fact, interruption of the accessory pathway and elimination of AV reciprocating tachycardia usually prevent recurrence of the AF. AF presents a potentially serious risk because of the possibility for very rapid conduction over the accessory pathway. At more rapid rates, the refractory period of the accessory pathway can shorten significantly and permit an extremely rapid ventricular response during atrial flutter or AF (**see Fig. 37.14B**). The rapid ventricular response can exceed the ability of the ventricle to follow in an organized manner; it can result in fragmented, disorganized ventricular activation and hypotension and lead to VF (**Fig. 37.22**). Alternatively, a supraventricular discharge bypassing AV nodal delay can activate the ventricle during the vulnerable period of the antecedent T wave and precipitate VF. Patients who have had VF exhibit ventricular cycle lengths during AF in the range of 240 milliseconds or less.

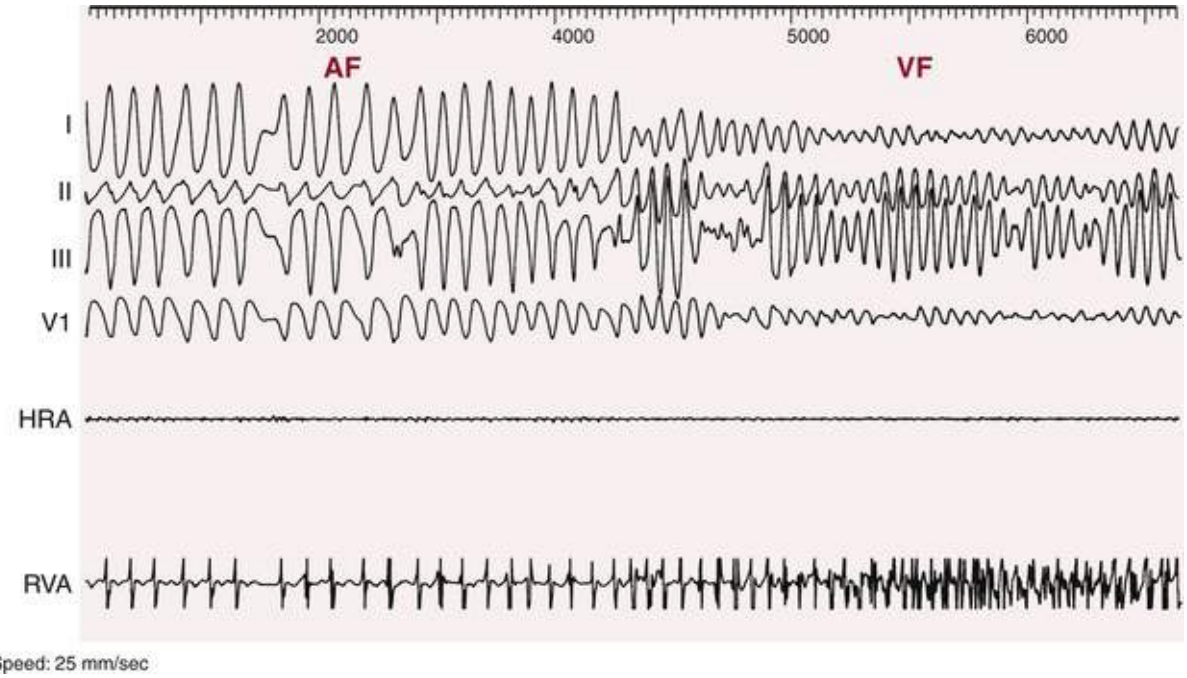

FIGURE 37.22 Atrial fibrillation (AF) becoming ventricular fibrillation (VF). In the left portion of this panel, the ECG demonstrates AF with conduction over an accessory pathway producing a rapid ventricular response, at times in excess of 390 beats/min. In the midportion of the tracing, VF can be seen to develop. I, II, III, and V_1 are scalar electrocardiographic leads. *HRA,* High right atrial electrogram; *RVA,* right ventricular apex electrogram.

Patients with preexcitation syndrome can have other causes of tachycardia, such as AV nodal reentry (sometimes with dual AV nodal curves), sinus nodal reentry, or even VT unrelated to the accessory pathway. Some accessory pathways can conduct anterogradely only; more often, pathways conduct retrogradely only. If the pathway conducts only anterogradely, it cannot participate in the usual form of

reciprocating tachycardia (**see Fig. 37.18A**). It can, however, participate in antidromic tachycardia (**see Fig. 37.18C**), as well as conduct to the ventricle during atrial flutter or AF (**see Fig. 37.18E**). Some data suggest that the accessory pathway demonstrates automatic activity, which could conceivably be responsible for some cases of tachycardia.

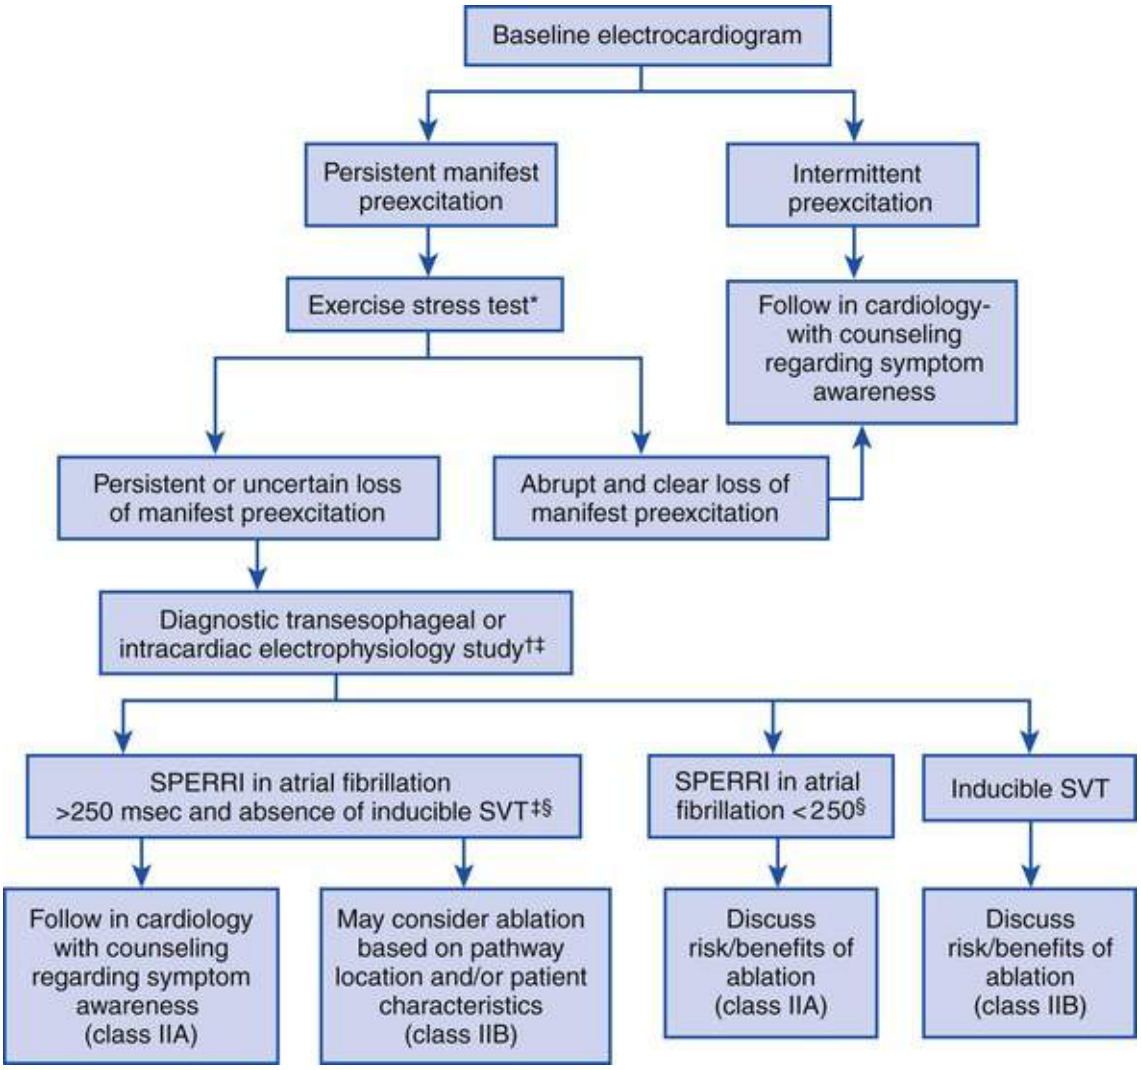
"Wide-QRS" Tachycardias

In patients with preexcitation syndrome, so-called wide-QRS tachycardias can be caused by multiple mechanisms. These include sinus or atrial tachycardias, AV nodal reentry, and atrial flutter or fibrillation with anterograde conduction over the accessory pathway; orthodromic reciprocating tachycardia with functional or preexisting BBB; antidromic reciprocating tachycardia; reciprocating tachycardia with anterograde conduction over one accessory pathway and retrograde conduction over a second pathway; tachycardias using nodofascicular or atriofascicular fibers; and VT.

Clinical Features

The reported incidence of preexcitation syndrome depends in large measure on the population studied and varies from 0.1 to 3 per 1000 in apparently healthy individuals, with an average of about 1.5 per 1000. The incidence of the electrocardiographic pattern of WPW conduction in 22,500 healthy aviation personnel was 0.25%, with a prevalence of documented tachyarrhythmias of 1.8%. Left free wall accessory pathways were most common, followed in frequency by posteroseptal, right free wall, and anteroseptal locations. WPW syndrome is found in all age-groups from the fetal and neonatal periods to the elderly, as well as in identical twins. The prevalence is higher in men and decreases with age, apparently because of loss of preexcitation. Most adults with preexcitation syndrome have normal hearts, although various acquired and congenital cardiac defects have been reported, including Ebstein anomaly, mitral valve prolapse, and cardiomyopathies. Patients with Ebstein anomaly often have multiple right-sided accessory pathways, either in the posterior septum or in the posterolateral wall, with preexcitation localized to the atrialized ventricle (**see Chapter 75**). They frequently have reciprocating tachycardia with a long VA interval and RBBB morphology.

The frequency of paroxysmal tachycardia apparently increases with age, from 10 per 100 patients with WPW syndrome in the 20- to 39-year-old group to 36 per 100 in patients older than 60 years. Approximately 80% of patients with tachycardia have a reciprocating tachycardia, 15% to 30% have AF, and 5% have atrial flutter. VT occurs infrequently. The anomalous complexes can mask or mimic myocardial infarction (**see Chapter 58**), BBB, or ventricular hypertrophy, and the presence of preexcitation syndrome can suggest an associated cardiac defect. For most patients with recurrent tachycardia, the prognosis is good, but sudden death does occur rarely, with an estimated frequency of 0.1%. Risk stratification includes a stress test and electrophysiologic study (EPS) in selected patients[14] (**eFig. 37.4**).



EFIGURE 37.4 Baseline electrocardiogram. *Patients unable to perform an exercise stress test should undergo risk-stratification with an electrophysiologic study. †Before invasive testing, patients and parents/guardians should undergo counseling to discuss the risks and benefits of proceeding with invasive studies, the risks associated with observation only, and risks related to the medication strategy. ‡Patients participating in moderate- to high-level competitive sports should be counseled with regard to the risks and benefits of ablation (class IIA) and follow the 36th Bethesda Conference guidelines. §In the absence of inducible atrial fibrillation, the shortest preexcited RR interval as determined by rapid atrial pacing is a reasonable surrogate. *SPERRI,* Shortest preexcited RR interval. (From Cohen MI, Triedman JK, Cannon BC, et al. PACES/HRS expert consensus statement on the management of the asymptomatic young patient with a Wolff-Parkinson-White [WPW, ventricular preexcitation] electrocardiographic pattern: Developed in partnership between the Pediatric and Congenital Electrophysiology Society [PACES] and the Heart Rhythm Society [HRS]. Endorsed by the governing bodies of PACES, HRS, American College of Cardiology Foundation [ACCF], American Heart Association [AHA], American Academy of Pediatrics [AAP], and Canadian Heart Rhythm Society [CHRS]. Heart Rhythm 2012;9:1006.)

It is highly likely that an accessory pathway is congenital, although its manifestations may be detected in later years and appear to be acquired. Relatives of patients with preexcitation, particularly those with multiple pathways, have an increased prevalence of preexcitation, thus suggesting a hereditary mode of acquisition. Some children and adults can lose their tendency for the development of tachyarrhythmias as they grow older, possibly as a result of fibrotic or other changes at the site of insertion of the accessory pathway. Pathways can lose their ability to conduct anterogradely. Tachycardia beginning in infancy can disappear but frequently recurs. Tachycardia still present after 5 years of age persists in 75% of patients, regardless of the location of the accessory pathway. Intermittent preexcitation during sinus rhythm and abrupt loss of conduction over the accessory pathway after IV administration of procainamide and with exercise suggest that the refractory period of the accessory pathway is long and that the patient is not at risk for a rapid ventricular rate should atrial flutter or fibrillation develop. These approaches are

relatively specific but not very sensitive, with low positive predictive accuracy. Exceptions to these safeguards can occur; the only way to be certain of the accessory pathway's properties and propensity for rapid conduction is by performing an EPS.

Treatment

For patients without symptoms, risk stratification to determine the risk for sudden death as a result of rapid conduction over the accessory pathway inducing VF, although rare, may be necessary in some patients. Patients with asymptomatic intermittent ventricular preexcitation do not require further evaluation or therapy and should simply be observed.[14] Young patients (8 to 21 years of age) who have only persistent electrocardiographic abnormalities, without tachyarrhythmias or a history of palpitations, should undergo stress testing to determine whether abrupt loss of preexcitation occurs. If loss of preexcitation does not occur or is equivocal or not abrupt, an invasive EPS is recommended to risk-stratify patients further[14] (**eFig. 37.4**). For patients with frequent episodes of symptomatic tachyarrhythmia, therapy should be initiated.

Two therapeutic options exist, catheter ablation and pharmacologic therapy. Drugs are chosen to prolong conduction time or refractoriness in the AV node, the accessory pathway, or both to prevent rapid rates from occurring. If successful, such therapy prevents maintenance of an AV reciprocating tachycardia or a rapid ventricular response to atrial flutter or AF. Some drugs can suppress premature complexes that precipitate the arrhythmias.

Adenosine, verapamil, propranolol, and digitalis prolong conduction time and refractoriness in the AV node. Verapamil and propranolol do not directly affect conduction in the accessory pathway, and digitalis has had variable effects. Because digitalis has been reported to shorten refractoriness in the accessory pathway and to speed the ventricular response in some patients with AF, it is advisable to not use digitalis as a single drug in patients with WPW syndrome. Instead, drugs that prolong the refractory period in the accessory pathway should be used, such as class IA and IC drugs (**see Chapter 36**).

The class IC and class III drugs can affect both the AV node and the accessory pathway. Lidocaine does not generally prolong refractoriness of the accessory pathway. Verapamil and IV lidocaine can increase the ventricular rate during AF in patients with WPW syndrome. IV verapamil can precipitate VF when given to a patient with WPW syndrome who has a rapid ventricular rate during AF. This effect does not seem to occur with oral verapamil. Catecholamines can expose WPW syndrome, shorten the refractory period of the accessory pathway, and reverse the effects of some AADs.

Termination of an Acute Episode

Termination of an acute episode of reciprocating tachycardia, suspected electrocardiographically from a normal QRS complex, regular R-R intervals, a rate of approximately 200 beats/min, and a retrograde P wave in the ST segment, should be approached similar to AV nodal reentry. After vagal maneuvers, adenosine followed by IV verapamil or diltiazem is the initial treatment of choice. AF can occur after drug administration, particularly adenosine, along with a rapid ventricular response. An external cardioverter-defibrillator should be immediately available if necessary. For atrial flutter or AF (with AF suspected because of an anomalous QRS complex and grossly irregular R-R intervals; **see Fig. 37.14B and eFig. 37.3**), drugs must be used that prolong refractoriness in the accessory pathway (procainamide, amiodarone), often coupled with drugs that prolong AV nodal refractoriness. In many patients, particularly those with a very rapid ventricular response and any signs of hemodynamic impairment, electrical cardioversion is the initial treatment of choice.

Prevention

For long-term therapy to prevent recurrence, RF catheter ablation of the accessory pathway has become the first-line therapy for most patients. Decisions about ablation depend on (1) risk of AF conducting rapidly over the accessory pathway causing VF, (2) frequency and severity of symptoms from tachycardia, and (3) risk of the procedure (largely determined by location of the accessory pathway). For patients with frequent symptomatic arrhythmias not fully controlled by drugs, those who are drug intolerant, or those who choose not to take drugs, ablation is advisable. This option should be considered early in the course of treatment of a symptomatic patient because of its high success rate, low frequency of complications, and potential cost-effectiveness. Ablation is the treatment of choice in patients with AF and rapid conduction over an accessory pathway. Even though transvenous catheter ablation is generally effective, epicardial ablation through a pericardial approach or surgical interruption of the accessory pathway may be necessary in rare cases. Septal accessory pathways near the AV node (anteroseptal) may require cryoablation instead of RF ablation, to minimize the risk of AV block complicating the procedure.[15]

Drug therapy is an alternative to ablation or is used in rare cases of failed ablation attempts, but it is not always possible to predict which drugs may be most effective for an individual patient. Some drugs can actually increase the frequency of episodes of reciprocating tachycardia by prolonging the duration of anterograde and not retrograde refractory periods of the accessory pathway, thereby making it easier for a PAC to block conduction anterogradely in the accessory pathway and to initiate tachycardia. Oral administration of two drugs, such as flecainide and propranolol, to decrease conduction capability in both limbs of the reentrant circuit can be beneficial. Amiodarone and sotalol, which prolong refractoriness in both the accessory pathway and the AV node, can be effective. Depending on the clinical situation, empiric drug trials or serial electrophysiologic drug testing can be used to determine optimal drug therapy for patients with reciprocating tachycardia. For patients who have AF with a rapid ventricular response, induction of AF while the patient is receiving therapy is essential to be certain that the ventricular rate is controlled. Patients who have accessory pathways with very short refractory periods may be poor candidates for drug therapy because the refractory periods may be insignificantly prolonged in response to the standard agents.

Summary of Electrocardiographic Diagnosis of Supraventricular Tachycardias

Electrocardiographic clues that permit differentiation among the various SVTs are often present. P waves during tachycardia that are identical to sinus P waves and that occur with a long RP interval and a short PR interval are most likely caused by sinus nodal reentry, sinus tachycardia, or an AT arising from the right atrium near the sinus node. Retrograde (inverted in leads II, III, and aVF) P waves usually represent reentry involving the AV junction, either AV nodal reentry or reciprocating tachycardia using a paraseptal accessory pathway. Depression of the ST segment during a narrow-complex tachycardia generally signifies AV reentrant tachycardia using an accessory pathway. Tachycardia without manifest P waves is probably caused by AV nodal reentry (retrograde P waves buried in the QRS complex), whereas a tachycardia with an RP interval exceeding 90 milliseconds can be caused by an accessory pathway. AV dissociation or AV block during tachycardia excludes the participation of an AV accessory pathway and makes AV nodal reentry less likely. Multiple tachycardias can occur at different times in the same patient. QRS alternans, thought to be a feature of AV reciprocating tachycardia, is more likely a rapid rate–related phenomenon independent of the tachycardia mechanism. RP-PR relationships help differentiate SVTs

(**Table 37.6**). QRS voltage can increase during SVT.

TABLE 37.6

Supraventricular Tachycardias

SHORT RP, LONG PR INTERVAL	LONG RP, SHORT PR INTERVAL
AV nodal reentry	Atrial tachycardia
AV reentry	Sinus node reentry
	Atypical AV nodal reentry
	AVRT with a slowly conducting accessory pathway (e.g., PJRT)

AVRT, Atrioventricular reciprocating tachycardia; *PJRT,* paroxysmal junctional reciprocating tachycardia.

Atrial Fibrillation: Clinical Features, Mechanisms, and Management

Fred Morady, Douglas P. Zipes

Electrocardiographic Features

Atrial fibrillation (AF) is a supraventricular arrhythmia characterized electrocardiographically by low-amplitude baseline oscillations (fibrillatory or f waves from the fibrillating atria) and an irregularly irregular ventricular rhythm. The f waves, 300 to 600 beats/min, are variable in amplitude, shape, and timing. Atrial flutter waves have a rate of 250 to 350 beats/min and are constant in timing and morphology (**Fig. 38.1**). In lead V_1, f waves sometimes appear uniform and can mimic flutter waves (**Fig. 38.2**). In some patients, f waves are very small and not perceptible on the electrocardiogram, and the diagnosis of AF is based on the irregularly irregular ventricular rhythm (**Fig. 38.3**).

FIGURE 38.1 Comparison between the f waves of AF **(top panel)** and the flutter waves of atrial flutter **(bottom panel).** Note that f waves are variable in rate, shape, and amplitude, whereas flutter waves are constant in rate and all aspects of morphology. Shown are leads V_1 and II.

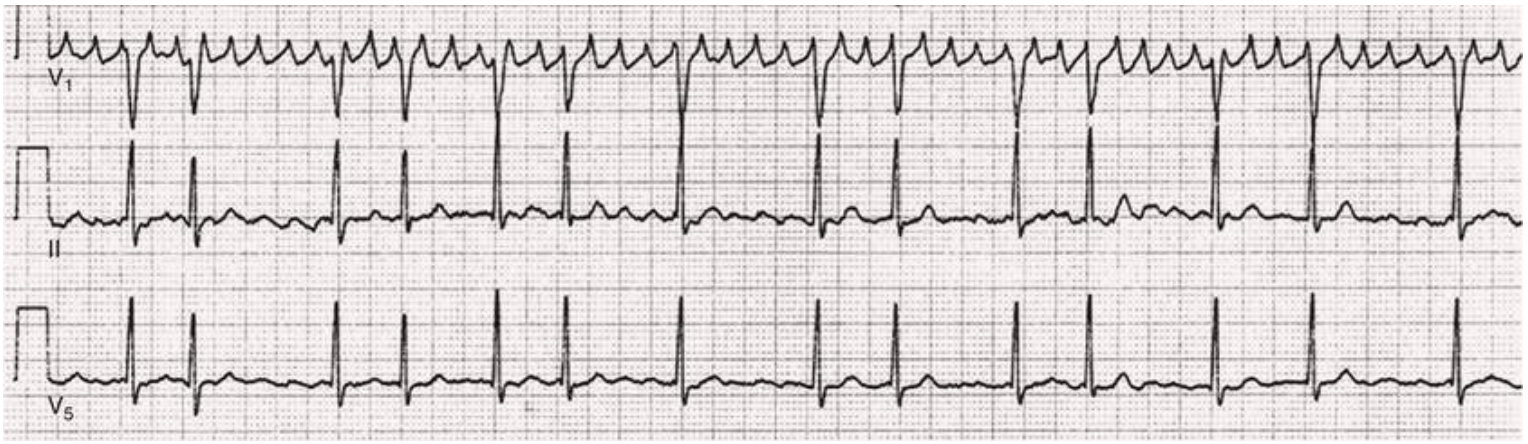

FIGURE 38.2 An example of AF with prominent f waves in V_1 that mimic atrial flutter waves. Note that typical f waves are present in leads II and V_5, establishing the diagnosis of AF.

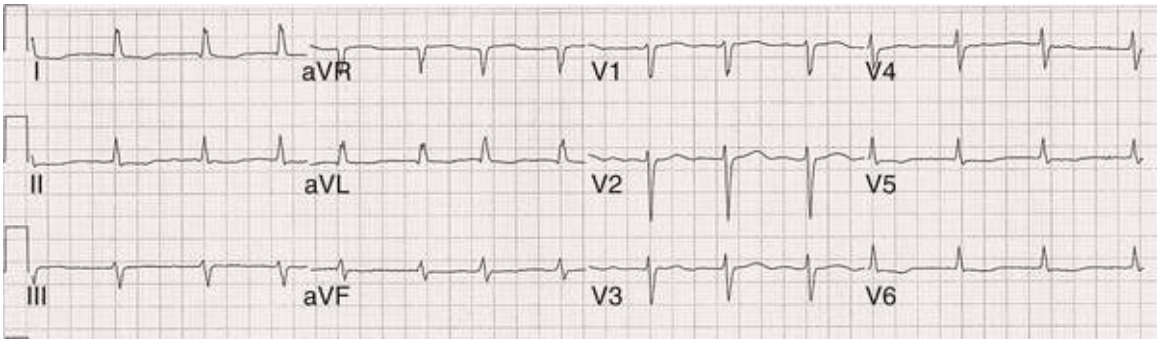

FIGURE 38.3 A 12-lead electrocardiogram of AF in which f waves are not discernible. The irregularly irregular ventricular rate indicates that this is AF.

The ventricular rate during untreated AF typically is 100 to 160 beats/min. Patients with the Wolff-Parkinson-White (WPW) syndrome can experience ventricular rates during AF exceeding 250 beats/min because of conduction over the accessory pathway (**see Chapter 37**). The ventricular rate during AF can appear more regular when the rate is extremely rapid (>170 beats/min) (**Fig. 38.4**), when a junctional tachycardia independently controls the ventricles, when there is high-degree atrioventricular (AV) block with a regular escape rhythm (**Fig. 38.5**), or when the QRS complexes are fully paced. In these cases the diagnosis of AF is based on the presence of f waves. Infrequently, a junctional tachycardia can exhibit a Wenckebach exit block (often during digitalis toxicity) to cause a regularly irregular ventricular rate.

FIGURE 38.4 A recording of AF with a rapid ventricular rate of 160 beats/min. Shown are leads V_1, II, and V_5. On quick review, there may appear to be a regular rate consistent with paroxysmal supraventricular tachycardia. On closer inspection, it is clear that the rate is irregularly irregular.

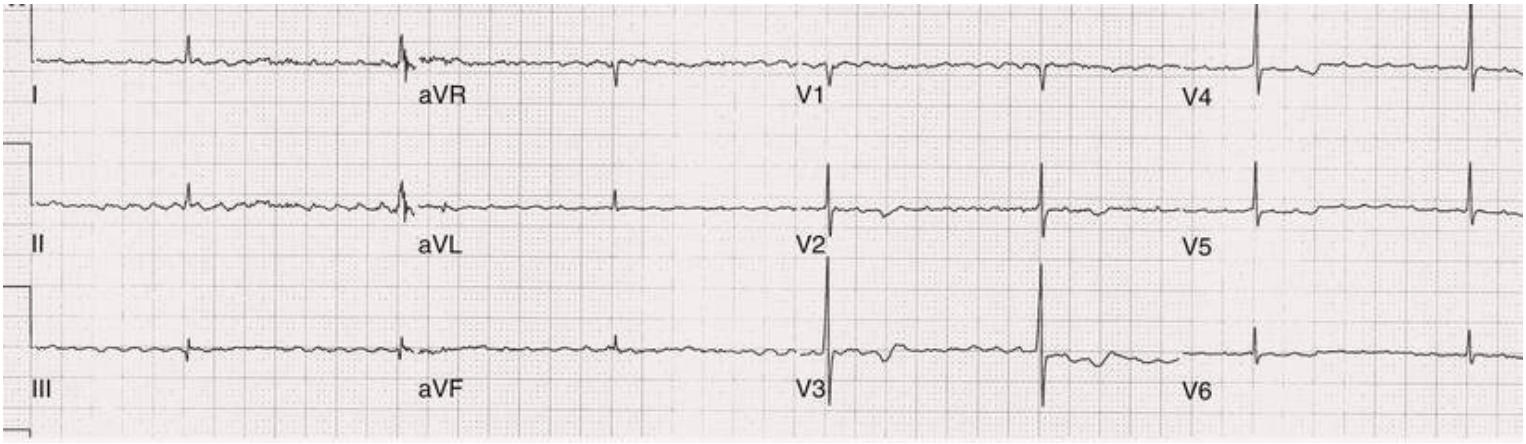

FIGURE 38.5 Atrial fibrillation and a regular junctional rhythm at a rate of 43 beats/min. There is either underlying third-degree AV block or second-degree AV block with extremely slow atrioventricular conduction allowing a junctional escape rhythm to become manifest.

Classification of Atrial Fibrillation

Atrial fibrillation that terminates spontaneously within 7 days is termed *paroxysmal*, and AF present continuously for more than 7 days is called *persistent*. AF that persists for longer than 1 year is termed *longstanding persistent*, whereas longstanding AF refractory to cardioversion is termed *permanent*. However, "permanent AF" is not necessarily permanent in the literal sense because it may be successfully eliminated by surgical or catheter ablation.

Some patients with paroxysmal AF occasionally can have episodes that are persistent, and vice versa. The predominant form of AF determines how it should be categorized.

A confounding factor in the classification of AF is cardioversion and antiarrhythmic drug (AAD) therapy. For example, if a patient undergoes transthoracic cardioversion 24 hours after AF onset, it is unknown whether the AF would have persisted for more than 7 days. Furthermore, AAD therapy can change persistent AF into paroxysmal AF. It is generally thought that the classification of AF should not be altered on the basis of the effects of electrical cardioversion or AAD therapy.

Lone atrial fibrillation refers to AF that occurs in patients younger than 60 years who do not have hypertension or any evidence of structural heart disease. This designation is clinically relevant because

patients with lone AF are at lower risk of thromboembolic complications, eliminating the necessity for anticoagulation. They also may be more likely to have familial or genetic causes. In addition, the absence of structural heart disease allows the safe use of rhythm-control drugs such as flecainide in patients with lone AF.

Paroxysmal AF also can be classified clinically on the basis of the autonomic setting in which it most often occurs. Approximately 25% of patients with paroxysmal AF have *vagotonic* AF, during which AF is initiated in the setting of high vagal tone, typically in the evening when the patient is relaxing or during sleep. Drugs exerting a vagotonic effect (e.g., digitalis) can aggravate vagotonic AF, and drugs with a vagolytic effect (e.g., disopyramide) may be particularly appropriate for prophylactic therapy. Adrenergic AF occurs in approximately 10% to 15% of patients with paroxysmal AF in the setting of high sympathetic tone, as during strenuous exertion. In patients with adrenergic AF, beta blockers not only provide rate control but can prevent the onset of AF. Most patients have a mixed or random form of paroxysmal AF, with no consistent pattern of onset. In some, alcohol can be a precipitant.

Epidemiology of Atrial Fibrillation

Atrial fibrillation is the most common arrhythmia treated in clinical practice and the most common arrhythmia for which patients are hospitalized; approximately 33% of arrhythmia-related hospitalizations are for AF. AF is associated with approximately a fivefold increase in the risk of cerebrovascular accident (stroke) and a twofold increase in the risk of all-cause mortality.[1] AF also is associated with the development of heart failure and has been linked to sudden death.

The incidence of AF is age and gender related, ranging from 0.1% per year before age 40 to more than 1.5% per year in women and more than 2% per year in men older than 80. Congestive heart failure, aortic and mitral valve disease, left atrial enlargement, hypertension, and advanced age are independent risk factors for the development of AF, as are obesity and obstructive sleep apnea[2] (**see Chapter 87**). Another risk factor is psoriasis, which, when severe, triples the risk of AF in patients younger than 50.[3]

A community-based cohort study in Olmstead County, Minnesota, reported that the age-adjusted incidence of AF per 1000 person-years increased significantly between 1980 and 2000 from 4.4 to 5.4 in men and from 2.4 to 2.8 in women.[4] There was a relative increase of 0.6% per year in the age-adjusted AF incidence. An increase in obesity accounted for 60% of the age-adjusted increase in AF incidence. The number of patients with AF in the United States was estimated to be 3.2 million in 1980 and 5.1 million in 2000 and was projected to be 12.1 to 15.9 million in 2050, all of which are higher than previous estimates.

Mechanisms of Atrial Fibrillation

The mechanisms responsible for AF are complex. Triggering events may differ from maintenance mechanisms. In addition, the clinical phenotypes of paroxysmal, persistent, and longstanding persistent have different electrophysiologic characteristics because of remodeling and different clinical modulators that affect the substrate, such as heart failure, atrial stretch and ischemia, sympathovagal influences, inflammation, and fibrosis.

The two likely electrophysiologic mechanisms of AF are one or more automatic, triggered, or microreentrant foci, so-called *drivers*, which fire at rapid rates and cause fibrillation-like activity, and multiple reentrant circuits meandering throughout the atria, annihilating and reforming wavelets that

perpetuate the fibrillation. In many studies the left atrium contains the site of dominant frequency discharge, with a left-to-right gradient. Both mechanisms may be present simultaneously and can change as the atria remodel. In the CONFIRM trial, computational maps were obtained in patients by signal processing of multiple electrograms recorded simultaneously during AF.[5] This technique can reveal rotors and focal sources. A mean of 2.1 sources was found in 97% of 101 patients, with 70% being rotors and 30% being focal sources.

Rapid discharges from the pulmonary veins are the most common triggers of AF and also may play a perpetuating role, more so in paroxysmal AF than in persistent AF. This is why pulmonary vein isolation is particularly effective for elimination of paroxysmal AF. In persistent AF, changes in the atrial substrate, including interstitial fibrosis that contributes to slow, discontinuous, and anisotropic conduction, may give rise to complex fractionated atrial electrograms (CFAEs) and reentry. Therefore, pulmonary vein isolation alone often is insufficient to eliminate persistent AF (**see Chapter 36**).

Genetic Factors

Several mutations that are responsible for familial AF and that predispose to AF have been identified. These mutations cause a gain of function of repolarization potassium currents that results in shortening of atrial refractoriness and facilitation of atrial reentry. Multiple polymorphisms associated with idiopathic AF or structural heart disease or occurring postoperatively also have been identified.[6] These polymorphisms are in genes that affect potassium and sodium channels, sarcolipin, the renin-angiotensin system, connexin-40, endothelial nitric oxide synthase, and interleukin-10. The end results are changes in calcium handling, fibrosis, conduction, and inflammation that predispose to AF.

Causes of Atrial Fibrillation

The majority of patients with AF have hypertension (usually with left ventricular hypertrophy; **Chapters 46 and 47**) or some other form of structural heart disease. In addition to hypertensive heart disease, the most common cardiac abnormalities associated with AF are ischemic heart disease (**Chapter 58**), mitral valve disease (**Chapter 69**), hypertrophic cardiomyopathy (**Chapter 78**), and dilated cardiomyopathy (**Chapter 77**). Less common causes of AF are restrictive cardiomyopathies such as amyloidosis (**Chapter 77**), constrictive pericarditis (**Chapter 83**), and cardiac tumors (**see Chapter 95**). Severe pulmonary hypertension often is associated with AF (**Chapter 85**).

Obstructive sleep apnea and obesity are associated with each other, and both independently increase the risk of AF (**see Chapter 87**). The possible mechanisms of AF in patients with sleep apnea include hypoxia, surges in autonomic tone, and hypertension.[2] Available data suggest that atrial dilation and an increase in systemic inflammatory factors are responsible for the relationship between obesity and AF. Obesity also is associated with increased deposits of epicardial fat (**see Chapter 50**). The most likely mechanisms by which epicardial fat predisposes to AF are slow or anisotropic conduction caused by adipocyte infiltration into atrial muscle, atrial fibrosis caused by adipokines secreted by epicardial fat, and the local secretion of proinflammatory factors (e.g., IL-6, IL-8, TNF-α).[7] The LEGACY study demonstrated that sustained weight loss and exercise can reduce the AF burden.[8]

AF can have causes that are temporary or reversible. The most common temporary causes are excessive alcohol intake (“holiday heart”), open heart or thoracic surgery, myocardial infarction (**see Chapters 58 and 59**), pericarditis (**Chapter 83**), myocarditis (**Chapter 79**), and pulmonary embolism

(**Chapter 84**). The most common correctable cause is hyperthyroidism (**Chapter 92**).

AF is sometimes caused by tachycardia. Patients with tachycardia-induced AF most often have AV nodal reentrant tachycardia or a tachycardia related to WPW syndrome that degenerates into AF. AF in a patient with a history of rapid and regular palpitations before the onset of irregular palpitations or with a WPW electrocardiographic pattern should suggest tachycardia-induced AF. Treatment of the tachycardia that triggers the AF often (but not always) prevents recurrences of AF.

Clinical Features

The symptoms of AF range from none to severe and functionally disabling. The most common symptoms are palpitations, fatigue, dyspnea, effort intolerance, and lightheadedness. Polyuria can occur because of release of atrial natriuretic peptide. Many patients with symptomatic paroxysmal AF also have asymptomatic episodes, and some patients with persistent AF have symptoms only intermittently, making it difficult to assess accurately the frequency and duration of AF on the basis of symptoms.

An estimated 25% of patients with AF are asymptomatic, more often elderly patients and patients with persistent AF. Such patients sometimes are erroneously classified as having “asymptomatic” AF despite having symptoms of fatigue or effort intolerance. Because fatigue is a nonspecific symptom, it may not be clearly caused by persistent AF. A “diagnostic cardioversion” may be helpful by maintaining sinus rhythm for at least a few days to determine whether a patient feels better in sinus rhythm. This can provide a basis to pursue a rhythm-control versus rate-control strategy.

Syncope, an uncommon symptom of AF, can be caused by a long sinus pause on termination of AF in a patient with the sick sinus syndrome. Syncope also can occur during AF with a rapid ventricular rate because of neurocardiogenic (vasodepressor) syncope triggered by the tachycardia or because of a severe drop in blood pressure caused by a reduction in cardiac output.

Asymptomatic or minimally symptomatic AF patients are not prompted to seek medical care and can present with a thromboembolic complication such as stroke or the insidious onset of heart failure symptoms, eventually presenting in florid congestive heart failure.

The hallmark of AF on physical examination is an irregularly irregular pulse. Short R-R intervals during AF do not allow adequate time for left ventricular diastolic filling, resulting in a low stroke volume and the absence of palpable peripheral pulse. This results in a “pulse deficit,” during which the peripheral pulse is not as rapid as the apical rate. Other manifestations of AF on the physical examination are irregular jugular venous pulsations and variable intensity of the first heart sound.

Diagnostic Evaluation

In a patient who describes irregular or rapid palpitations suggestive of paroxysmal AF, ambulatory monitoring is useful to document whether AF is responsible for the symptoms. If the symptoms occur on a daily basis, a 24-hour Holter recording is appropriate. However, extended monitoring for 2 to 4 weeks with an event monitor or by mobile cardiac outpatient telemetry is appropriate for patients whose symptoms are sporadic (**see Chapter 32**).

The history should be directed at determination of the type and severity of symptoms, the first onset of AF, whether the AF is paroxysmal or persistent, the triggers of AF, whether the episodes are random or occur at particular times (e.g., during sleep), and the frequency and duration of episodes. When it is unclear from the history, 2 to 4 weeks of ambulatory monitoring with an autotrigger event monitor or by

mobile cardiac outpatient telemetry is useful to determine whether AF is paroxysmal or persistent and to quantitate the AF burden in patients with paroxysmal AF. The history also should be directed at identification of potentially correctible causes (e.g., hyperthyroidism, excessive alcohol intake), structural heart disease, and comorbidities.

Laboratory testing should include thyroid, liver, and renal function tests. Echocardiography always is appropriate to evaluate atrial size and left ventricular function and to look for left ventricular hypertrophy, congenital heart disease (**see Chapter 75**), and valvular heart disease (**Chapters 68 and 69**). Chest radiography is appropriate if the history or physical examination is suggestive of pulmonary disease (**Chapter 15**). A stress test is appropriate for evaluation of ischemic heart disease in at-risk patients (**Chapter 13**).

Prevention of Thromboembolic Complications

Risk Stratification

A major goal of therapy in patients with AF is to prevent thromboembolic complications such as stroke. Warfarin and other oral anticoagulants are more effective than aspirin for prevention of thromboembolic complications.[9] However, because of the risk of hemorrhage from anticoagulants, their use should be limited to patients whose risk of thromboembolic complications is greater than the risk of hemorrhage. Therefore, it is useful to risk stratify patients with AF to identify appropriate candidates for anticoagulation.

The strongest predictors of ischemic stroke and systemic thromboembolism are a history of stroke or transient ischemic episode and mitral stenosis. When patients with AF and a prior ischemic stroke are treated with aspirin, the risk of another stroke is very high, in the range of 10% to 12% per year. At the other end of the risk spectrum are patients with lone AF, whose cumulative 15-year risk of stroke is in the range of 1% to 2%. Aside from prior stroke, the best-established risk factors for stroke in patients with nonvalvular AF are diabetes (relative risk [RR], 1.7), hypertension (RR, 1.6), heart failure (RR, 1.4), and age 70 or older (RR, 1.4 per decade).[2]

A simple clinical scheme to risk stratify patients on the basis of the major risk factors is the $CHADS_2$ (cardiac failure, hypertension, age, diabetes, stroke) score. Each of the first four risk factors counts as 1 point, and a prior stroke or transient ischemic event is 2 points. There is a direct relationship between the $CHADS_2$ score and the annual risk of stroke in the absence of aspirin or warfarin therapy. The clinical value of the $CHADS_2$ score lies in its simplicity and predictive value. However, the $CHADS_2$ score has been superseded by the CHA_2DS_2-VASc score because it more accurately discriminates low-risk from intermediate-risk patients.[10] In this risk-scoring system, cardiac failure, hypertension, diabetes, vascular disease, age 65 to 74 years, and female gender are 1 point each, and age 75 or older and prior stroke or transient ischemic event are 2 points. The annual risk of stroke is zero or close to zero when the CHA_2DS_2-VASc score is 0, compared to approximately 2% when the $CHADS_2$ score is 0.[11] A score of 1 is associated with an annual stroke risk of approximately 3% with the $CHADS_2$ score, compared to 0.7% with the CHA_2DS_2-VASc score (**Fig. 38.6**).

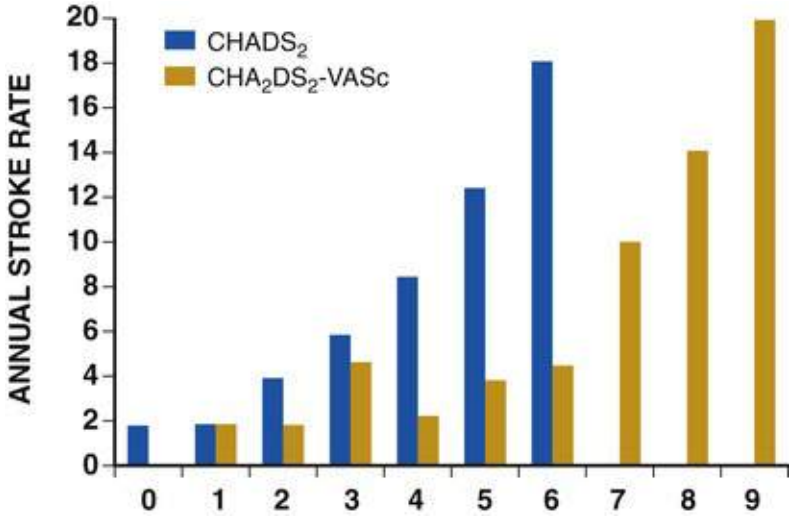

FIGURE 38.6 The annual risk of stroke (percent risk/year) based on the $CHADS_2$ and CHA_2DS_2-VASc scores. (Based on data from Lip GY. Implications of the CHA(2)DS(2)-VASc and HAS-BLED Scores for thromboprophylaxis in atrial fibrillation. Am J Med 2011;124:111-4.)

Renal failure also is an independent risk factor for stroke in patients with AF.[12] The relative risk of a thromboembolic event in the absence of anticoagulation was 1.4 in patients with non–end-stage chronic kidney disease and 1.8 in patients requiring hemodialysis or a renal transplant. The predictive strength of chronic kidney disease for a thromboembolic event appears to be equivalent to that of heart failure and advanced age. Therefore, it may be appropriate to take into account chronic kidney disease in evaluating the risk profile of a patient with AF.

By definition, the burden of AF is greater in patients with persistent AF than in patients with paroxysmal AF. It may seem reasonable to assume that the risk of stroke is lower in patients with occasional episodes of self-limited AF than in patients with AF continuously. However, the available data in fact indicate that the risk of thromboembolic complications is the same in patients with paroxysmal and persistent AF. Accordingly, guideline recommendations for anticoagulation are the same in patients with paroxysmal and persistent AF.[2,13]

Current dual-chamber pacemakers and implantable cardioverter-defibrillators (ICDs) are capable of detecting short episodes of asymptomatic AF that otherwise would not have been detected clinically. In a recent multicenter prospective study, subclinical atrial tachyarrhythmias (atrial rate >190 beats/min for >6 minutes) were detected by device interrogation in 10.1% of patients 65 years or older with hypertension and no history of AF who received a pacemaker or ICD.[14] Subclinical atrial tachyarrhythmias were independently associated with a 2.5-fold increase in the risk of stroke.

An important consideration in patients treated with an oral anticoagulant is the risk of bleeding. Several risk-scoring systems have been developed to assess a patient's susceptibility to hemorrhagic complications. The scoring system with the best balance of simplicity and accuracy is the HAS-BLED score.[15] The components of this score are hypertension, abnormal renal or liver function, stroke, bleeding history or predisposition, labile international normalized ratio (INR), elderly (>75 years), and concomitant drug (antiplatelet agent or nonsteroidal anti-inflammatory drug) or alcohol use. Each of these components is 1 point. As the score increases from 0 to the maximum of 9, there is a stepwise increase in the risk of bleeding in patients treated with warfarin. For example, in one study the annual rate of major bleeds was 1.1% in patients with a HAS-BLED score of 0, 3.7% with a score of 3, and 12.5% with a score of 5.[16]

In two large-scale cohort studies of 132,372 and 170,292 patients with nonvalvular AF, the CHA_2DS_2-VASc and HAS-BLED scores were calculated for each patient.[17,18] The net clinical benefit of warfarin

was defined as the number of strokes off warfarin minus the number of intracranial bleeds on warfarin. In both studies, warfarin was associated with a net clinical benefit except when the CHA_2DS_2-VASc score was 0. In patients with a CHA_2DS_2-VASc score of 1 or more, the risk of stroke in the absence of warfarin exceeded the number of bleeding complications during treatment with warfarin.

Despite the results of these large cohort studies, the decision to anticoagulate a patient in clinical practice should be individualized. At times it may be appropriate not to anticoagulate a patient with a CHA_2DS_2-VASc score 1 or greater. For example, the annual risk of stroke in a patient with a CHA_2DS_2-VASc score of 2 is approximately 2%, which usually justifies the use of warfarin. However, if that patient has a HAS-BLED score of 5 or more, which is associated with an annual risk of major bleeding of 12% or greater, it would be imprudent to treat that patient with warfarin.

The HAS-BLED score was developed and validated in patients anticoagulated with warfarin. Except for labile INR, the components of the HAS-BLED score likely also apply to patients who are anticoagulated with one of the novel (new) oral anticoagulants (NOACs), either a direct thrombin inhibitor or factor Xa inhibitor. However, clinical trials have indicated that the risk of major bleeding is lower with NOACs than with warfarin (see later). Accordingly, the benefit of anticoagulation with warfarin is estimated to be greater than the risk of bleeding when the annual stroke risk is at least 1.7%, compared to an annual stroke risk of at least 0.9% in patients treated with a NOAC.[19]

Aspirin and Other Antithrombotic Agents

Aspirin does not prevent thromboembolic complications as effectively as warfarin or NOACs in patients with AF. In a meta-analysis of five randomized clinical trials, aspirin did not significantly reduce the risk of stroke compared to placebo in patients with AF.[9] In a large cohort study of patients with non-valvular AF, aspirin had no therapeutic efficacy for preventing strokes.[17] Therefore, if aspirin is used for prophylactic therapy, this should be only in patients at lowest risk of thromboembolic complications (CHA_2DS_2-VASc score of 0). However, the 2014 American College of Cardiology (ACC), American Heart Association (AHA), and /Heart Rhythm Society (HRS) guidelines for management of patients with AF recommend that for patients with nonvalvular AF and a CHA_2DS_2-VASc score of 0, it is reasonable to omit all antithrombotic therapy, including aspirin. When the CHA_2DS_2-VASc score is 1, the guidelines recommend that either no antithrombotic therapy or treatment with an oral anticoagulant or aspirin may be considered.[2] Because of the negligible therapeutic effect of aspirin, a risk of bleeding complications that is close to the risk of oral anticoagulants, and the ability of the CHA_2DS_2-VASc score to accurately identify low-risk patients, the most recent guidelines of the European Society of Cardiology (ESC) recommend no antithrombotic therapy when the CHA_2DS_2-VASc score is 0 and an individualized decision between no antithrombotic therapy versus an oral anticoagulant when the CHA_2DS_2-VASc score is 1.[20]

If aspirin is used for stroke prevention in patients with AF, the appropriate daily dose is 81 to 325 mg/day. No data indicate superiority of a particular dose for prevention of thromboembolism.

In patients with a $CHADS_2$ score greater than 1 who are not able to tolerate anticoagulation with warfarin or a NOAC, combination therapy with aspirin and the platelet inhibitor clopidogrel is more efficacious than aspirin alone for prevention of thromboembolic complications.[21] The potential benefit of combination therapy with aspirin plus clopidogrel may outweigh the increased risk of bleeding complications in high-risk patients who are not suitable candidates for warfarin or a NOAC.

Warfarin and Direct Thrombin Inhibitors

A meta-analysis of the major randomized clinical trials that compared warfarin with placebo for prevention of thromboembolism in patients with AF demonstrated that warfarin reduced the risk of all strokes (ischemic and hemorrhagic) by approximately 60%.[9] The target INR should be 2.0 to 3.0. This range of INRs provides the best balance between stroke prevention and hemorrhagic complications. In clinical practice, maintenance of the INR in therapeutic range has been challenging, and a large proportion of patients often have an INR of less than 2.0. A large prospective study of community-based practices demonstrated that the mean time in therapeutic range in patients treated with warfarin was only 66% and that the time in therapeutic range was less than 60% in 34% of patients.[22] Maintaining the INR at a level of 2.0 or higher is important because even a relatively small decrease in INR from 2.0 to 1.7 more than doubles the risk of stroke.

The annual risk of a major hemorrhagic complication during anticoagulation with warfarin is in the range of 1% to 2%, and a strong predictor of major bleeding events is an INR greater than 3.0. For example, the risk of intracranial bleeding is approximately twice as high at an INR of 4.0 than 3.0. This emphasizes the importance of maintaining the INR in the range of 2.0 to 3.0.

Some studies have indicated that advanced age can be a risk factor for intracranial hemorrhage in patients with AF treated with warfarin. The concern of hemorrhagic complications may lead some clinicians to favor the use of aspirin over warfarin or one of the NOACs in elderly patients. However, the available data indicate that the risk-to-benefit ratio of warfarin and the NOACs is more favorable than that of aspirin even in patients older than 75.[23]

It is well established that genetic factors influence the dose of warfarin required to maintain the INR within therapeutic range. Several single-nucleotide polymorphisms that affect warfarin metabolism have been identified. Algorithms based on pharmacogenetic and clinical factors improve the accuracy of warfarin dose initiation compared with algorithms based only on clinical factors.[24] Additional studies are required to determine whether the clinical benefits of genotyping of warfarin candidates justify the cost of genetic testing (**see Chapter 8**).

Novel Oral Anticoagulants

Direct thrombin inhibitors and factor Xa inhibitors have several advantages over vitamin K antagonists such as warfarin, the most notable being a fixed dosing regimen that eliminates the need for monitoring of a laboratory test such as the INR. Dabigatran, an oral direct thrombin inhibitor, and rivaroxaban and apixaban, factor Xa inhibitors, are approved by the U.S. Food and Drug Administration (FDA) for prevention of stroke/embolism in patients with nonvalvular AF. Randomized clinical trials demonstrated that each of these three NOACs is noninferior or superior to warfarin in efficacy and safety in patients with nonvalvular AF who had risk factors for stroke.[25] One of the most serious risks of anticoagulation is intracranial hemorrhage. Recent studies have indicated that the risk of intracranial hemorrhage is about 50% lower with NOACs compared to warfarin.[26]

The NOACs, in addition to eliminating the need for laboratory monitoring, have other advantages over warfarin: fewer drug interactions, no food interactions, and rapid onset of action that obviates the need for bridging therapy. However, they also have some disadvantages compared to warfarin: higher cost, more gastrointestinal side effects in the case of dabigatran, twice-daily dosing for dabigatran and apixaban, and the absence of a readily available laboratory test to verify compliance. Furthermore, these agents cannot be used safely in patients with severe renal disease. Another limitation is that there are no

specific reversal agents for all the NOACs. The FDA recently approved idarucizumab, an antibody fragment that reverses the anticoagulant effects of dabigatran within minutes.[27] Prothrombin complex concentrate can reverse the anticoagulant effect of the NOACs,[28] but specific and rapid-acting antidotes for rivaroxaban and apixaban are not yet available. Nonetheless, for many patients with AF, the advantages of the newer anticoagulants outweigh the disadvantages.

Older studies showed underutilization of warfarin in patients with AF and risk factors for stroke. The inconvenience and potential risks of warfarin likely contributed to its underutilization. However, underutilization of an oral anticoagulant in patients with AF continues to be the case even with the advent of NOACs and even in patients with a CHA_2DS_2-VASc score 3 or higher.[29]

The major professional societies have incorporated recommendations regarding the use of the factor Xa and direct thrombin inhibitors into their most recent updated guidelines for the management of AF. The ACC/AHA/HRS practice guidelines recommend dabigatran, rivaroxaban, and apixaban as useful alternatives to warfarin for prevention of stroke or systemic embolism in patients with nonvalvular paroxysmal or persistent AF and risk factors for stroke.[2] This recommendation is limited to patients without a prosthetic valve, with creatinine clearance higher than 15 mL/min, and without impaired clotting function from advanced liver disease. The ESC guidelines recommend dabigatran, rivaroxaban, or apixaban for patients with AF in whom maintenance of a therapeutic INR during treatment with warfarin is difficult and state that one of these NOACs should be considered instead of dose-adjusted warfarin for most patients with nonvalvular AF, based on their net clinical benefits.[13] These guidelines recommend that the NOACs not be used in patients with a creatinine clearance of less than 30 mL/min.

The results of a prospective randomized clinical trial and post hoc analysis of three other randomized clinical trials indicate that the NOACs are as effective as warfarin for prevention of thromboembolic complications associated with cardioversion.[30] This is the case regardless of whether a transesophageal echocardiogram is performed before cardioversion to look for left atrial thrombus.

The onset of action of dabigatran, rivaroxaban, and apixaban is approximately 1.5 to 2 hours after a dose. The half-life of dabigatran and apixaban ranges between 10 and 16 hours, and that of rivaroxaban is 5 to 9 hours. These anticoagulants lose most of their effect by 24 hours after discontinuation. The rapid onset of action and washout eliminates the need for bridging therapy with heparin when treatment with one of the NOACs is interrupted for a surgical or invasive procedure. Recent data indicate that the risk of major periprocedural complications does not differ significantly between patients who undergo radiofrequency catheter ablation of AF during uninterrupted therapy with warfarin and patients anticoagulated with a NOAC when the last dose of the NOAC is 1 to 2 days before the procedure and dosing is restarted 6 hours after the procedure, without bridging therapy.[31]

Low-Molecular-Weight Heparin

Low-molecular-weight heparin (LMWH) has a longer half-life than unfractionated heparin and a predictable antithrombotic effect that is attained with a fixed dosage administered subcutaneously twice daily. Because LMWH can be self-injected outside the hospital, it is a practical alternative to unfractionated heparin for initiation of anticoagulation with warfarin in patients with AF. Bridging therapy with LMWH be continued until the INR is 2.0 or higher.

Because of its high cost, LMWH rarely is used in clinical practice as a substitute for long-term conventional anticoagulation. LMWH typically is used as a temporary bridge to therapeutic anticoagulation when therapy with warfarin is initiated or in high-risk patients for a few days before and after a medical or dental procedure when anticoagulation with warfarin has been suspended.

Excision or Closure of the Left Atrial Appendage

Approximately 90% of left atrial thrombi form in the left atrial appendage (LAA), and therefore successful excision or closure of the LAA should greatly reduce the risk of thromboembolic complications in patients with AF. Surgical techniques consist of either excision or closure by suturing or stapling. The efficacy of these techniques is variable and probably dependent on both the technique and the operator.[32] Transesophageal echocardiography (TEE) should be performed after surgical closure of the LAA to confirm successful closure before discontinuation of anticoagulation.

In recent years, several percutaneous LAA occlusion and suturing devices have been developed as alternatives to surgical closure techniques. These devices have their greatest utility in high-risk AF patients who cannot tolerate or who refuse to take an oral anticoagulant.

The only percutaneous occlusion device approved by the FDA specifically for stroke prevention as an alternative to warfarin is the WATCHMAN (Boston Scientific, Marlborough, Massachusetts). This nitinol plug covered with fenestrated fabric became widely available for clinical use after FDA approval in 2015. After implantation of the WATCHMAN using femoral vein access and transseptal catheterization, anticoagulation with warfarin is necessary for at least 45 days, at which time anticoagulation can be discontinued if there is no TEE evidence of peridevice flow. The most recent clinical trial and registry data indicated an implantation success rate of 95% and a procedural complication rate of approximately 2% to 3%, the most common complication being pericardial effusion requiring drainage.[32] Approximately 95% of patients are able to discontinue warfarin at 45 days after implant. Clinical trial data have demonstrated noninferiority of the WATCHMAN compared to warfarin for stroke prevention and a significantly lower risk of hemorrhagic stroke during long-term follow-up.[32]

Another device used in the United States for LAA occlusion is the LARIAT (Sentreheart, Redwood City, California). This device has FDA approval as a method for soft tissue approximation (not stroke prevention) and has been used “off label” in clinical practice in the United States and Europe for LAA occlusion. A guidewire with a magnetic tip is inserted into the left atrium after transseptal catheterization and is positioned at the tip of the LAA and functions as a rail for an epicardial snare. Entry into the pericardial space is attained using a percutaneous approach. A snare with a pretied suture is inserted into the pericardial space and guided toward the LAA. The pretied suture then is tightened to occlude the LAA. In a large multicenter registry, complete LAA closure was achieved in 94% of 712 patients.[33] There was one procedure-related death, and cardiac perforation occurred in 3.4% of patients, with open heart surgery required to repair the perforation in 1.4% of patients.[33] Clinical trial data demonstrating efficacy of the LARIAT for stroke prevention are lacking.

Acute Management of Atrial Fibrillation

Patients who present to the emergency department because of AF often have a rapid ventricular rate, and control of the ventricular rate is most rapidly achieved with intravenous diltiazem or esmolol. If the patient is hemodynamically unstable, immediate transthoracic cardioversion may be appropriate. Cardioversion should be preceded by TEE to rule out a left atrial thrombus if the AF has been present for longer than 48 hours or if the duration is unclear and the patient is not already anticoagulated.

If the patient is hemodynamically stable, the decision to restore sinus rhythm by cardioversion is based on several factors, including symptoms, prior AF episodes, age, left atrial size, and current AAD therapy. For example, in an elderly patient whose symptoms resolve once the ventricular rate is controlled and who already has had early recurrences of AF despite rhythm-control drug therapy, further attempts at

cardioversion usually are not appropriate. On the other hand, cardioversion usually is appropriate for patients with symptomatic AF who present with a first episode of AF or who have had long intervals of sinus rhythm between prior episodes.

If cardioversion is decided for a hemodynamically stable patient who presents with AF that does not appear to be self-limited, two management decisions must be made: early versus delayed cardioversion and pharmacologic versus electrical cardioversion.

The advantages of early cardioversion are rapid relief of symptoms, avoidance of the need for TEE or therapeutic anticoagulation for 3 to 4 weeks before cardioversion if cardioversion is performed within 48 hours of AF onset, and possibly a lower risk of early AF recurrence because of less atrial remodeling (**see Chapter 36**). A reason to defer cardioversion is the unavailability of TEE in an unanticoagulated patient with AF of unclear duration or duration more than 48 hours. Other reasons include a left atrial thrombus by TEE (**see Chapter 14**), a suspicion (based on prior AF episodes) that AF will convert spontaneously within a few days, or a correctable cause of AF (e.g., hyperthyroidism).

When cardioversion is performed early in the course of an episode of AF, there is the option of either pharmacologic or electrical cardioversion. Pharmacologic cardioversion has the advantage of not requiring general anesthesia or deep sedation. In addition, the probability of an immediate recurrence of AF is lower with pharmacologic cardioversion than with electrical cardioversion. However, pharmacologic cardioversion is associated with the risk of adverse drug effects and is not as effective as electrical cardioversion. Pharmacologic cardioversion is unlikely to be effective if the duration of AF is longer than 7 days.

Drugs that can be administered intravenously for cardioversion of AF consist of ibutilide, procainamide, and amiodarone. For AF episodes less than 2 to 3 days in duration, efficacy is approximately 60% to 70% for ibutilide, 40% to 50% for amiodarone, and 30% to 40% for procainamide. To minimize the risk of QT prolongation and polymorphic ventricular tachycardia (torsades de pointes; **see Chapter 39**), the use of ibutilide should be limited to patients with an ejection fraction greater than 35%.

Acute pharmacologic cardioversion of AF also can be attempted with oral drugs in patients without structural heart disease. The most common oral agents for acute conversion of AF are propafenone (300 to 600 mg) and flecainide (100 to 200 mg). It is prudent to administer these drugs under surveillance at first use. If no adverse drug effects are observed, the patient may then be an appropriate candidate for episodic, self-administered AAD therapy on an outpatient basis.

The efficacy of transthoracic cardioversion is approximately 95%. Biphasic waveform shocks convert AF more effectively than monophasic waveform shocks and allow the use of lower energy shocks, resulting in less skin irritation. An appropriate first-shock strength using a biphasic waveform is 150 to 200 J, followed by higher output shocks if needed. If a 360-J biphasic shock is unsuccessful, ibutilide should be infused before another shock is delivered because it lowers the defibrillation energy requirement and improves the success rate of transthoracic cardioversion.

Transthoracic cardioversion can fail to restore sinus rhythm. An increase in shock strength or infusion of ibutilide often results in successful repeat cardioversion. The second type of failure is an immediate recurrence of AF within a few seconds of successful conversion to sinus rhythm. This occurs in approximately 25% for episodes less than 24 hours in duration and 10% for episodes more than 24 hours in duration. For this type of cardioversion failure, an increase in shock strength is of no value. If the patient has not been receiving an oral rhythm-control agent, infusion of ibutilide may be helpful to prevent an immediate recurrence of AF.

Regardless of whether cardioversion is performed pharmacologically or electrically, therapeutic

anticoagulation is necessary for 3 weeks or more before cardioversion to prevent thromboembolic complications if the AF has been ongoing for more than 48 hours. If the time of onset of AF is unclear, for the sake of safety, the AF duration should be assumed to be more than 48 hours. These patients should be therapeutically anticoagulated for 4 weeks after cardioversion to prevent thromboembolic complications that may occur because of atrial stunning. If the duration of AF is known to be less than 48 hours, cardioversion can be performed without anticoagulation. To improve the safety margin, it may be appropriate to use a 24-hour cutoff for the AF duration that allows safe cardioversion without anticoagulation. Postcardioversion atrial stunning and thromboembolic events are possible in patients with comorbidities even when the AF duration is less than 48 hours, and anticoagulation for 4 weeks is appropriate when the CHA_2DS_2-VASc score is more than 2.[34]

When AF duration exceeds 48 hours or is unclear, an alternative to 3 weeks of therapeutic anticoagulation before cardioversion is anticoagulation with heparin and TEE to check for a left atrial thrombus. If no thrombi are seen, the patient can be cardioverted safely but still requires 4 weeks of therapeutic anticoagulation after cardioversion to prevent thromboembolism related to atrial stunning. The major clinical benefit of the TEE-guided approach over the conventional approach is that sinus rhythm is restored several weeks sooner. Compared with the conventional approach, the TEE approach has not been found to reduce the risk of stroke or major bleeding or to affect the proportion of patients still in sinus rhythm at 8 weeks after cardioversion.

Long-Term Management of Atrial Fibrillation

Pharmacologic Rate Control Versus Rhythm Control

Several randomized studies have compared a rate-control strategy with a rhythm-control strategy in patients with AF. Overall, these studies have demonstrated a significantly lower rate of rehospitalization with a rate-control strategy, but no significant differences in other major outcomes, such as all-cause mortality, strokes, bleeding events, worsening heart failure, or quality of life.[35]

The results of these randomized studies should not be applied systematically to all patients with AF. It is important to note that many patients in the rhythm-control arms of these studies continued to have AF, and that the possible beneficial effects of sinus rhythm over AF could have been negated by adverse effects of the AADs. Furthermore, many of the patients included in these studies were elderly and had minimal or no symptoms from the AF.

The decision to pursue a rhythm-control strategy versus a rate-control strategy should be individualized with consideration of several factors. These include the nature, frequency, and severity of symptoms; the length of time that AF has been present continuously in patients with persistent AF; left atrial size; comorbidities; the response to prior cardioversions; age; the side effects and efficacy of the AADs already used to treat the patient; and the patient's preference.

The randomized studies convincingly demonstrated that a rate-control strategy is preferable to a rhythm-control strategy in asymptomatic or minimally symptomatic patients age 65 or older. When the AF is persistent, it is reasonable to restore sinus rhythm with AAD therapy or transthoracic cardioversion at least once in patients younger than 65 and in patients 65 or older who are symptomatic from the AF despite adequate heart rate control. If the AF has been continuous for more than 1 year or if the left atrial diameter is very large (>5.0 cm), there is a high probability of an early recurrence of AF, and this should be taken into account in deciding on the best strategy. After cardioversion, the decision to maintain the patient on AAD therapy to delay the next episode of AF is based on the patient's preference, the perceived

risk of an early recurrence of AF, and the duration of sinus rhythm between prior cardioversions. Treatment by cardioversion without daily AAD therapy is acceptable if episodes of AF are separated by at least 6 months. Treatment with a rhythm-control drug usually is appropriate when AF recurs within a few months of cardioversion.

The most realistic goal of AAD therapy in patients with persistent AF is to delay the onset of the next episode by at least several months, not for several years. It often is appropriate to continue therapy with a particular AAD at a constant dosage if recurrences of AF are limited to approximately one episode per year.

In patients with symptomatic paroxysmal AF, the aggressiveness with which a rhythm-control strategy is pursued should be dictated by the frequency and severity of symptoms and how well AAD therapy is tolerated. Drug therapy is more likely to be judged successful when patients are reminded that the goal of therapy is not complete suppression of AF but a clinically meaningful reduction in frequency, duration, and severity of episodes.

A pharmacologic rhythm-control strategy does not necessarily require daily AAD therapy. Episodic drug therapy (the “pill-in-the-pocket” approach) is useful for patients whose episodes of AF are relatively infrequent. Episodic drug therapy is a reasonable option for patients who are clearly aware of the onset and termination of AF episodes and who have lone AF or only minimal structural heart disease. A typical AAD regimen consists of a class IC drug (flecainide or propafenone) plus a short-acting beta blocker (e.g., propranolol) or calcium channel blocker (e.g., verapamil) for rate control. Many patients with infrequent episodes prefer this approach because it eliminates the inconvenience, cost, and possible side effects of daily prophylactic therapy. However, patients who are disabled by severe symptoms during AF may prefer daily prophylactic therapy even if episodes are infrequent.

Many patients with symptomatic AF also have asymptomatic episodes. Therefore, daily antithrombotic therapy to prevent thromboembolic events is appropriate for all patients being treated for recurrent AF, whether it is persistent or paroxysmal and whether a rhythm-control or rate-control strategy is employed. The choice of no therapy, an oral anticoagulant, aspirin, or aspirin plus clopidogrel should be dictated by an analysis of risk factors.

Pharmacologic Rate Control

An excessively rapid ventricular rate during AF often results in uncomfortable symptoms and decreased effort tolerance and can cause a tachycardia-induced cardiomyopathy if it is sustained for several weeks to months. Optimal heart rates during AF vary with age and should be similar to the heart rates that a patient would have at a particular degree of exertion during sinus rhythm. Heart rate control must be assessed both at rest and during exertion. At rest, the ideal ventricular rate during AF is in the range of 60 to 80 beats/min. During mild to moderate exertion (e.g., rapid walking), the target rate should be 90 to 115 beats/min. During strenuous exercise, the ideal rate is in the range of 120 to 160 beats/min. Optimal assessment of the degree of heart rate control is provided by an ambulatory 24-hour Holter recording or an exercise test.

Oral agents available for long-term heart rate control in patients with AF are digitalis, beta blockers, calcium channel antagonists, and amiodarone. The first-line agents for rate control are beta blockers and the calcium channel antagonists verapamil and diltiazem. A combination is often used to improve efficacy or to limit side effects by allowing the use of smaller dosages of the individual drugs. In patients with sinus node dysfunction and tachycardia-bradycardia syndrome, the use of a beta blocker with intrinsic sympathomimetic activity (pindolol, acebutolol) may provide rate control without aggravating sinus

bradycardia.

Digitalis may adequately control the rate at rest but often does not provide adequate rate control during exertion. However, its use for rate control of AF is controversial because digitalis has been shown to increase the risk of all-cause mortality, particularly among patients with AF.[36]

Amiodarone is much less frequently used for rate control than the other negative dromotropic agents because of the risk of organ toxicity associated with long-term therapy. Amiodarone can be an appropriate choice for rate control if the other agents are not tolerated or are ineffective. For example, amiodarone would be an appropriate choice for a patient with persistent AF, heart failure, and reactive airway disease who cannot tolerate either a calcium channel antagonist or a beta blocker and who has a rapid ventricular rate despite treatment with digitalis.

Strict heart rate control can be difficult to achieve pharmacologically. Based on the results of a single randomized study that demonstrated no significant differences in major outcomes between a lenient rate-control strategy (resting rate <110 beats/min) and a strict rate-control strategy (resting heart rate <80 beats/min, rate during moderate exercise <110 beats/min), a lenient rate-control strategy is reasonable if the patient remains asymptomatic and left ventricular systolic function is not compromised.[2] However, strict rate control often still is an appropriate goal for relief of symptoms, improvement in functional capacity, and avoidance of tachycardia-induced cardiomyopathy during long-term follow-up.

Pharmacologic Rhythm Control

The results of published studies on the efficacy of AADs for AF suggest that all the available drugs except amiodarone have similar efficacy and are associated with a 50% to 60% reduction in the odds of recurrent AF during 1 year of treatment. The one drug that stands out as having higher efficacy than the others is amiodarone. In studies that directly compared amiodarone with sotalol or class I drugs, amiodarone was 60% to 70% more effective in suppressing AF. However, because of the risk of organ toxicity, amiodarone is not appropriate first-line drug therapy for many patients with AF. Because the efficacy of rhythm-control agents other than amiodarone is in the same general range, the selection of an AAD to prevent AF often is dictated by the issues of safety and side effects.

Ventricular proarrhythmia from class IA agents (quinidine, procainamide, disopyramide) and class III agents (sotalol, dofetilide, dronedarone, amiodarone) is manifested as QT prolongation and polymorphic ventricular tachycardia (torsades de pointes). Risk factors for this type of proarrhythmia include female gender, left ventricular dysfunction, and hypokalemia. The risk of torsades de pointes appears to be much lower with dronedarone and amiodarone than with the other class III drugs. The ventricular proarrhythmia from class IC agents (flecainide and propafenone) manifests as monomorphic ventricular tachycardia, sometimes associated with widening of the QRS complex during sinus rhythm but not QT prolongation. Drugs most likely to result in ventricular proarrhythmia are quinidine, flecainide, sotalol, and dofetilide. In controlled studies, these agents increased the risk of ventricular tachycardia by a factor of 2 to 6.

Adverse drug events or side effects resulting in discontinuation of drug therapy are fairly common with rhythm-control drugs, with discontinuation rates reported to be as high as 40%.[37]

The best options for drug therapy to suppress AF depend on the patient's comorbidities. In patients with lone AF or minimal heart disease (e.g., mild left ventricular hypertrophy), flecainide, propafenone, sotalol, and dronedarone are reasonable first-line drugs, and amiodarone and dofetilide can be considered if the first-line agents are ineffective or not tolerated. In patients with substantial left ventricular hypertrophy (left ventricular wall thickness >15 mm), the hypertrophy heightens the risk of ventricular proarrhythmia, and the safest choices for drug therapy are amiodarone and dronedarone.[2] In

patients with coronary artery disease (CAD), several of the class I drugs have been found to increase the risk of death, and the safest first-line options are dofetilide and sotalol, with amiodarone reserved for use as a second-line agent. In patients with heart failure, several AADs have been associated with increased mortality, and the only two drugs known to have a neutral effect on survival are amiodarone and dofetilide (**see Chapter 36**).

At the time of FDA approval, it was known that dronedarone increases mortality in NYHA Class IV heart failure or patients with a recent episode of decompensated heart failure. After approval, the categories of patients in which dronedarone is contraindicated expanded based on the results of a randomized clinical trial that was discontinued prematurely because of major adverse drug effects.[38] Dronedarone should be avoided in patients age 65 or older with permanent AF and CAD, prior stroke, or symptomatic heart failure and in those age 75 or older with hypertension and diabetes.

Rhythm Control with Agents Other Than Antiarrhythmic Drugs

Experimental studies indicate that angiotensin-converting enzyme (ACE) inhibitors and angiotensin receptor blockers (ARBs) have favorable effects on electrical and structural remodeling (**see Chapter 34**). This explains why some studies have shown that ACE inhibitors and ARBs prevent AF. However, other studies have demonstrated that these agents do not prevent AF. A meta-analysis demonstrated that the strongest beneficial effects have been observed with ARBs and in patients with heart failure.[39] However, the quality of the data in the meta-analysis studies was low, and at present, there is insufficient evidence to support the use of ACE inhibitors and ARBs for the sole purpose of preventing AF.

Some evidence indicates that statins prevent AF, perhaps because of their anti-inflammatory effects. A systematic review of 16 observational studies demonstrated a 12% reduction in the relative risk of new-onset AF and a 15% reduction in recurrent AF in patients treated with statins.[40] However, a meta-analysis of 11 randomized clinical trials concluded that statins do not prevent AF in patients who have not undergone open heart surgery.[40] Therefore, the available data do not support the use of statins for the prevention of AF.

Omega-3 polyunsaturated fatty acids (PUFAs) have anti-inflammatory and antioxidant effects and also can have direct ion channel effects. Epidemiologic studies suggested that fish oil could prevent AF, which lead to several randomized clinical trials that assessed the efficacy of PUFAs for AF prevention. These trials reported conflicting results, but the predominance of the data indicate that the daily intake of PUFAs or fish oil does not prevent recurrent AF after cardioversion or episodes of paroxysmal AF.[41]

Nonpharmacologic Management of Atrial Fibrillation

Pacing to Prevent Atrial Fibrillation

Multiple studies have been performed to determine whether various atrial pacing strategies can prevent or terminate AF. Overall, there has been no convincing evidence that any atrial pacing strategy is effective in preventing or terminating episodes of AF, and therefore atrial pacing is not indicated for prevention of AF in patients without bradycardia. In patients with a bradycardia indication for a pacemaker and paroxysmal AF or recurrent episodes of persistent AF, the available data clearly support the use of atrial-based pacing and programming to minimize the amount of ventricular pacing.[42]

Catheter Ablation of Atrial Fibrillation

Catheter ablation reliably and permanently eliminates several types of arrhythmias, such as atrioventricular nodal reentrant tachycardia (AVNRT) and accessory pathway–mediated tachycardias (**see Chapters 36 and 37**). Success rates greater than 95% are attainable when the arrhythmia substrate is well defined, localized, and temporally stable. In contrast, the arrhythmia substrate of AF is not well understood, usually is widespread, is variable between patients, and may be progressive. Furthermore, several factors that promote AF cannot be addressed simply by catheter ablation, including comorbidities (e.g., hypertension, obesity, obstructive sleep apnea), structural remodeling of the atria, inflammatory factors, and genetic factors (**see Chapter 7**). Therefore, whereas late recurrences of AVNRT or accessory pathway conduction are very rare, AF can recur more than 2 or 3 years after an initially successful ablation procedure.

Selection of Patients

Given the limitations of catheter ablation of AF, it usually is appropriate to treat the patient with at least one rhythm-control drug before catheter ablation is considered. This is particularly true if the AF is persistent because the efficacy of catheter ablation is lower for persistent AF than for paroxysmal AF. The most appropriate candidates for catheter ablation have symptomatic AF affecting quality of life and not adequately responding to drug therapy. The ideal candidate has lone AF or only minimal structural heart disease. The recommendation for catheter ablation should depend on the severity of symptoms, AF burden, prior responses to drug therapy or transthoracic cardioversion, and estimated probability of success. Catheter ablation is least likely to be successful when the left atrium is extremely dilated or if the AF has been persistent for more than 3 or 4 years.

Catheter ablation of AF usually is contraindicated in patients who have a left atrial thrombus or who cannot tolerate anticoagulation for at least 6 to 8 weeks after ablation. Catheter ablation usually is also inappropriate in asymptomatic individuals with a CHA_2DS_2-VASc score greater than 1 whose only motivation to undergo the procedure is to eliminate the need for anticoagulation.

Although usually reserved for patients who have not responded adequately to ADD treatment, catheter ablation of AF can also be appropriate first-line therapy in patients younger than 35 with symptomatic AF, patients with sinus node dysfunction in whom ADD therapy is likely to create the need for a permanent pacemaker, and patients who express a strong preference for catheter ablation over drug therapy.

Radiofrequency Catheter Ablation

A commonly used energy for catheter ablation of AF is radiofrequency (RF) energy. RF energy is delivered point by point, typically in association with a three-dimensional electroanatomic mapping system as a navigation guide and to create a visual record of the sites that already have been ablated (**Fig. 38.7**). To improve anatomic accuracy, the electroanatomic map of the left atrium can be merged with a computed tomography scan or magnetic resonance image of the left atrium and pulmonary veins (PVs) or with an ultrasound image generated by intracardiac echocardiography. An important determinant of lesion depth and durability is *contact force,* and the newest generation of RF ablation catheters provides the operator with immediate feedback on contact force.

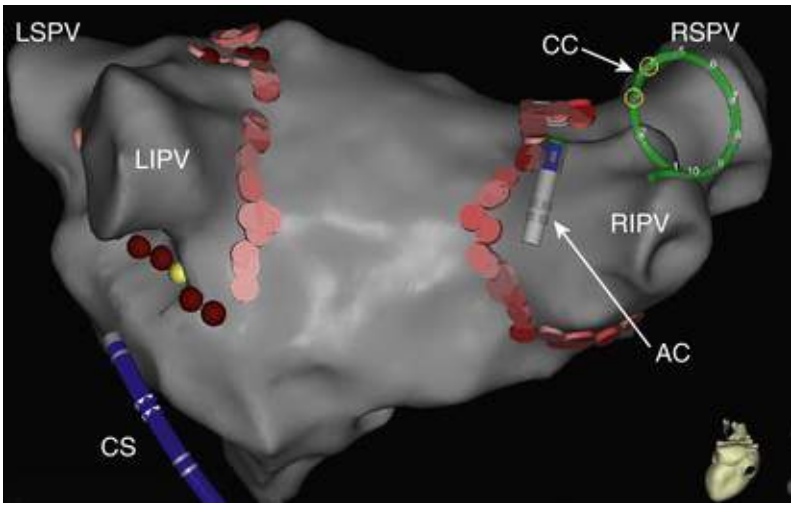

FIGURE 38.7 An electroanatomic map of the left atrium. Icons representing the distal portion of the ablation catheter (*AC*), circular catheter (*CC*) in the right superior pulmonary vein (*RSPV*), and a catheter positioned within the coronary sinus (*CS*) are visualized in real time. Circumferential antral ablation was performed around the left and right pulmonary veins. Each one of the *pink, red,* and *yellow* tags represents a site at which radiofrequency energy was delivered. *LIPV,* Left inferior pulmonary vein; *LSPV,* left superior pulmonary vein; *RIPV,* right inferior pulmonary vein.

Because of their important role in triggering and maintaining episodes of AF, almost all ablation strategies include electrical isolation of the PVs (**Fig. 38.8**). This is often sufficient for patients with paroxysmal AF and sometimes sufficient for patients with persistent AF. Pulmonary vein (PV) isolation can be accomplished by either ostial ablation or wide-area ablation 1 to 2 cm away from the ostia, in the antral regions of the PVs. Most of the available data indicate that wide-area ablation is more effective than ostial ablation, probably because it also targets drivers that are in the antrum, outside the PV itself.[43] Triggers of AF can also arise from other thoracic veins, such as the superior vena cava, coronary sinus, and the vein of Marshall. After the PVs have been isolated, infusion of isoproterenol is helpful to determine whether any non–PV triggers are present.

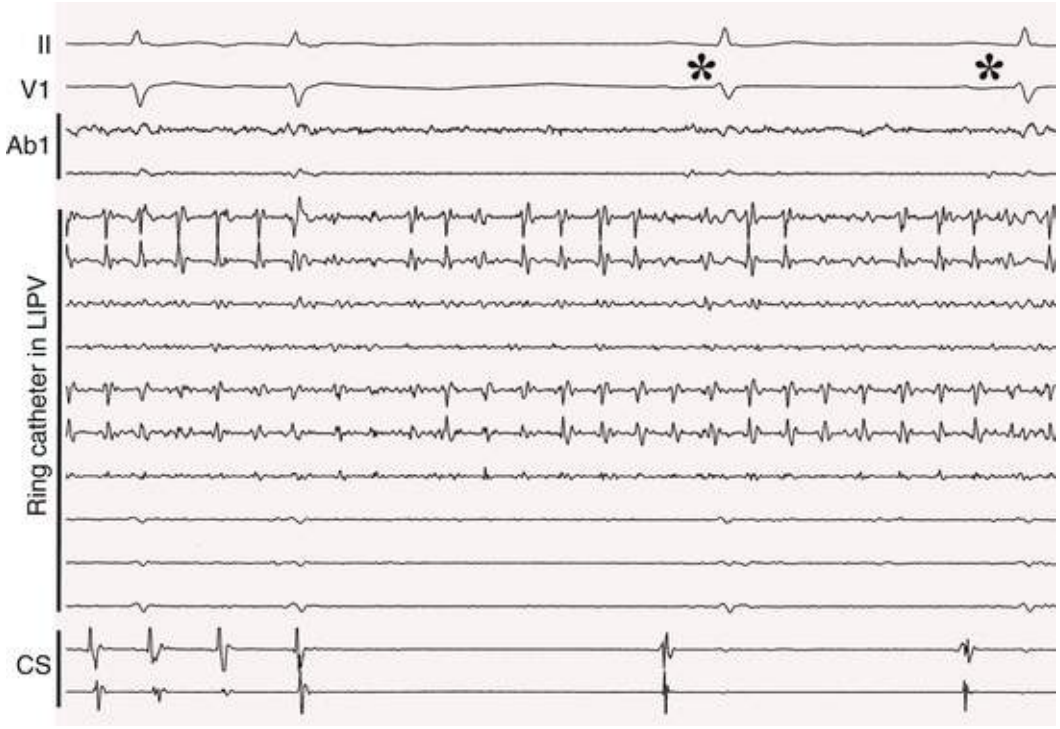

FIGURE 38.8 A tachycardia with a cycle length of 80 milliseconds arising in a left inferior pulmonary vein (*LIPV*) during AF. AF converted to sinus rhythm (*asterisks*) during radiofrequency ablation when the LIPV became electrically isolated. The pulmonary vein tachycardia was still present inside the vein. Conversion to sinus rhythm on electrical isolation of the LIPV is strong evidence that the tachycardia arising in the muscle sleeve of this pulmonary vein was the driver of AF in this patient. Shown are leads II and V_1, the electrograms recorded by the ablation catheter (*Abl*), by a ring catheter in the LIPV, and in the coronary sinus (*CS*).

A variety of ablation strategies have been used for persistent AF after the PVs have been isolated: linear ablation across the left atrial roof, mitral isthmus, or cavotricuspid isthmus; ablation of complex fractionated atrial electrograms (CFAEs) in the left atrium, coronary sinus, or right atrium; various combinations of linear and CFAE ablation; and ablation of ganglionated plexi.[43] The endpoint of catheter ablation of persistent AF is either completion of a prespecified lesion set (in which case sinus rhythm is restored by cardioversion) or stepwise ablation until the AF converts to sinus rhythm. Recent randomized studies have demonstrated that antral PV isolation is as effective as PV isolation plus linear ablation and/or ablation of CFAEs.[44,45]

A novel approach to ablation of AF is based on the hypothesis that AF is sustained by localized sources, either rotors or focal impulses.[5] Signal processing using proprietary software allows identification of focal impulses and rotors that are targeted for RF ablation during ongoing episodes of AF. In one of the first clinical studies using this approach, AF termination or slowing was successfully achieved by ablation of the localized sources in 86% of cases. At a median of 9 months of follow-up, 82% of patients were free of AF, compared to 45% of patients in a control group who underwent conventional ablation.[5] These early results suggested that focal impulse and rotor modulation can improve outcomes of catheter ablation of AF. However, more recent studies in patients with paroxysmal, persistent, and longstanding persistent AF have not confirmed the initial results of ablation of rotors and/or focal impulses. The single-procedure freedom from AF/atrial tachycardia (AT) off AADs at 6 to 18 months of follow-up was only 17% to 21% in these studies.[46,47] Therefore, although focal impulse and rotor modification is potentially an important step forward in understanding the mechanism of AF, its clinical value in patients undergoing catheter ablation of AF is unsettled.

When the efficacy of catheter ablation of AF is evaluated, recurrences of AF in the first 3 months after ablation usually are ignored. A 3-month blanking period excludes early recurrences that are caused by a

transient inflammatory response or incomplete lesion maturation. Even in patients with symptomatic AF, postablation recurrences can be asymptomatic. Therefore, accurate assessment of efficacy requires monitoring for at least 7 days and preferably for 1 month with a device capable of detecting asymptomatic episodes of AF. Ideally, the monitoring should be performed at 6 and 12 months. Continuous monitoring for recurrent AF is possible in patients who have a pacemaker or ICD and an atrial lead. A miniaturized insertable cardiac monitor with wireless telemetry for remote monitoring (Reveal LINQ, Medtronic, Minneapolis, Minnesota) also allows for intense monitoring for postablation AF.[48]

A wide range of success rates has been reported for RF catheter ablation of AF. When the latest-generation ablation catheters are used by experienced operators, 12-month freedom from AF/AT off AADs after a single procedure generally is 70% to 75% for paroxysmal AF[49,50] and 50% to 60% for persistent AF.[44,45]

Recurrent AF after PV isolation in patients with paroxysmal AF most often is attributable to electrical reconnection of one or more PVs but sometimes is caused by triggers or drivers of AF originating in structures such as the superior vena cava or coronary sinus or in the atria themselves. After reisolation of the PVs and ablation of triggers outside the PVs, 12-month efficacy of 85% to 90% can be expected.

Redo ablation procedures in patients with persistent AF usually consist of re-isolation of the PVs if necessary, and additional ablation directed at substrate modification by targeting CFAEs or creating lines of conduction block at sites such as the left atrial roof or mitral isthmus.[43] A 12-month success rate of 75% to 85% typically is achieved after multiple ablation procedures for persistent AF.

Most recurrences of AF after RF catheter ablation occur within the first year of follow-up. However, recurrences continue to occur at a rate of approximately 10% per year at 1 to 3 years, then approximately 4% to 5%/year at 3 to 12 years after ablation.[51] The predictors of late recurrences of AF include a history of persistent AF before the initial ablation procedure, age, left atrial size, diabetes, valvular heart disease, cardiomyopathy, and sleep apnea.[43] In addition, obesity and lack of cardiovascular conditioning have been reported to predispose to recurrences of postablation AF. Treatment of sleep apnea, weight loss, and improvement in cardiovascular fitness have been found independently to reduce the risk of recurrent AF after an ablation procedure.[52,53]

Atrial tachyarrhythmias that occur after catheter ablation of AF can take the form of atrial tachycardia/flutter that can be either focal or reentrant. When the ablation strategy consists only of PV isolation, postablation focal ATs often are attributable to partial recovery of PV conduction. The incidence of reentrant AT/flutter after ablation is related to the extent of ablation at atrial sites other than around the PVs. When extensive ablation is performed in the left atrium or in both atria, AT/flutter can occur during follow-up in up to 50% or more of patients. These arrhythmias do not respond well to AAD therapy and often require another ablation procedure for elimination.

The risk of a major complication from RF catheter ablation of AF is reported to be 5% to 6%.[54,55] The most common major complications are cardiac tamponade, PV stenosis, and cerebral thromboembolism, each with a prevalence of approximately 1%. The risk of a femoral vascular injury is reported to be 1% to 2%. The risk of a major complication is more than twofold higher when the annual operator volume is less than 25 cases compared to more than 25 cases.[54]

The risk of esophageal perforation is reported in the range of 0.01% to 0.02%.[56] Despite its rarity, this complication is of great concern because it often is lethal. Patients typically present 3 to 14 days after ablation with one of more of the following: dysphagia, odynophagia, fever, leukocytosis, bacteremia, and septic, thrombotic, or air emboli. Computed tomography of the chest with intravenous contrast is the diagnostic test of choice. The presence of contrast in the esophagus or air in the mediastinum or cardiac chambers is indicative of esophageal perforation or fistula formation. Instrumentation of the esophagus

should be avoided.

Monitoring of the position of the esophagus and intraluminal esophageal temperature monitoring have been used to prevent esophageal injury during ablation along the posterior wall. Although these maneuvers may reduce the risk, they clearly do not prevent all cases of esophageal injury, since 90% of patients with an esophageal perforation had undergone monitoring of the esophageal position or temperature.[56] There is evidence that limiting the power of RF energy applications to 20 to 25 watts for less than 30 seconds when ablating along the posterior left atrial wall and the use of periprocedural proton pump inhibitors reduce the risk of esophageal injury.[57]

Based on the results of a recent global survey, 72% of patients with an esophageal perforation had evidence of an atrial-esophageal fistula, and mortality among these patients was 79%. In contrast, among the 28% of patients with an esophageal perforation who did not have an atrial-esophageal fistula, mortality was 13%.[56] This highlights the importance of early diagnosis and treatment of esophageal perforations. Early surgical intervention is appropriate regardless of whether an atrial-esophageal fistula is present.

A recently recognized complication of RF ablation is silent cerebral ischemic lesions. Cerebral magnetic resonance imaging has demonstrated silent cerebral ischemic lesions in 2% to 14% of patients in whom an irrigated-tip RF ablation catheter is used.[58] The long-term clinical significance of these lesions is unclear.

Recent randomized clinical trials have demonstrated that RF catheter ablation of AF is superior to AAD therapy for prevention of AF. In previously untreated patients with paroxysmal AF, there was an absolute difference of 18% in the 12-month risk of recurrent AF in favor of RF catheter ablation over AAD therapy.[59] Among patients with persistent AF, there was an absolute difference of 27% in the 12-month risk of recurrent AF in favor of RF catheter ablation over AAD therapy.[60]

Cryoballoon Ablation

In 2010 a cryoballoon catheter designed to isolate PVs became widely available for use in the United States. In contrast to point-by-point RF ablation around the PVs, the cryoballoon was designed to fit into the antrum of a PV and to create a circumferential ablation lesion using cryoenergy. Cryoenergy is delivered through the entire distal half of the second-generation cryoballoon catheter currently in clinical use. Complete occlusion of the PV by the inflated balloon is necessary for reliable PV isolation (**Fig. 38.9**). Two 4-minute applications of cryoenergy initially were recommended for each of the PVs. With the second-generation cryoballoon catheter, a single 3- or 4-minute application of cryoenergy often is sufficient to create durable PV isolation in a majority of PVs **(Fig. 38.10**). Among patients with paroxysmal AF, with a mean of 1.1 to 1.7 applications of cryoenergy per PV, 1-year freedom from recurrent AF was 80% to 82% using a single-freeze protocol.[61,62]

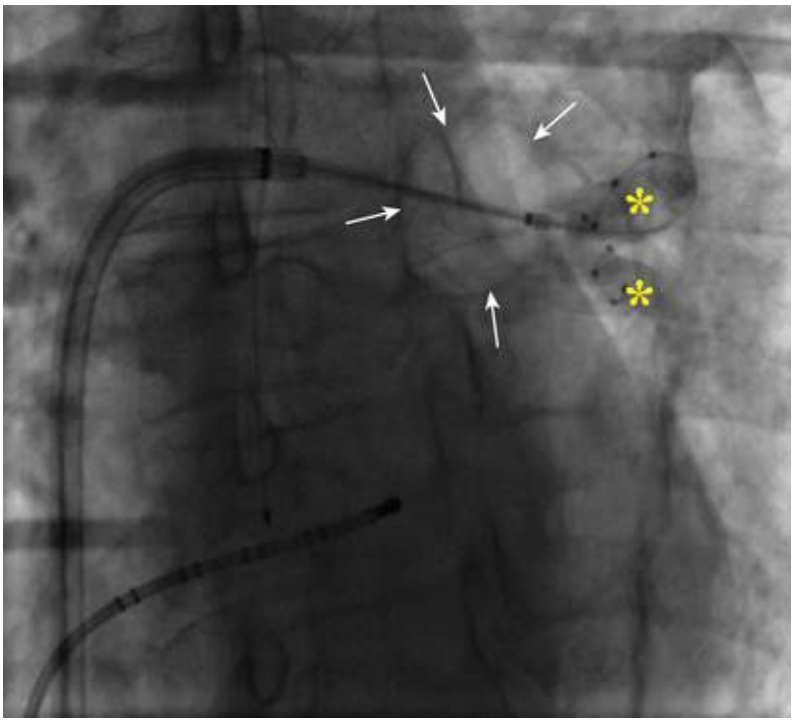

FIGURE 38.9 A left anterior oblique fluoroscopic image of the heart showing a cryoballoon catheter positioned in the antrum of the left inferior pulmonary vein. The 28-mm balloon (*arrows*) is inflated, and there is no leakage of contrast injected through the lumen of the cryoballoon catheter into the vein (*asterisks*). This indicates complete occlusion of the vein, a necessary requirement for durable pulmonary vein isolation. A diagnostic ring catheter is positioned within the vein.

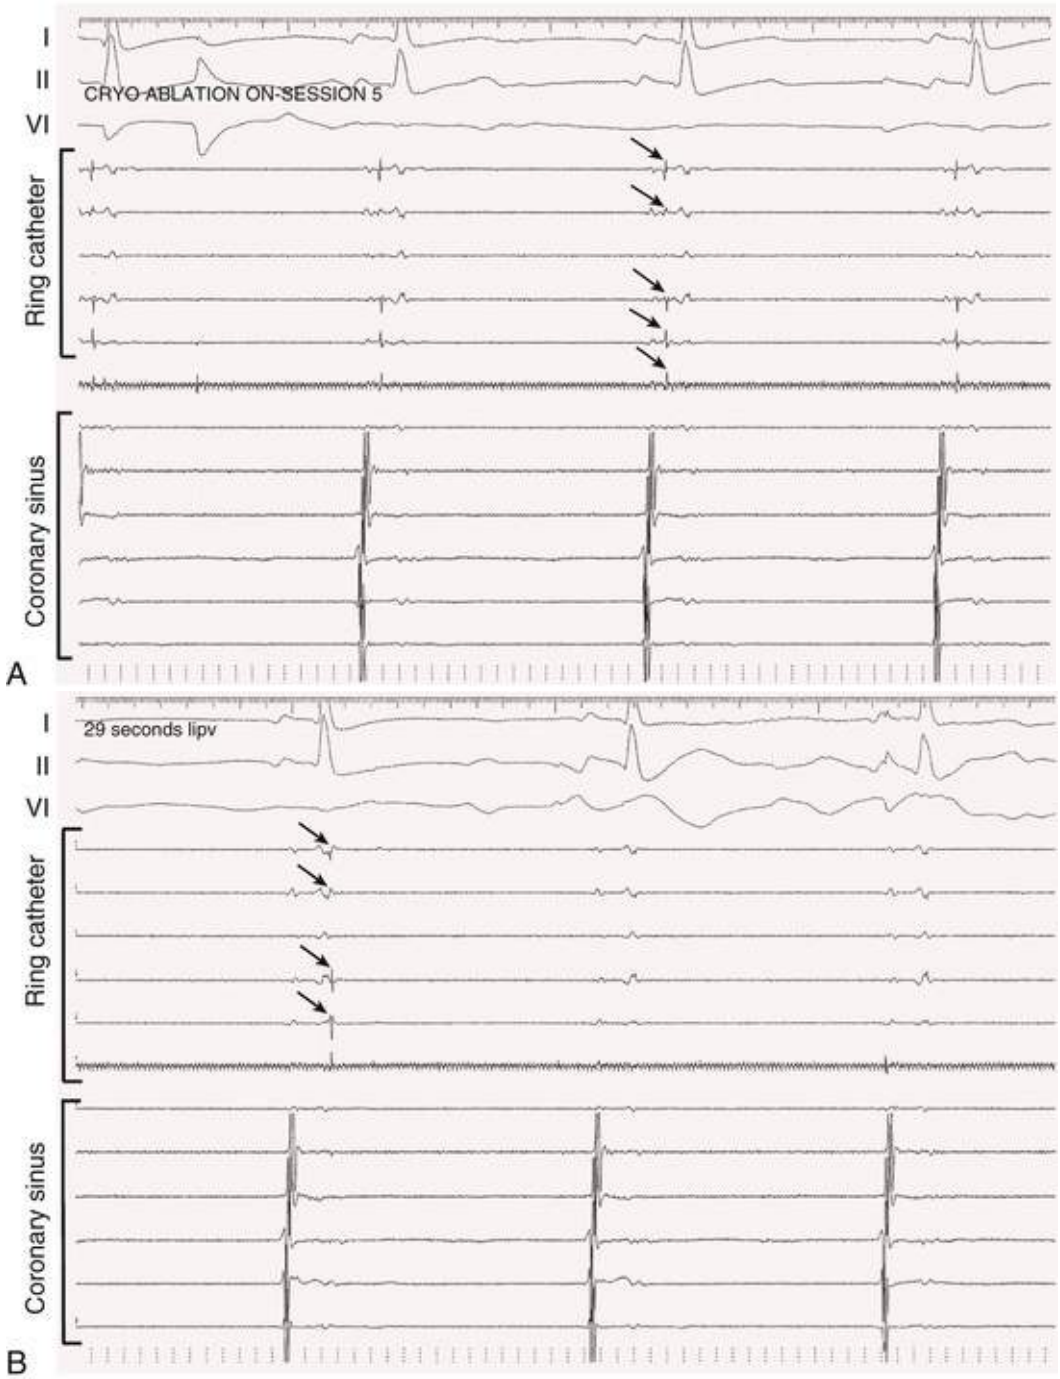

FIGURE 38.10 **A,** Pulmonary vein potentials (*arrows*) recorded from within the left inferior pulmonary vein at the onset of an application of cryoenergy, during sinus rhythm at a rate of 54 beats/min. **B,** At 29 seconds into an application of cryoenergy, there is a conduction delay in the pulmonary vein potentials (*arrows*) followed by their complete disappearance, indicating isolation of the left inferior pulmonary vein (*lipv*). The application of cryoenergy was continued for a total of 4 minutes.

Avoidance of entry of the cryoballoon into the luminal portion of a PV is important to avoid PV stenosis. The most commonly used cryoballoon catheter has a 28-mm diameter when the balloon is fully inflated. The relatively large size of the balloon typically allows occlusion of a PV from the antrum. With use of the 28-mm balloon, up to 40% of the posterior wall between the left and right PVs is rendered electrically silent.[63]

A multielectrode catheter inserted through a central lumen of the cryoballoon catheter often allows recording of PV potentials during an application of cryoenergy. Disappearance or dissociation of PV potentials within the first minute of a cryoenergy application is a strong independent predictor of durable PV isolation[64] (**Fig. 38.10**). Other independent predictors are achieving a balloon temperature of −40°C in less than 60 seconds during an application of cryoenergy and an interval thaw time to 0°C of longer than

10 seconds on completion of a cryoenergy application.[64,65]

There is a lower clinical success rate with use of the cryoballoon catheter in patients with persistent AF than in those with paroxysmal AF. Among patients with persistent AF who undergo PV isolation using the 28-mm cryoballoon catheter, freedom from AF at 12 months of follow-up was 60%.[66] This is similar to the clinical results achieved in similar patients when wide-area circumferential PV isolation is performed by point-by-point RF catheter ablation.[66]

Possible complications associated with the cryoballoon catheter have the same risk as with RF catheter ablation of AF, including cardiac tamponade (approximately 1%) and femoral vascular injury (1% to 2%).

The most common complication of cryoballoon ablation is phrenic nerve injury. During early experience with the cryoballoon catheter, the incidence of right phrenic nerve injury was approximately 10%, with the injury resolving within 12 months in almost all patients.[67] Injury to the left phrenic nerve is possible but rare. It now is standard clinical practice to pace the phrenic nerve with a catheter positioned in the superior vena cava or right subclavian vein during cryoballoon ablation at the right PVs. Various strategies are available to monitor diaphragmatic contraction or phrenic nerve function during phrenic nerve pacing, including direct palpation of diaphragmatic contraction and monitoring the diaphragmatic compound motor action potential.[68] The immediate discontinuation of an application of cryoenergy on the first evidence of phrenic nerve injury greatly reduces the risk of long-lasting or permanent injury. In recent experience with the 28-mm cryoballoon catheter, the risk of right phrenic nerve injury is as low as 1.5% to 2%.[62,69]

A small number of case reports have made it clear that death from an atrial-esophageal fistula is a potential complication of cryoballoon ablation. Measures to minimize the risk of esophageal injury are appropriate, including the periprocedural use of a proton pump inhibitor and monitoring of intraluminal esophageal temperature during cryoablation. It is common practice to discontinue cryoablation if the esophageal temperature drops to 30°C. This provides a large safety margin for avoiding esophageal injury.[70]

Radiofrequency Catheter Ablation Versus Cryoballoon Ablation for Atrial Fibrillation

A small number of randomized studies have compared the efficacy of RF catheter ablation versus cryoballoon ablation to isolate the PVs. These studies have shown no major differences in outcomes. The largest multicenter, randomized clinical trial that compared the safety and efficacy of RF catheter ablation versus cryoballoon ablation was performed in 693 patients with paroxysmal AF who underwent PV isolation using either an irrigated-tip radiofrequency ablation catheter (n = 341) or a cryoballoon catheter (n = 341).[71] Ideally, the most advanced versions of these catheters would have been used in all patients; however in the cryoablation arm, 82% of the cases were performed using the second-generation balloon, but in the RF ablation arm, only 26% of cases were performed using a contact-force-sensing catheter.

Designed to be a noninferiority trial,[71] the primary efficacy endpoint was a combination of recurrence of an atrial tachyarrhythmia longer than 30 seconds, AAD prescription, or a repeat ablation procedure. The primary safety endpoint was a combination of death, stroke, or a treatment-related serious adverse event. A primary efficacy endpoint occurred by 12 months of follow-up in 35.9% of patients in the RF catheter ablation arm and 34.6% of patients in the cryoablation arm. There was also no significant difference in the incidence of primary safety endpoints between the two groups (13.6% in RF catheter ablation arm versus 11.0% in cryoballoon ablation arm). The prevalence of serious adverse events did

not differ significantly between the RF catheter ablation group (9%) and the cryoablation group (7.5%). The mean procedure time was 16 minutes shorter in the cryoballoon ablation arm. This study demonstrated that cryoballoon ablation is not inferior to RF catheter ablation in regard to efficacy or safety.

Given that outcomes are similar with point-by-point RF ablation and cryoballoon ablation, the most important factor in deciding which approach to use is operator preference. The advantages of RF catheter ablation include greater versatility, with the ability to ablate AF triggers or drivers that are outside the pulmonary venous antral regions; greater flexibility in energy delivery (e.g., being able to cut back on power delivery when ablating close to esophagus); a lower risk of phrenic nerve injury; ability to use the same catheter to ablate other arrhythmias (e.g., atrial flutter, AVNRT); and lower cost. The advantages of cryoballoon ablation include a shorter learning process, less demand for technical expertise in catheter manipulation, and a shorter procedure time.

Remote Magnetic Navigation

Two systems currently are available for remote navigation of an RF ablation catheter. One system has large magnets positioned on each side of the patient and small magnets embedded in the tip of the ablation catheter that allow remote navigation by shifting the magnetic field vectors. The other has an ablation catheter navigated remotely by a robotic steerable sheath system. The advantages of these systems are improved catheter stability, marked reduction in radiation exposure to the operator, and avoidance of the technical challenges of manual catheter manipulation. The experience to date with remote magnetic navigation for catheter ablation of AF suggests that safety and efficacy outcomes are similar to the outcomes achieved with manual RF catheter ablation.[72]

Ablation of the Atrioventricular Node

Radiofrequency catheter ablation of the AV node results in complete AV nodal block and substitutes a regular, paced rhythm for an irregular and rapid native rhythm. It is a useful strategy in patients who are symptomatic from AF because of a rapid ventricular rate that cannot be adequately controlled pharmacologically as a result of inefficacy or intolerance to rate-control drugs, and who either are not good candidates for AF ablation or already have undergone unsuccessful attempts at ablation. AV node ablation also can be helpful in patients with heart failure and AF to maximize the benefits of cardiac resynchronization therapy (CRT) if there already is not 100% ventricular pacing.[73]

In patients with AF and an uncontrolled ventricular rate, AV node ablation improves the left ventricular ejection fraction (EF) if there is a tachycardia-induced cardiomyopathy. AV node ablation also has been shown to improve symptoms, quality of life, and functional capacity and to reduce the use of health care resources.[74]

The disadvantages of AV node ablation are that it creates a lifelong need for ventricular pacing and does not restore AV synchrony. Although symptoms and functional capacity typically improve after AV node ablation in patients with AF and an uncontrolled ventricular rate, some patients may not feel as well as during sinus rhythm.

Atrioventricular node ablation is a technically simple procedure with an acute and long-term success rate of 98% or higher and a very low risk of complications. In patients with persistent AF, a ventricular pacemaker is implanted. A dual-chamber pacemaker is appropriate if the AF is paroxysmal. Most patients have a good clinical outcome with right ventricular pacing, but in patients with left ventricular dysfunction, biventricular pacing for CRT is appropriate.[75] In patients with an ischemic or nonischemic

cardiomyopathy and EF of 30% to 35% or lower, an ICD may be appropriate for primary prevention of sudden death. However, a pacemaker without the ICD often is adequate for patients with a borderline EF (30% to 35%) and a rapid ventricular rate because the EF is likely to improve after the ventricular rate has been controlled by AV node ablation.[74] His bundle pacing can be considered in some patients to avoid problems with right ventricular pacing.

Surgical Approaches to Atrial Fibrillation

The most effective surgical procedure for AF is the "cut-and-sew" maze procedure developed by Cox in 1987. This operation involves multiple atrial incisions to isolate the PVs and to create lines of block in the left atrium and right atrium. In addition, the left and right atrial appendages are excised. In a study from a highly experienced surgical center in patients who underwent periodic 24-hour Holter monitoring during follow-up, there was 83% freedom from AF off drugs at a median follow-up of 5.9 years after the most recent version of the cut-and-sew maze procedure (Cox maze III).[76] However, because continuous monitoring for only 24 hours at a time often is insufficient to detect recurrent episodes of AF, the 83% long-term freedom from AF likely was an overestimate.

The cut-and-sew Cox maze procedure has not been widely performed because it requires cardiopulmonary bypass, is technically difficult, and is associated with a mortality rate of 1% to 2%.

A large variety of surgical ablation tools have been developed to simplify the Cox maze III procedure. These tools allow the surgeon to substitute an ablation line for a surgical incision. Some surgeons use a minimally invasive approach in which the ablation tools are inserted through small incisions between the ribs, and thoracoscopic video-assisted epicardial ablation is performed. Several different types of energy have been used for surgical ablation: RF energy, cryoenergy, microwave, laser, and high-intensity focused ultrasound. The tool that most consistently produces transmural ablation lesions is a clamp device developed to isolate the PVs using bipolar RF energy.

Various surgical ablation strategies have been used, including PV isolation, left atrial ablation, and the Cox maze lesion set (Cox maze IV) in which a combination of RF and cryothermal ablation lines replace most of the surgical incisions. In a large series of patients with AF who underwent the Cox maze IV procedure, freedom from AF off AADs at 5 years was 66%, with no difference in efficacy between patients with paroxysmal versus persistent AF or between patients with a stand-alone procedure versus a concomitant procedure.[77]

Surgical therapy for AF is appropriate as a concomitant procedure in patients with symptomatic AF undergoing open heart surgery for CAD or valvular disease. A stand-alone surgical procedure for AF is an option for patients who have not had a successful outcome from catheter ablation, who are not good candidates for catheter ablation, or who prefer a surgical approach over catheter ablation.

Hybrid Approach to Ablation of Atrial Fibrillation

Some AF ablation centers use a hybrid approach that combines surgical and catheter ablation, either on the same day or staged, with the two components separated by days to weeks. The rationale for the hybrid approach is that it capitalizes on the strengths of the two approaches and minimizes their limitations.[78] The surgical component is performed first, allowing exclusion of the left atrial appendage, direct visualization of the antrum of the PVs, access to epicardial structures such as the ligament of Marshall and ganglionated plexi, and avoidance of damage to the esophagus and phrenic nerve. A subsequent catheter ablation procedure consists of additional ablation as needed, for PV isolation, conduction block across epicardial

ablation lines, ablation of complex fractionated electrograms or rotors, and ablation of sites that are not accessible from the epicardium, such as the tricuspid or mitral isthmus.

The 12-month freedom from AF off AADs after the hybrid approach has varied widely, from as low as 37% to as high as approximately 80%.[78] This wide range of success rates likely is attributable to differences in patient selection, operator skill, specific technologies used for ablation, and lesion sets.

In the absence of data from prospective randomized studies, the incremental value of the hybrid approach over surgical or catheter ablation alone has remained unclear.

Specific Clinical Syndromes

Postoperative Atrial Fibrillation

Atrial fibrillation is common after open heart surgery and is reported to occur in 25% to 40% of patients who undergo coronary artery bypass graft (CABG) surgery or valve replacement (**see Chapter 11**). AF is associated with a twofold increase in the risk of postoperative stroke and is the most common reason for prolonged hospitalization. The incidence of AF peaks on the second postoperative day. The pathogenesis of postoperative AF is multifactorial and probably involves adrenergic activation, inflammation, atrial ischemia, electrolyte disturbances, and genetic factors. Several risk factors for AF after open heart surgery have been identified, including age over 70 years, history of prior AF, male gender, left ventricular dysfunction, left atrial enlargement, chronic lung disease, diabetes, and obesity.

The AADs that decrease the risk of postoperative AF are amiodarone and sotalol by 50% to 65%, and beta blockers by approximately 30%.[79] Hypomagnesemia is common after open heart surgery and can heighten the risk of AF. Magnesium administration is reported to decreases the risk of postoperative AF by 20% to 40%.[79]

Right atrial or biatrial pacing using temporary electrodes attached to the right and left atrium is reported to reduce the risk of postoperative AF by approximately 40%.[79]

Colchicine, atorvastatin, and steroids also have been demonstrated in randomized studies to reduce the risk of AF after open heart surgery by approximately 35% to 40%.[79,80] The main mechanism by which these agents prevent AF probably is an anti-inflammatory effect. Omega-3 PUFAs also have an anti-inflammatory effect, but randomized studies on their efficacy for preventing postoperative AF have reported conflicting results.[79]

A novel approach to the prevention of AF after cardiac surgery is injection of botulinum toxin into the four major epicardial fat pads at operation. This causes temporary autonomic blockade and has been shown to reduce the incidence of AF after CABG to less than 10%.[81]

Patients who develop postoperative AF can be managed using a rate- or rhythm-control strategy. In a randomized comparison of rate- and rhythm-control strategies in patients with AF after cardiac surgery, there were no significant differences between the two strategies in the number of days of hospitalization, mortality, or adverse events.[81] The decision on which type of strategy to employ in these patients should be based on the severity of symptoms, hemodynamic effects of the AF, and the patient-specific risk of side effects or adverse reactions to the various rate- and rhythm-control drugs.

AF that occurs after cardiac surgery often resolves within 3 months. In a randomized comparison of rate control versus rhythm control in patients with new-onset AF after cardiac surgery, approximately 95% of patients in both groups were in sinus rhythm at 60 days and had not experienced AF during the prior 30 days.[81] Treatment with an oral anticoagulant should be continued after discharge. Because new-onset AF after cardiac surgery often does not recur after 60 to 90 days, rhythm-control medications can be

discontinued at that time, and if there is no subsequent evidence of symptomatic or asymptomatic AF, as confirmed by monitoring (e.g., 3- to 4-week autotrigger event monitor), anticoagulation can be safely discontinued unless needed for another indication.

New-onset AF occurs postoperatively in less than 5% of patients undergoing major noncardiac surgery. Some of the possible mechanisms of postoperative AF after cardiac surgery (e.g., sympathetic activation, electrolyte abnormalities, hypoxia) most likely also play a role in AF after noncardiac surgery. Beta blockers have been shown to reduce the risk of AF after major noncardiac surgery by approximately 25%.[79]

Wolff-Parkinson-White Syndrome

Patients with the WPW syndrome and an accessory pathway with a short refractory period can experience a very rapid ventricular rate during AF (**see Chapters 36 and 37**). Ventricular rates greater than 250 to 300 beats/min can result in loss of consciousness or precipitate ventricular fibrillation and a cardiac arrest. Patients with WPW syndrome who present in AF with a rapid ventricular rate should undergo transthoracic cardioversion if there is hemodynamic instability. If the patient is hemodynamically stable, intravenous procainamide or ibutilide can be used for pharmacologic cardioversion. Procainamide may be preferable to ibutilide because it blocks accessory pathway conduction and slows the ventricular rate before AF has converted to sinus rhythm. Digitalis and calcium channel antagonists are contraindicated in patients with WPW syndrome and AF. These agents selectively block conduction in the AV node and can result in acceleration of conduction through the accessory pathway.

The preferred therapy for patients with WPW syndrome and AF with a rapid ventricular rate is catheter ablation of the accessory pathway. The efficacy of catheter ablation is 95% or higher for most types of accessory pathways, and the risk of a major complication is very low. AF typically no longer recurs after successful accessory pathway ablation, probably because AF in the WPW syndrome often is induced by tachycardia and a result of atrioventricular reciprocating tachycardia (AVRT).

Congestive Heart Failure

Atrial fibrillation is a common arrhythmia in patients with heart failure, with a prevalence ranging from 10% in patients with New York Heart Association (NYHA) functional Class I up to 50% in Class IV patients (**see Chapters 24 and 25**). AF may be the cause of heart failure in patients who present with a nonischemic cardiomyopathy and AF with a rapid ventricular rate. Occasionally, AF causes left ventricular dysfunction and heart failure even when the ventricular rate is not rapid. In patients with structural heart disease and preexisting left ventricular dysfunction, AF can worsen the heart failure. The deleterious hemodynamic effects of AF are mediated by a rapid and/or irregular ventricular rate and loss of AV synchrony.

The most appropriate rate-control drugs in patients with systolic heart failure are beta blockers and digitalis. If necessary, amiodarone also can be used for rate control. In patients with diastolic heart failure, nondihydropyridine calcium antagonists can be used safely for rate control. Amiodarone and dofetilide are the only two rhythm-control drugs that are not associated with an increased risk of death in patients with heart failure.

As in other patients with AF, the decision to pursue a rate-control or a rhythm-control strategy in patients with heart failure should be individualized. If the heart failure is a result of AF, a rhythm-control strategy should be employed. In patients with heart failure who develop AF, there are no significant

differences in all-cause mortality, cardiovascular mortality, or worsening heart failure between patients treated with a rate-control strategy or a pharmacologic rhythm-control strategy.[2] However, although symptoms improve with both a rate- and rhythm-control strategy, sinus rhythm is associated with greater improvement in NYHA functional class and quality of life.[82]

A limitation of a pharmacologic rhythm-control strategy is that many patients continue to experience episodes of AF. Catheter ablation is more effective than AADs for preventing recurrent AF and therefore could have incremental benefit over drug therapy in patients with heart failure and AF. In patients with heart failure and persistent AF who were randomly assigned to either catheter ablation or treatment with amiodarone, freedom from AF at 24 months was 70% in the catheter ablation group compared to 34% in the amiodarone group, and the relative risks of unplanned hospitalizations and mortality were reduced by 45% to 55% in the catheter ablation group.[83] The EF increases by approximately 13% when AF is successfully eliminated in patients with left ventricular dysfunction.[84]

Four small-scale randomized studies (sample sizes of 41 to 81 patients) compared catheter ablation to either pharmacologic rate control or AV junction ablation in patients with left ventricular dysfunction, and NYHA Class II to IV heart failure.[85] A majority of the patients had persistent AF. Freedom from AF ranged from 50% to 81% at 6 months and was 88% at 12 months after catheter ablation. Compared to rate control, catheter ablation was associated with significantly greater improvements in EF, functional capacity, brain natriuretic peptide levels, and quality of life.

These results suggest that maintenance of sinus rhythm is preferable to rate control in patients with heart failure and that catheter ablation of the AF should be considered if sinus rhythm is not maintained by amiodarone or dofetilide. Large-scale multicenter trials currently are in progress and will be helpful in clarifying the role of catheter ablation in patients with heart failure and AF.

A rate-control strategy is appropriate for patients who do not respond adequately to amiodarone or dofetilide and either are not suitable candidates for catheter ablation of the AF or have had an unsuccessful outcome from ablation. AV node ablation is appropriate for patients when ventricular rate during AF is not adequately controlled by drug therapy. Because left ventricular dysfunction and heart failure can be aggravated by right ventricular pacing, biventricular pacing should be performed after AV node ablation. The decision to implant a biventricular pacemaker versus a biventricular ICD is based on clinical judgment. If it seems likely that the EF will remain less than 30% to 35% after optimal heart rate control, a biventricular ICD is appropriate for primary prevention of sudden cardiac death.

In patients with heart failure who undergo CRT, AF often results in intrinsic and/or fused QRS complexes even when the rate is considered to be adequately controlled. This can limit the extent of biventricular capture. If this is the case in a patient with heart failure and AF, AV node ablation can maximize the benefit of CRT by resulting in 100% biventricular capture.[73]

Hypertrophic Cardiomyopathy

Atrial fibrillation occurs in approximately 25% of patients with hypertrophic cardiomyopathy (HCM) and can cause severe hemodynamic impairment because of an inadequate diastolic filling time and loss of atrial-ventricular synchrony. Because of a high risk of thromboembolic complications, anticoagulation is indicated in AF patients with HCM, independent of the CHA_2DS_2-VASc score.

Severe left ventricular hypertrophy increases the risk of drug-induced torsade de pointes, and the only rhythm-control agents recommended for patients with HCM and a wall thickness greater than 1.5 cm are dronedarone and amiodarone.[2] Catheter ablation of AF also is an option. However, the responses to drug therapy and catheter ablation often are suboptimal because of the extensive atrial remodeling that may be

present in patients with HCM.

Eight observational cohort studies reported on the results of RF catheter ablation of AF in patients with HCM.[86] The median follow-up in these studies was 18 to 19 months, and the rate of redo ablation procedures was 43%. Freedom from AF in these studies was a median of 66% to 86% for patients with paroxysmal AF and 42% to 65% for patients with persistent AF. These results indicate that catheter ablation is a reasonable option in patients with HCM and AF who do not respond well to AAD therapy. However, because of the prominent structural atrial abnormalities that can be associated with HCM, AF is likely to recur during long-term follow-up in many of these patients.

Percutaneous Coronary Intervention for Coronary Artery Disease

In patients with stable ischemic heart disease, treatment with aspirin plus clopidogrel (double-antiplatelet [-antithrombotic] therapy, DAPT) is recommended for a minimum of 1 month after placement of a bare metal stent and for a minimum of 6 months after placement of a drug-eluting stent. In patients with an acute coronary syndrome who undergo percutaneous coronary intervention with either a bare metal stent or a drug-eluting stent, DAPT is recommended for at least 12 months.

In patients who require long-term anticoagulation for AF, the addition of DAPT increases the risk of serious bleeding. The results of a randomized clinical trial indicated that therapy with a vitamin K inhibitor plus clopidogrel after stent placement reduces the risk of major bleeding events compared to therapy with a vitamin K inhibitor plus DAPT, without increasing the risk of adverse outcomes such as myocardial infarction, death, or stent thrombosis.[87]

Pregnancy

The prevalence of AF during pregnancy is very low, approximately 60/100,000 pregnancies. When it occurs, AF often is in the setting of underlying congenital or valvular heart disease, thyrotoxicosis, or electrolyte abnormalities. Pregnancy is associated with a hypercoagulable state, but no data indicate that pregnancy increases the risk of thromboembolic complications related to AF. In women with paroxysmal AF before pregnancy, the frequency of episodes may or may not increase during pregnancy.

The decision to anticoagulate a pregnant woman with AF should be made using the same criteria as in nonpregnant women. If anticoagulation is deemed necessary, warfarin (not an NOAC) is recommended from the second trimester until 1 month before the due date, and subcutaneous low-molecular-weight heparin is recommended during the first trimester and during the final month of pregnancy.

Transthoracic cardioversion is considered safe at all stages of pregnancy. The recommended pharmacologic agents for acute management of AF consist of intravenous metoprolol for rate control and flecainide or sotalol for conversion to sinus rhythm. If ongoing therapy is deemed necessary, the recommended rate-control drug is digoxin. If ineffective, a beta blocker can be used, but only after the first trimester. If there is no structural heart disease, flecainide and sotalol are recommended for long-term rhythm control.[88] In the patient with structural heart disease, amiodarone is recommended for rhythm control.

Future Perspectives

The ideal antiarrhythmic drug to prevent atrial fibrillation would affect only the atrium, thereby eliminating the potential for ventricular proarrhythmia. Such AADs are under development and may improve the safety and efficacy of pharmacologic therapy for AF. It is likely that drugs that modify a single channel will not be as effective as those with multiple actions, and targeting nonchannel functions (e.g., prevention of atrial fibrosis) may prove useful.

In the past few years, significant progress has been made in the field of catheter ablation of AF, but much room remains for improvement in efficacy and procedure duration. The failure to create enduring pulmonary vein isolation often accounts for recurrences of AF after both radiofrequency catheter ablation and cryoballoon ablation. The development of new ablation tools that improve the ability safely to create transmural lesions could reduce the need for redo ablation procedures. The cryoballoon catheter has improved the efficiency of PV isolation compared to point-by-point RF ablation. However, its use is limited to the antral regions of the PVs. The development of ablation catheters that ablate large areas of atrial myocardium with single applications of energy could improve the efficiency of catheter ablation of persistent AF.

In patients with persistent AF, a better understanding of AF mechanisms could result in more efficient and successful ablation strategies. The identification of presumptive localized sources of AF (focal impulses and/or atrial rotors) by computed signal analysis in humans in the past few years possibly represents an important step in this direction.[5] However, the excellent early clinical results have not been consistently reproduced in subsequent studies.[46,47] Better understanding of AF mechanisms in humans is clearly needed. Several studies have shown that a rhythm-control strategy in patients with AF provides no advantages in outcomes over a rate-control strategy. The results of these studies most likely were influenced by the suboptimal safety and efficacy of the drugs used for rhythm control.

To date, no randomized trials have demonstrated that catheter ablation of AF improves outcomes such as stroke or survival. An ongoing trial, Catheter Ablation versus Antiarrhythmic Drug Therapy for Atrial Fibrillation (CABANA), has a primary endpoint of mortality and secondary endpoints of cardiovascular mortality and stroke. If this study shows improved outcomes with AF ablation, it will strengthen the case for rhythm control by ablation.

Guidelines

Atrial Fibrillation

Fred Morady and Douglas P. Zipes

Recent updates have been incorporated into the comprehensive guidelines for the management of atrial fibrillation (AF) published in 2006 by the American College of Cardiology/American Heart Association (ACC/AHA) Task Force on Practice Guidelines and the European Society of Cardiology Committee for Practice Guidelines.[1] The following classification system was used for recommendations and for the level of evidence on which the recommendations are based:

Class I: conditions for which there is evidence and/or general agreement that the test is useful and effective
Class IIa: weight of evidence or opinion is in favor of usefulness/efficacy
Class IIb: usefulness or efficacy is less well established by evidence or opinion

Class III: conditions for which there is evidence and/or general agreement that the test is not useful or effective and in some cases may be harmful

Level A recommendations are derived from data from multiple randomized clinical trials.

Level B recommendations are derived from a single randomized trial or nonrandomized studies.

Level C recommendations are based on the consensus opinion of experts.

The guidelines do not necessarily define the standard of care. Management decisions must be individualized on the basis of the particular circumstances of a patient, and there are situations in which a deviation from the guidelines may be appropriate.

Classification of Atrial Fibrillation

The terminology used to classify AF in the guidelines is as follows: *paroxysmal* AF is defined as episodes of AF that last less than 7 days; *persistent* AF is defined as AF that lasts more than 7 days; and *longstanding* AF refers to AF that has been persistent for more than 1 year. These designations are not altered by termination of AF by drug therapy or electrical cardioversion. AF that is resistant to electrical cardioversion is referred to as *permanent* AF. AF is considered recurrent after two or more episodes have occurred.

Some patients with paroxysmal AF occasionally have episodes that are persistent, and vice versa. In this event, the AF should be categorized on the basis of the predominant form. *Lone* AF refers to AF in patients younger than 60 years who do not have structural heart disease or hypertension. AF that is secondary to acute myocardial infarction (MI), cardiac surgery, pericarditis, myocarditis, hyperthyroidism, or an acute pulmonary process is considered separately because the AF often resolves after treatment of the underlying disorder.

Management of Atrial Fibrillation

The guidelines address five aspects of the management of AF: pharmacologic rate control, prevention of thromboembolic complications, cardioversion, maintenance of sinus rhythm, and special considerations, including postoperative AF, MI, Wolff-Parkinson-White (WPW) syndrome, hyperthyroidism, pregnancy, hypertrophic cardiomyopathy (HCM), and pulmonary disease.

An important aspect in the management of patients with AF that is not specifically addressed in the guidelines is how to decide on a rate-control strategy versus a rhythm-control strategy. Several clinical trials have demonstrated that pharmacologic rhythm-control and rate-control strategies result in similar outcomes, even in patients with AF who have left ventricular dysfunction and heart failure. On the other hand, a randomized trial of left atrial radiofrequency catheter ablation versus atrioventricular (AV) node ablation and biventricular pacing demonstrated significantly greater improvement in left ventricular (LV) function, exercise capacity, and quality of life in patients with heart failure who were treated by ablation. It is possible that the side effects from the drugs used for rhythm control offset the benefits of sinus rhythm. Specific recommendations regarding rhythm-control versus rate-control strategies are difficult to provide because the decision must be individualized on the basis of several factors, including age, symptom severity, functional limitations, patient preference, comorbidities, sinus node function, and response to drug therapy.

Pharmacologic Rate Control During Atrial Fibrillation (Table 38G.1)

In addition to specific recommendations on the use of particular drugs for control of the ventricular rate, the guidelines recommend that the effects of drug therapy on ventricular rate be measured at rest and during exercise to ensure adequate heart rate control. The criteria used for rate control are rates of 60 to 80 beats/min at rest and 90 to 115 beats/min during moderate exercise.

TABLE 38G.1

ACC/AHA Recommendations for Pharmacologic Rate Control of Atrial Fibrillation

CLASS	INDICATION	LEVEL OF EVIDENCE
Class I (indicated)	Measurement of the heart rate at rest and control of the rate with pharmacologic agents (either a beta blocker or nondihydropyridine calcium channel antagonist, in most cases) are recommended for patients with persistent or permanent AF.	B
	In the absence of preexcitation, intravenous administration of beta blockers (esmolol, metoprolol, or propranolol) or nondihydropyridine calcium channel antagonists (verapamil, diltiazem) is recommended to slow the ventricular response to AF in the acute setting, exercising caution in patients with hypotension or heart failure.	B
	Intravenous administration of digoxin or amiodarone is recommended to control heart rate in patients with AF and heart failure who do not have an accessory pathway.	B
	In patients who experience symptoms related to AF during activity, the adequacy of heart rate control should be assessed during exercise, adjusting pharmacologic treatment as necessary to keep the rate in the physiologic range.	C
	Digoxin is effective after oral administration to control the heart rate at rest in patients with AF and is indicated for patients with heart failure or left ventricular dysfunction and for sedentary individuals.	C
Class IIa (reasonable)	A combination of digoxin and either a beta blocker or nondihydropyridine calcium channel antagonist is reasonable to control the heart rate both at rest and during exercise in patients with AF. The choice of medication should be individualized and the dose modulated to avoid bradycardia.	B
	It is reasonable to use ablation of the AV node or accessory pathway to control heart rate when pharmacologic therapy is insufficient or associated with side effects.	B
	Intravenous amiodarone can be useful to control heart rate in patients with AF when other measures are unsuccessful or contraindicated.	C
	When electrical cardioversion is not necessary in patients with AF and an accessory pathway, intravenous procainamide or ibutilide is a reasonable alternative.	C
Class IIb (may be considered)	When the ventricular rate cannot be adequately controlled both at rest and during exercise in patients with AF by a beta blocker, nondihydropyridine calcium channel antagonist, or digoxin, alone or in combination, oral amiodarone may be administered to control the heart rate.	C
	Intravenous procainamide, disopyramide, ibutilide, or amiodarone may be considered for hemodynamically stable patients with AF involving conduction over an accessory pathway	B
	When the rate cannot be controlled with pharmacologic agents or tachycardia-mediated cardiomyopathy is suspected, catheter-directed ablation of the AV node may be considered in patients with AF to control the heart rate.	C
Class III (not indicated)	Strict rate control (<80 beats/min at rest or <110 beats/min during 6-minute walk) is not beneficial compared to a resting rate <110 beats/min in asymptomatic patients with persistent AF and an ejection fraction >40%, although uncontrolled tachycardia can lead to reversible left ventricular dysfunction over time.	B
	Digitalis should not be used as the sole agent to control the rate of ventricular response in patients with paroxysmal AF.	B
	Catheter ablation of the AV node should not be attempted without a prior trial of medication to control the ventricular rate in patients with AF.	C
	In patients with decompensated heart failure and AF, intravenous administration of a nondihydropyridine calcium channel antagonist may exacerbate hemodynamic compromise and is not recommended.	C
	Intravenous administration of digitalis glycosides or nondihydropyridine calcium channel antagonists to patients with AF and a preexcitation syndrome may paradoxically accelerate the ventricular response and is not recommended.	C

A 2011 recommendation states that a resting rate of less than 110 beats/min is a reasonable rate-control target in patients with persistent AF and no arrhythmia-related symptoms who have an ejection fraction (EF) greater than 40%. However, the guidelines caution that tachycardia can result in a decline in LV function over time.

Digitalis is much less effective for control of the ventricular rate during exercise than at rest and is indicated for patients with heart failure or LV dysfunction and for sedentary patients. A combination of digitalis and either a beta blocker or nondihydropyridine calcium channel antagonist is appropriate to control the rate at rest and during exercise. The guidelines recommend that digitalis not be used as the sole agent for rate control in patients with paroxysmal AF. Catheter ablation of the AV node should be reserved for patients whose ventricular rate cannot be adequately controlled by drug therapy because of either inefficacy or drug intolerance.

Prevention of Thromboembolism (Table 38G.2)

The 2006 guidelines recommend antithrombotic therapy with either aspirin or a vitamin K antagonist such as warfarin for all patients with AF except those who have lone AF or contraindications. An updated 2011 recommendation is that the direct thrombin inhibitor dabigatran is a useful alternative to warfarin for

stroke/embolism prevention in patients with AF. The choice between aspirin and an anticoagulant is based on the patient's risk profile. The factors associated with the highest risk of thromboembolism are a prior thromboembolic event and rheumatic mitral stenosis, and warfarin or dabigatran is recommended for patients with one of these risk factors. The risk factors associated with a moderate risk of thromboembolism are age 75 years or older, hypertension, heart failure, EF of 35% or less, and diabetes. Aspirin is recommended if none of these risk factors is present, and an anticoagulant is recommended for patients with one or more of these risk factors. In patients with only one of the moderate risk factors, either aspirin or an anticoagulant is reasonable, and the choice should be individualized.

TABLE 38G.2

ACC/AHA Recommendations for Prevention of Thromboembolism in Atrial Fibrillation

CLASS	INDICATION	LEVEL OF EVIDENCE
Class I (indicated)	Antithrombotic therapy to prevent thromboembolism is recommended for all patients with AF, except those with lone AF or contraindications.	A
	The selection of the antithrombotic agent should be based on the absolute risks of stroke and bleeding and the relative risk and benefit for a given patient.	A
	For patients without mechanical heart valves at high risk of stroke, chronic oral anticoagulant therapy with a vitamin K antagonist is recommended in a dose adjusted to achieve the target intensity international normalized ratio (INR) of 2.0 to 3.0 unless contraindicated. Factors associated with highest risk for stroke in patients with AF are prior thromboembolism (stroke, transient ischemic attack, or systemic embolism) and rheumatic mitral stenosis.	A
	Anticoagulation with a vitamin K antagonist is recommended for patients with more than one moderate risk factor. Such factors include age ≥75 years, hypertension, heart failure, impaired left ventricular systolic function (ejection fraction ≤35% or fractional shortening <25%), and diabetes mellitus.	A
	INR should be determined at least weekly during initiation of therapy and monthly when anticoagulation is stable.	A
	Dabigatran is a useful alternative to warfarin in patients with AF and risk factors for stroke who do not have a prosthetic heart valve or significant valve disease, a creatinine clearance <15 mL/min, or advanced liver disease.	B
	Aspirin, 81 to 325 mg daily, is recommended as an alternative to vitamin K antagonists in low-risk patients or in those with contraindications to oral anticoagulation.	A
	For patients with AF who have mechanical heart valves, the target intensity of anticoagulation should be based on the type of prosthesis, maintaining an INR of at least 2.5.	B
	Antithrombotic therapy is recommended for patients with atrial flutter as for those with AF.	C
Class IIa (reasonable)	For primary prevention of thromboembolism in patients with nonvalvular AF who have just one of the following validated risk factors, antithrombotic therapy with either aspirin or a vitamin K antagonist is reasonable, based on an assessment of the risk of bleeding complications, ability to safely sustain adjusted chronic anticoagulation, and the patient's preferences: age ≥75 years (especially in female patients), hypertension, heart failure, impaired left ventricular function, or diabetes mellitus	A
	For patients with nonvalvular AF who have one or more of the following less well-validated risk factors, antithrombotic therapy with either aspirin or a vitamin K antagonist is reasonable for prevention of thromboembolism: age 65 to 74 years, female gender, or coronary artery disease. The choice of agent should be based on the risk of bleeding complications, ability to sustain adjusted chronic anticoagulation, and the patient's preferences.	B
	It is reasonable to select antithrombotic therapy by the same criteria irrespective of the pattern (i.e., paroxysmal, persistent, or permanent) of AF.	B
	In patients with AF who do not have mechanical prosthetic heart valves, it is reasonable to interrupt anticoagulation for up to 1 week without substituting heparin for surgical or diagnostic procedures that carry a risk of bleeding.	C
	It is reasonable to reevaluate the need for anticoagulation at regular intervals.	C
Class IIb (may be considered)	In patients ≥75 years at increased risk of bleeding but without frank contraindications to oral anticoagulant therapy, and in other patients with moderate risk factors for thromboembolism who are unable to safely tolerate anticoagulation at the standard intensity of INR 2.0 to 3.0, a lower INR target of 2.0 (range, 1.6 to 2.5) may be considered for prevention of ischemic stroke and systemic embolism.	C
	When surgical procedures require interruption of oral anticoagulant therapy for longer than 1 week in high-risk patients, unfractionated heparin may be administered or low-molecular-weight heparin given by subcutaneous injection, although the efficacy of these alternatives in this situation is uncertain.	C
	After percutaneous coronary intervention or revascularization surgery in patients with AF, low-dose aspirin (<100 mg/day) and/or clopidogrel (75 mg/day) may be given concurrently with anticoagulation to prevent myocardial ischemic events, but these strategies have not been thoroughly evaluated and are associated with an increased risk of bleeding.	C
	In patients undergoing percutaneous coronary intervention, anticoagulation may be interrupted to prevent bleeding at the site of peripheral arterial puncture, but the vitamin K antagonist should be resumed as soon as possible after the procedure and the dose adjusted to achieve an INR in the therapeutic range. Aspirin may be given temporarily during the hiatus, but the maintenance regimen should then consist of the combination of clopidogrel, 75 mg daily, plus warfarin (INR, 2.0 to 3.0). Clopidogrel should be given for a minimum of 1 month after implantation of a bare-metal stent, at least 3 months for a sirolimus-eluting stent, at least 6 months for a paclitaxel-eluting stent, and 12 months or longer in selected patients, following which warfarin may be continued as monotherapy in the absence of a subsequent coronary event. When warfarin is given in combination with clopidogrel or low-dose aspirin, the dose intensity must be carefully regulated.	C
	In patients with AF younger than 60 years without heart disease or risk factors for thromboembolism (lone AF), the risk of thromboembolism is low without treatment, and the effectiveness of aspirin for primary prevention of stroke relative to the risk of bleeding has not been established.	C
	In patients with AF who sustain ischemic stroke or systemic embolism during treatment with low-intensity anticoagulation (INR, 2.0 to 3.0), rather than add an antiplatelet agent, it may be reasonable to raise the intensity of the anticoagulation to a maximum target INR of 3.0 to 3.5.	C
	Clopidogrel plus aspirin may be considered in patients who cannot tolerate or who refuse an oral anticoagulant.	B
Class III (not indicated)	Long-term anticoagulation with a vitamin K antagonist is not recommended for primary prevention of stroke in patients younger than 60 years without heart disease (lone AF) or any risk factors for thromboembolism.	C

Rivaroxaban was approved by the FDA in 2011, after publication of the updated guidelines dealing with dabigatran. It seems appropriate to generalize the recommendations regarding dabigatran to the factor Xa inhibitor rivaroxaban.

Another update to the 2006 guidelines addresses combination therapy with aspirin and clopidogrel. This combination has been demonstrated to be less effective than warfarin for preventing strokes, but more effective than aspirin alone. The guidelines now recommend that aspirin plus clopidogrel be considered for stroke prevention in patients who cannot tolerate or refuse to take an oral anticoagulant.

Cardioversion of Atrial Fibrillation (Table 38G.3)

The first-line drugs recommended for cardioversion are flecainide, dofetilide, propafenone, and ibutilide. Amiodarone is considered a reasonable option. The guidelines state that digoxin and sotalol may be harmful when they are used for cardioversion and recommend against use of these agents for that purpose.

TABLE 38G.3

ACC/AHA Recommendations for Cardioversion of Atrial Fibrillation

CLASS	INDICATION	LEVEL OF EVIDENCE
Pharmacologic Cardioversion		
Class I (indicated)	Administration of flecainide, dofetilide, propafenone, or ibutilide is recommended for pharmacologic cardioversion of AF.	A
Class IIa (reasonable)	Administration of amiodarone is a reasonable option for pharmacologic cardioversion of AF.	A
	A single oral bolus dose of propafenone or flecainide ("pill-in-the-pocket") can be administered to terminate persistent AF outside the hospital once treatment has proved safe in the hospital for selected patients without sinus or AV node dysfunction, bundle branch block, QT interval prolongation, the Brugada syndrome, or structural heart disease. Before antiarrhythmic medication is initiated, a beta blocker or nondihydropyridine calcium channel antagonist should be given to prevent rapid AV conduction in the event atrial flutter occurs.	C
	Administration of amiodarone can be beneficial on an outpatient basis in patients with paroxysmal or persistent AF when rapid restoration of sinus rhythm is not deemed necessary.	C
Class IIb (may be considered)	Administration of quinidine or procainamide might be considered for pharmacologic cardioversion of AF, but the usefulness of these agents is not well established.	C
Class lII (not indicated)	Digoxin and sotalol may be harmful when used for pharmacologic cardioversion of AF and are not recommended.	A
	Quinidine, procainamide, disopyramide, and dofetilide should not be started out of the hospital for conversion of AF to sinus rhythm.	B
Direct-Current Cardioversion		
Class I (indicated)	When a rapid ventricular response does not respond promptly to pharmacologic measures for patients with AF with ongoing myocardial ischemia, symptomatic hypotension, angina, or heart failure, immediate R wave–synchronized direct-current cardioversion is recommended.	C
	Immediate direct-current cardioversion is recommended for patients with AF involving preexcitation when very rapid tachycardia or hemodynamic instability occurs.	B
	Cardioversion is recommended in patients without hemodynamic instability when symptoms of AF are unacceptable to the patient. In case of early relapse of AF after cardioversion, repeated direct-current cardioversion attempts may be made after administration of antiarrhythmic medication.	C
Class IIa (reasonable)	Direct-current cardioversion can be useful to restore sinus rhythm as part of a long-term management strategy for patients with AF.	B
	The patient's preference is a reasonable consideration in the selection of infrequently repeated cardioversions for the management of symptomatic or recurrent AF.	C
Class III (not indicated)	Frequent repetition of direct-current cardioversion is not recommended for patients who have relatively short periods of sinus rhythm between relapses of AF after multiple cardioversion procedures despite prophylactic antiarrhythmic drug therapy.	C
	Electrical cardioversion is contraindicated in patients with digitalis toxicity or hypokalemia.	C
Pharmacologic Enhancement of Direct-Current Cardioversion		
Class IIa (reasonable)	Pretreatment with amiodarone, flecainide, ibutilide, propafenone, or sotalol can be useful to enhance the success of direct-current cardioversion and to prevent recurrent AF.	B
	In patients who relapse to AF after successful cardioversion, it can be useful to repeat the procedure after prophylactic administration of antiarrhythmic medication.	C
Class IIb (may be considered)	For patients with persistent AF, administration of beta blockers, disopyramide, diltiazem, dofetilide, procainamide, or verapamil may be considered, although the efficacy of these agents to enhance the success of direct-current cardioversion or to prevent early recurrence of AF is uncertain.	C
	Out-of-hospital initiation of antiarrhythmic medications may be considered in patients without heart disease to enhance the success of cardioversion of AF.	C
	Out-of-hospital administration of antiarrhythmic medications may be considered to enhance the success of cardioversion of AF in patients with certain forms of heart disease once the safety of the drug has been verified for the patient.	C
Prevention of Thromboembolism in Patients With Atrial Fibrillation Undergoing Cardioversion		
Class I (indicated)	For patients with AF of 48-hour duration or longer, or when the duration of AF is unknown, anticoagulation (INR 2.0 to 3.0) is recommended for at least 3 weeks before and 4 weeks after cardioversion, regardless of the method (electrical or pharmacologic) used to restore sinus rhythm.	B
	For patients with AF of more than 48-hour duration requiring immediate cardioversion because of hemodynamic instability, heparin should be administered concurrently (unless contraindicated) by an initial intravenous bolus injection, followed by a continuous infusion in a dose adjusted to prolong the activated partial thromboplastin time to 1.5 to 2 times the reference control value. Thereafter, oral anticoagulation (INR, 2.0 to 3.0) should be provided for at least 4 weeks, as for patients undergoing elective cardioversion. Limited data support subcutaneous administration of low-molecular-weight heparin in this indication.	C
	For patients with AF of less than 48-hour duration associated with hemodynamic instability (angina pectoris, myocardial infarction, shock, or pulmonary edema), cardioversion should be performed immediately, without delay, for prior initiation of anticoagulation.	C
Class IIa (reasonable)	During the 48 hours after onset of AF, the need for anticoagulation before and after cardioversion may be based on the patient's risk of thromboembolism.	C
	As an alternative to anticoagulation before cardioversion of AF, it is reasonable to perform transesophageal echocardiography in search of thrombus in the left atrium or left atrial appendage.	B
	a. For patients with no identifiable thrombus, cardioversion is reasonable immediately after anticoagulation with unfractionated heparin (e.g., initiated by intravenous bolus injection and an infusion continued at a dose adjusted to prolong the activated partial thromboplastin time to 1.5 to 2 times the control value until oral anticoagulation has been established with an oral vitamin K antagonist [e.g., warfarin] as evidenced by an INR ≥2.0).	B
	Thereafter, continuation of oral anticoagulation (INR, 2.0 to 3.0) is reasonable for a total anticoagulation period of at least 4 weeks, as for patients undergoing elective cardioversion.	B
	Limited data are available to support the subcutaneous administration of a low-molecular-weight heparin in this indication.	C
	b. For patients in whom thrombus is identified by transesophageal echocardiography, oral anticoagulation (INR, 2.0 to 3.0) is reasonable for at least 3 weeks before and 4 weeks after restoration of sinus rhythm, and a longer period of anticoagulation may be appropriate even after apparently successful cardioversion because the risk of thromboembolism often remains elevated in such cases.	C
	For patients with atrial flutter undergoing cardioversion, anticoagulation can be beneficial according to the recommendations as for patients with AF.	C

Direct-current (DC) cardioversion is recommended when there is a rapid ventricular rate that does not respond quickly to drug therapy in patients with myocardial ischemia, hypotension, or heart failure and in patients with the WPW syndrome and AF with a very rapid rate or hemodynamic instability. If there is an

early recurrence of AF after DC cardioversion, repeated cardioversion is recommended after treatment with an antiarrhythmic drug (AAD).

If AF has been present for more than 48 hours or if the duration is unknown, anticoagulation with warfarin and an international normalized ratio (INR) of 2 to 3 is recommended for 3 weeks or longer before cardioversion, whether pharmacologic or electrical, and for 4 weeks afterward. It is reasonable to presume that dabigatran or rivaroxaban are suitable alternatives to warfarin.

When cardioversion is performed within 48 hours of the onset of AF, anticoagulation before and after cardioversion may be based on the patient's risk profile.

In patients with AF for more than 48 hours or in whom the duration is unknown, an alternative to anticoagulation for 3 or more weeks before cardioversion is to perform transesophageal echocardiography, to anticoagulate the patient with heparin, to initiate oral anticoagulation, and to proceed with immediate cardioversion if no thrombi are present in the left atrium or left atrial appendage. In patients receiving warfarin, heparin should be continued until the INR is 2, and oral anticoagulation with an INR of 2 to 3 should be continued for 4 weeks or longer. In patients treated with dabigatran or rivaroxaban, heparin can be discontinued 3 to 4 hours after the first oral dose. As with warfarin, anticoagulation therapy should be continued for 4 weeks or longer.

Maintenance of Sinus Rhythm (Table 38G.4)

A reasonable outcome of AAD therapy is infrequent recurrences of well-tolerated AF. Initiation of a rhythm-control medication is reasonable on an outpatient basis in patients without heart disease when the medication is well tolerated. The updated guidelines now recommend dronedarone as being a reasonable option in patients with paroxysmal AF or after conversion of persistent AF. The guidelines recommend catheter ablation of symptomatic paroxysmal AF for patients who have failed treatment with an AAD and have little or no left atrial enlargement and normal or mildly reduced LV function.

TABLE 38G.4

ACC/AHA Recommendations for Maintenance of Sinus Rhythm in Patients With Atrial Fibrillation

CLASS	INDICATION	LEVEL OF EVIDENCE
Class I (indicated)	Before initiation of antiarrhythmic drug therapy, treatment of precipitating or reversible causes of AF is recommended.	C
	Catheter ablation by an experienced operator is useful in selected patients with symptomatic paroxysmal AF who have failed treatment with an antiarrhythmic drug and have a normal or mildly dilated left atrium and normal or mildly reduced left ventricular function.	A
Class IIa (reasonable)	Pharmacologic therapy can be useful in patients with AF to maintain sinus rhythm and to prevent tachycardia-induced cardiomyopathy.	C
	Infrequent, well-tolerated recurrence of AF is reasonable as a successful outcome of antiarrhythmic drug therapy.	C
	Outpatient initiation of antiarrhythmic drug therapy is reasonable in patients with AF who have no associated heart disease when the agent is well tolerated.	C
	In patients with lone AF without structural heart disease, initiation of propafenone or flecainide can be beneficial on an outpatient basis in patients with paroxysmal AF who are in sinus rhythm at the time of drug initiation.	B
	Sotalol can be beneficial in outpatients in sinus rhythm with little or no heart disease, prone to paroxysmal AF, if the baseline uncorrected QT interval is shorter than 460 milliseconds, serum electrolyte values are normal, and risk factors associated with class III drug–related proarrhythmia are not present.	C
	Catheter ablation is a reasonable for treatment of symptomatic persistent AF.	A
Class IIb (may be considered)	Catheter ablation may be reasonable for patients with symptomatic paroxysmal AF and significant left atrial dilation or significant left ventricular dysfunction.	A
Class III (not indicated)	Antiarrhythmic therapy with a particular drug is not recommended for maintenance of sinus rhythm in patients with AF who have well-defined risk factors for proarrhythmia with that agent.	A
	Pharmacologic therapy is not recommended for maintenance of sinus rhythm in patients with advanced sinus node disease or AV node dysfunction unless they have a functioning electronic cardiac pacemaker.	C

Special Considerations (Table 38G.5)

Postoperative Atrial Fibrillation

The guidelines recommend prophylactic treatment with an oral beta blocker to prevent postoperative AF in patients undergoing cardiac surgery. Preoperative amiodarone also is considered to be appropriate prophylactic therapy to prevent postoperative AF. The use of cardioversion, rhythm-control medications, and antithrombotic medication should be based on the same considerations as in nonsurgical patients.

TABLE 38G.5

ACC/AHA Recommendations for Special Considerations in Atrial Fibrillation

CLASS	INDICATION	LEVEL OF EVIDENCE
Postoperative Atrial Fibrillation		
Class I (indicated)	Unless contraindicated, treatment with an oral beta blocker to prevent postoperative AF is recommended for patients undergoing cardiac surgery.	A
	Administration of AV nodal blocking agents is recommended to achieve rate control in patients who develop postoperative AF.	B
Class IIa (reasonable)	Preoperative administration of amiodarone reduces the incidence of AF in patients undergoing cardiac surgery and represents appropriate prophylactic therapy for patients at high risk for postoperative AF.	A
	It is reasonable to restore sinus rhythm by pharmacologic cardioversion with ibutilide or direct-current cardioversion in patients who develop postoperative AF, as advised for nonsurgical patients.	B
	It is reasonable to administer antiarrhythmic medications in an attempt to maintain sinus rhythm in patients with recurrent or refractory postoperative AF, as recommended for other patients who develop AF.	B
	It is reasonable to administer antithrombotic medication in patients who develop postoperative AF, as recommended for nonsurgical patients.	B
Class IIb (may be considered)	Prophylactic administration of sotalol may be considered for patients at risk for development of AF after cardiac surgery.	B
Acute Myocardial Infarction		
Class I (indicated)	Direct-current cardioversion is recommended for patients with severe hemodynamic compromise or intractable ischemia, or when adequate rate control cannot be achieved with pharmacologic agents in patients with acute myocardial infarction and AF.	C
	Intravenous administration of amiodarone is recommended to slow a rapid ventricular response to AF and to improve left ventricular function in patients with acute myocardial infarction.	C
	Intravenous beta blockers and nondihydropyridine calcium antagonists are recommended to slow a rapid ventricular response to AF in patients with acute myocardial infarction who do not display clinical left ventricular dysfunction, bronchospasm, or AV block.	C
	For patients with AF and acute myocardial infarction, administration of unfractionated heparin by either continuous intravenous infusion or intermittent subcutaneous injection is recommended in a dose sufficient to prolong the activated partial thromboplastin time to 1.5 to 2 times the control value, unless contraindications to anticoagulation exist.	C
Class IIa (reasonable)	Intravenous administration of digitalis is reasonable to slow a rapid ventricular response and to improve left ventricular function in patients with acute myocardial infarction and AF associated with severe left ventricular dysfunction and heart failure.	C
Class III (not indicated)	The administration of class IC antiarrhythmic drugs is not recommended in patients with AF in the setting of acute myocardial infarction.	C
Management of Atrial Fibrillation Associated With Wolff-Parkinson-White (WPW) Preexcitation Syndrome		
Class I (indicated)	Catheter ablation of the accessory pathway is recommended for symptomatic patients with AF who have WPW syndrome, particularly those with syncope due to rapid heart rate or those with a short bypass tract refractory period.	B
	Immediate direct-current cardioversion is recommended to prevent ventricular fibrillation in patients with a short anterograde bypass tract refractory period in whom AF occurs with a rapid ventricular response associated with hemodynamic instability.	B
	Intravenous procainamide or ibutilide is recommended to restore sinus rhythm in patients with WPW in whom AF occurs without hemodynamic instability in association with a wide QRS complex on the electrocardiogram (≥120-msec duration) or with a rapid preexcited ventricular response.	C
Class IIa (reasonable)	Intravenous flecainide or direct-current cardioversion is reasonable when very rapid ventricular rates occur in patients with AF involving conduction over an accessory pathway.	B
Class IIb (may be considered)	It may be reasonable to administer intravenous quinidine, procainamide, disopyramide, ibutilide, or amiodarone to hemodynamically stable patients with AF involving conduction over an accessory pathway.	B
Class III (not indicated)	Intravenous administration of digitalis glycosides or nondihydropyridine calcium channel antagonists is not recommended in patients with WPW syndrome who have preexcited ventricular activation during AF.	B
Hyperthyroidism		
Class I (indicated)	Administration of a beta blocker is recommended to control the rate of ventricular response in patients with AF complicating thyrotoxicosis, unless contraindicated.	B
	In circumstances when a beta blocker cannot be used, administration of a nondihydropyridine calcium channel antagonist (diltiazem or verapamil) is recommended to control the ventricular rate in patients with AF and thyrotoxicosis.	B
	In patients with AF associated with thyrotoxicosis, oral anticoagulation (INR, 2.0 to 3.0) is recommended to prevent thromboembolism, as recommended for AF patients with other risk factors for stroke.	C
	Once a euthyroid state is restored, recommendations for antithrombotic prophylaxis are the same as for patients without hyperthyroidism.	C
Management of Atrial Fibrillation During Pregnancy		
Class I (indicated)	Digoxin, a beta blocker, or a nondihydropyridine calcium channel antagonist is recommended to control the rate of ventricular response in pregnant patients with AF.	C
	Direct-current cardioversion is recommended in pregnant patients who become hemodynamically unstable because of AF.	C
	Protection against thromboembolism is recommended throughout pregnancy for all patients with AF (except those with lone AF and/or low thromboembolic risk). Therapy (anticoagulant or aspirin) should be chosen according to the stage of pregnancy.	C
Class IIb (may be considered)	Administration of heparin may be considered during the first trimester and last month of pregnancy for patients with AF and risk factors for thromboembolism. Unfractionated heparin may be administered either by continuous intravenous infusion in a dose sufficient to prolong the activated partial thromboplastin time to 1.5 to 2 times the control value or by intermittent subcutaneous injection in a dose of 10,000 to 20,000	B

	units every 12 hours, adjusted to prolong the midinterval (6 hours after injection) activated partial thromboplastin time to 1.5 times control.	
	Despite the limited data available, subcutaneous administration of low-molecular-weight heparin may be considered during the first trimester and last month of pregnancy for patients with AF and risk factors for thromboembolism.	C
	Administration of an oral anticoagulant may be considered during the second trimester for pregnant patients with AF at high thromboembolic risk.	C
	Administration of quinidine or procainamide may be considered to achieve pharmacologic cardioversion in hemodynamically stable patients who develop AF during pregnancy.	C
Management of Atrial Fibrillation in Patients With Hypertrophic Cardiomyopathy (HCM)		
Class I (indicated)	Oral anticoagulation (INR, 2.0 to 3.0) is recommended in patients with HCM who develop AF, as for other patients at high risk of thromboembolism.	B
Class IIa (may be considered)	Antiarrhythmic medications can be useful to prevent recurrent AF in patients with HCM. Available data are insufficient to recommend one agent over another in this situation, but (a) disopyramide combined with a beta blocker or nondihydropyridine calcium channel antagonist or (b) amiodarone alone is generally preferred.	C
Management of Atrial Fibrillation in Patients With Pulmonary Disease		
Class I (indicated)	Correction of hypoxemia and acidosis is the recommended primary therapeutic measure for patients who develop AF during an acute pulmonary illness or exacerbation of chronic pulmonary disease.	C
	A nondihydropyridine calcium channel antagonist (diltiazem or verapamil) is recommended to control the ventricular rate in patients with obstructive pulmonary disease who develop AF.	C
	Direct-current cardioversion should be attempted in patients with pulmonary disease who become hemodynamically unstable as a consequence of AF.	C
Class III (not indicated)	Theophylline and beta-adrenergic agonist agents are not recommended for patients with bronchospastic lung disease who develop AF.	C
	Beta blockers, sotalol, propafenone, and adenosine are not recommended in patients with obstructive lung disease who develop AF.	C

Acute Myocardial Infarction

Electrical cardioversion is recommended if there is hemodynamic compromise or ongoing ischemia or when adequate rate control cannot be achieved with drug therapy. The guidelines recommend intravenous (IV) amiodarone or digitalis to slow the ventricular rate in patients and to improve LV function in patients with an acute MI. If there is no LV dysfunction, bronchospasm, or AV block, an IV beta blocker or nondihydropyridine calcium antagonist is recommended for rate control.

Atrial Fibrillation in Wolff-Parkinson-White Syndrome

Catheter ablation of the accessory pathway is recommended in patients with symptomatic AF and the WPW syndrome. Immediate electrical cardioversion is recommended if there is AF with a rapid ventricular rate and hemodynamic instability. If the patient is hemodynamically stable, IV procainamide or ibutilide is recommended for pharmacologic conversion of AF. IV digitalis and nondihydropyridine calcium channel antagonists should be avoided in patients with ventricular preexcitation during AF.

Hyperthyroidism

The guidelines recommend a beta blocker as first-line therapy for rate control in patients with AF and thyrotoxicosis. If a beta blocker cannot be used, verapamil or diltiazem should be used for rate control. Recommendations for therapy to prevent thromboembolic complications are as for patients without hyperthyroidism.

Atrial Fibrillation During Pregnancy

The guidelines recommend digoxin, a beta blocker, or a nondihydropyridine calcium channel antagonist for rate control of AF during pregnancy. DC cardioversion is recommended if there is hemodynamic instability.

Except in patients with a low-risk profile, either aspirin or an anticoagulant is recommended for prevention of thromboembolic complications, depending on the stage of pregnancy (**see Chapter 90**). Unfractionated or low-molecular-weight heparin can be considered during the first trimester and last month of pregnancy in patients with risk factors for thromboembolism, and an oral anticoagulant can be considered during the second trimester in patients at high risk of thromboembolism.

When AF occurs during pregnancy, quinidine or procainamide can be considered for pharmacologic

cardioversion in hemodynamically stable patients.

Hypertrophic Cardiomyopathy

The guidelines point out that there are not adequate data on the best rhythm-control medication to use for AF in the setting of HCM. The preferred therapy is either disopyramide plus a beta blocker, verapamil, or diltiazem for rate control or amiodarone by itself.

Pulmonary Disease

The primary therapy for AF in the setting of an acute pulmonary illness or exacerbation of chronic pulmonary disease should be correction of hypoxemia and acidosis. Verapamil or diltiazem is recommended for rate control in patients with obstructive pulmonary disease. Theophylline and beta-adrenergic agonists are not recommended in patients with bronchospastic disease, and beta blockers, sotalol, propafenone, and adenosine are not recommended in patients with obstructive lung disease.

Ventricular Arrhythmias

Jeffrey E. Olgin, Gordon F. Tomaselli, Douglas P. Zipes

Ventricular rhythm disturbances are those rhythms whose driving circuit or focus originates in ventricular tissue, including myocardium, annuli, valve cusps, aorta, pulmonary artery, bundle branches, or Purkinje fibers (**see Table 37.1**). Ventricular arrhythmias are characterized by a wide QRS (>120 msec). Some supraventricular tachyarrhythmias can exhibit a wide complex (**see Chapter 35**). Because of the differences in prognosis and treatment, proper diagnosis of ventricular tachycardia (VT) is critically important and is largely based on electrocardiographic criteria, although history is important. For example, a patient presenting with a wide-complex tachycardia (WCT) and a past history of a myocardial infarction (MI) most likely has VT.

Premature Ventricular Complexes

Electrocardiographic Recognition

A premature ventricular complex (PVC) is characterized by the premature occurrence of a QRS complex that is abnormal in shape and has a duration usually exceeding the dominant QRS complex, generally longer than 120 milliseconds. The T wave is usually large and opposite in direction to the major deflection of the QRS. The QRS complex is not preceded by a premature P wave but can be preceded by a nonconducted sinus P wave occurring at its expected time. Diagnosis of a PVC can never be made with unequivocal certainty from the scalar electrocardiogram (ECG) because a supraventricular beat or rhythm can mimic the manifestations of ventricular arrhythmia (**Fig. 39.1**). Retrograde transmission to the atria from the PVC occurs fairly frequently but is often obscured by the distorted QRS complex and T wave. If

the retrograde impulse discharges and resets the sinus node prematurely, it produces a pause that is not fully compensatory. More often, the sinus node and atria are not discharged prematurely by the retrograde impulse because interference of impulses frequently occurs at the atrioventricular (AV) junction in the form of a collision between the anterograde impulse conducted from the sinus node and the retrograde impulse conducted from the PVC. Therefore, a fully compensatory pause usually follows a PVC—the R-R interval produced by the two sinus-initiated QRS complexes on either side of the PVC equals twice the normally conducted R-R interval. The PVC may not produce any pause and can therefore be interpolated (**Fig. 39.1E**). In patients with a normal heart, PVCs typically originate from similar sites as described for idiopathic VT (see later), and electrocardiographic morphology of PVCs can be used to determine site of origin similar to that for idiopathic VT (**Table 39.1**).

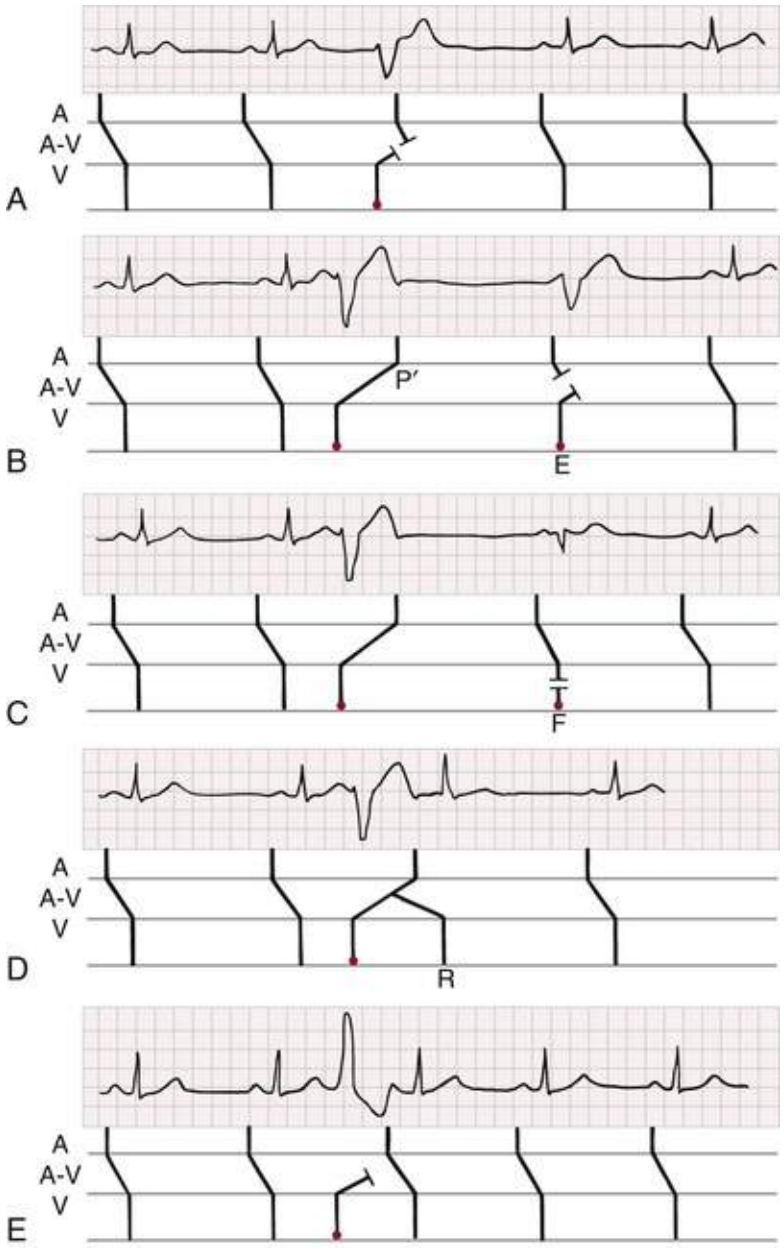

FIGURE 39.1 Premature ventricular complexes (PVCs). **A** to **D** were recorded in the same patient. **A,** Late PVC results in a compensatory pause. **B,** Slower sinus rate and slightly earlier PVC result in retrograde atrial excitation (*P′*). The sinus node is reset, followed by a noncompensatory pause. Before the sinus-initiated P wave that follows the retrograde P wave can conduct the impulse to the ventricle, ventricular escape (*E*) occurs. **C,** Events are similar to those in **B** except that a ventricular fusion beat (*F*) results after the PVC because of a slightly faster sinus rate. **D,** The impulse propagating retrogradely to the atrium reverses its direction after a delay and returns to reexcite the ventricles (*R*) and produce a ventricular echo. **E,** Interpolated PVC is followed by slightly prolonged PR interval of the sinus-initiated beat. The lead II ECG is shown. *Red circles* indicate the origin of the PVCs.

TABLE 39.1

Electrocardiographic Pattern of Idiopathic Ventricular Tachycardia (VT) by Anatomic Location

LOCATION	ECG PATTERN
Outflow Tract VT	LBBB morphology and inferior axis
Right ventricular outflow tract (RVOT)	Later precordial transition (V_3 or later) Narrower R wave duration and lower R/S wave amplitude ratio in V_1 and V_2
Left ventricular outflow tract (LVOT)	Early precordial transition (by V_3) Earlier precordial transition than SR Broader R wave duration and greater R/S wave amplitude ratio in V_1 and V_2 Notch (qrS) in V_1 or V_2
Left aortic cusp	"M" or "W" pattern in V_1 Monophasic R by V_1/V_2 Greater R wave II/III ratio Lead I QS or rS
Right aortic cusp	Monophasic R by V_2/V_3 Positive notched R-wave in lead I
Aortomitral continuity	qR in lead V_1 Positive concordance across precordium Rs/rs complex in lead I R wave ratio <1 in II/III
Epicardial	MDI >55% QS in lead I QS in leads II, III, and aVF (if superiorly directed, near MCV) Q-wave ratio in aVL/aVR >1.4 or S wave amplitude >1.2 mV "Transition break," specifically a loss of R from leads V_1 to V_2 (QS or rS) with prominent R by V_3 (suggests near anterior interventricular vein)
Pulmonary artery	Tall R wave in the inferior leads Larger Q wave ratio in aVL/aVR Larger R/S amplitude in lead V_2 Larger Q wave ratio in aVL/aVR Larger R/S amplitude in lead V_2
Tricuspid annular	LBBB morphology and inferior or superior axis R wave in lead I R or r with overall positive polarity in aVL Later precordial transition (>V_3)
Tricuspid inflow or parahisian	LBBB morphology and inferior axis Large R wave in lead I R wave with flat/positive polarity or "w" pattern in aVL
Mitral annular (MA)	RBBB pattern with concordance in leads V_1 to V_6 Anterior MAVT: positive QRS polarity in leads II, III, and aVF and negative QRS polarity in leads I and aVL Posterior or posteroseptal MAVT: negative QRS polarity in leads II, III, and aVF and positive QRS polarity in leads I and aVL
Fascicular VT	
Left posterior fascicle	RBBB and left axis deviation (LAFB pattern) rsR′ in V_1 q in I and aVL Narrow QRS ≤140 msec
Left anterior fascicle	RBBB and right axis deviation (LPFB pattern) Narrow QRS <140 msec
Left septal	Incomplete RBBB (QRSd ~100-110 msec) and normal axis
Papillary Muscle VT	RBBB; can have varied axes
Posterior papillary muscle	qR or R in V_1 Absent Q in leads I and aVL
Anterior papillary muscle	qR or R in V_1 rS in leads I and aVL
Crux VT	Leftward-superior axis QRS Delayed intrinsicoid deflection Basal crux: LBBB pattern with early precordial transition Apical crux: midprecordial transition with QS in V_5/V_6

LBBB, Left bundle branch block; *RBBB,* right bundle branch block.

Modified from Hoffmayer KS, Gerstenfeld EP. Diagnosis and management of idiopathic ventricular tachycardia. Curr Probl Cardiol 2013;38:131-58.

Interference within the ventricle can result in ventricular fusion beats caused by simultaneous activation of the ventricle by two foci, one from the supraventricular impulse and the other from the PVC. Infrequently, a fusion beat can be narrower than the dominant sinus beat, such as when a right bundle branch block (RBBB) pattern of a PVC arising in the left ventricle fuses with the sinus-initiated left

bundle branch block (LBBB) complex conducting through the AV junction, or when a sinus beat with an RBBB pattern fuses with a right ventricle–paced beat with an LBBB pattern. Narrow PVCs have also been explained as originating at a point equidistant from each ventricle in the ventricular septum and arising high in the fascicular system. Whether a compensatory or noncompensatory pause, retrograde atrial excitation, an interpolated complex, a fusion complex, or an echo beat occurs (**Fig. 39.1D**) is merely a function of how the AV junction conducts and the timing of the events taking place.

The term *bigeminy* refers to pairs of complexes and indicates a normal and premature complex; *trigeminy* indicates a premature complex that follows two normal beats; a premature complex that follows three normal beats is called *quadrigeminy*; and so on. Two successive PVCs are known as a *pair* or a *couplet*, whereas three successive PVCs are called a *triplet*. Arbitrarily, three or more successive PVCs are termed *ventricular tachycardia*. PVCs can have different contours and are often called *multifocal* (**Fig. 39.2**). More properly, these should be called *multiform*, *polymorphic*, or *pleomorphic* because it is not known whether multiple foci are discharging or whether conduction of the impulse originating from the same site is merely changing.

FIGURE 39.2 Multiform PVCs. The normally conducted QRS complexes exhibit a left bundle branch block contour (*arrowhead*) and are followed by PVCs with three different morphologies.

PVCs can exhibit fixed or variable coupling; that is, the interval between the normal QRS complex and the PVC can be relatively stable or variable. *Fixed coupling* can be caused by reentry, triggered activity (**see Chapter 34**), or other mechanisms. *Variable coupling* can be caused by parasystole, changing conduction in a reentrant circuit, or changing discharge rates of triggered activity. Usually, it is difficult to determine the precise mechanism responsible for the PVC on the basis of constant or variable coupling intervals.

Clinical Features

The prevalence of premature complexes increases with age, male sex, and hypokalemia. Symptoms of palpitations or discomfort in the neck or chest can result because of the greater-than-normal contractile force of the postextrasystolic beat or the feeling that the heart has stopped during the long pause after the premature complex. Long runs of frequent PVCs in patients with heart disease can produce angina, hypotension, or heart failure. Frequent interpolated PVCs actually represent a doubling of the heart rate and can compromise the patient's hemodynamic status. In some patients, frequent PVCs can cause heart failure, which can be reversed by ablation. Activity that increases the heart rate can decrease the patient's awareness of the premature systoles or reduce their number. Exercise can increase the number of premature complexes in some patients. Sleep is usually associated with a decrease in the frequency of ventricular arrhythmias, but some patients can experience an increase.

PVCs can be produced by direct mechanical, electrical, and chemical stimulation of the myocardium. Frequently, PVCs are noted during infection, in ischemic or inflamed myocardium, and during hypoxia,

anesthesia, or surgery. PVCs can be provoked by various medications, electrolyte imbalance, tension states, myocardial stretch, and excessive use of tobacco, caffeine, or alcohol. Autonomic stimulation has profound effects on the heart rate and can produce or suppress premature complexes.

Physical examination reveals a premature beat followed by a long pause. A fully compensatory pause can be distinguished from one that is not fully compensatory in that the former does not change the timing of the basic rhythm. The PVC is frequently accompanied by a decrease in intensity of heart sounds, often with auscultation of just the first heart sound, which can be sharp and snapping. A decreased or absent peripheral (e.g., radial) pulse can occur. The relationship of atrial to ventricular systole determines the presence of normal *a* waves or giant *a* waves in the jugular venous pulse, and the length of the PR interval determines the intensity of the first heart sound. The second heart sound can be split abnormally, depending on the origin of the ventricular complex.

The importance of PVCs depends on the clinical setting. In the absence of underlying heart disease, PVCs usually have no impact on longevity or limitation of activity; antiarrhythmic drugs are not indicated. Patients should be reassured if they are symptomatic. Frequent PVCs greater than 24% of all beats during 24-hour Holter monitoring, very wide-QRS PVCs, or PVCs of epicardial origin can cause a cardiomyopathy.[1-3] Ablation generally resolves the cardiomyopathy, although the left ventricular (LV) dysfunction may not resolve completely, depending on the duration and severity of the PVC-induced cardiomyopathy. In patients with acute myocardial infarction (AMI), PVCs are not particularly sensitive or specific predictors in determining who will develop VF.

Management

In most patients, PVCs (occurring as single PVCs, bigeminy, or trigeminy but excluding nonsustained VT; see later) do not need to be treated if the burden is low, particularly if the patient does not have an acute coronary syndrome, and treatment is usually dictated by the presence of symptoms attributable to the PVCs. PVCs accompanying slow ventricular rates can be abolished by increasing the basic rate with atropine or isoproterenol or by pacing, whereas slowing of the heart rate in some patients with sinus tachycardia can eradicate PVCs. In hospitalized patients, intravenous (IV) lidocaine is generally the initial treatment of choice to suppress PVCs but is rarely indicated (**see Chapter 36**). Frequent PVCs, even in the setting of AMI, need not be treated unless they directly contribute to hemodynamic compromise, which is rare. If maximum dosages of lidocaine are unsuccessful, IV procainamide can be tried. Propranolol is suggested if other drugs have been unsuccessful. IV magnesium may be useful.

In most patients, PVCs need not be treated, and reassurance that they are benign in those without structural heart disease is often sufficient for most patients. If treatment is warranted (dictated by symptoms), various class I, II, and III drugs or ablation can be useful. Beta blockers are often the first line of therapy. If they are ineffective, class IC drugs appear to be particularly successful in suppressing PVCs, but flecainide and moricizine have been shown to increase mortality in patients treated after MI and thus should be reserved for those without coronary artery disease (CAD) or LV dysfunction. Amiodarone can be effective, but because of its side effects, it should be reserved for highly symptomatic patients and those with structural heart disease. For patients with significant symptoms, particularly those with reduced cardiac function, radiofrequency (RF) ablation of the PVC focus can be effective and improve cardiac performance. Low levels of serum potassium and magnesium are associated with higher prevalence rates of ventricular arrhythmias. Ablation of PVCs may be warranted on occasion in patients with a high burden, regardless of ejection fraction (EF), or symptoms. Weighing the potential risk of ablation (largely based on PVC location) against the severity of symptoms or likelihood of developing cardiomyopathy is prudent in the absence of clear data.

Accelerated Idioventricular Rhythm

Electrocardiographic Recognition.

The ventricular rate, typically 60 to 110 beats/min, usually hovers within 10 beats of the sinus rate, so control of the cardiac rhythm shifts between these two competing pacemaker sites. Consequently, fusion beats often occur at the onset and termination of the arrhythmia as the pacemakers vie for control of ventricular depolarization (**Fig. 39.3**). Because of the slow rate, capture beats are common. The onset of this arrhythmia is generally gradual (nonparoxysmal) and occurs when the rate of the VT exceeds the sinus rate as a result of sinus slowing or sinoatrial (SA) or AV block. Precipitation of more rapid ventricular arrhythmias is rarely seen. Termination of the rhythm generally occurs gradually as the dominant sinus rhythm accelerates or as the ventricular rhythm decelerates. The ventricular rhythm can be regular or irregular and can occasionally show sudden doubling, which suggests the presence of an exit block. Many characteristics incriminate enhanced automaticity as the responsible mechanism.

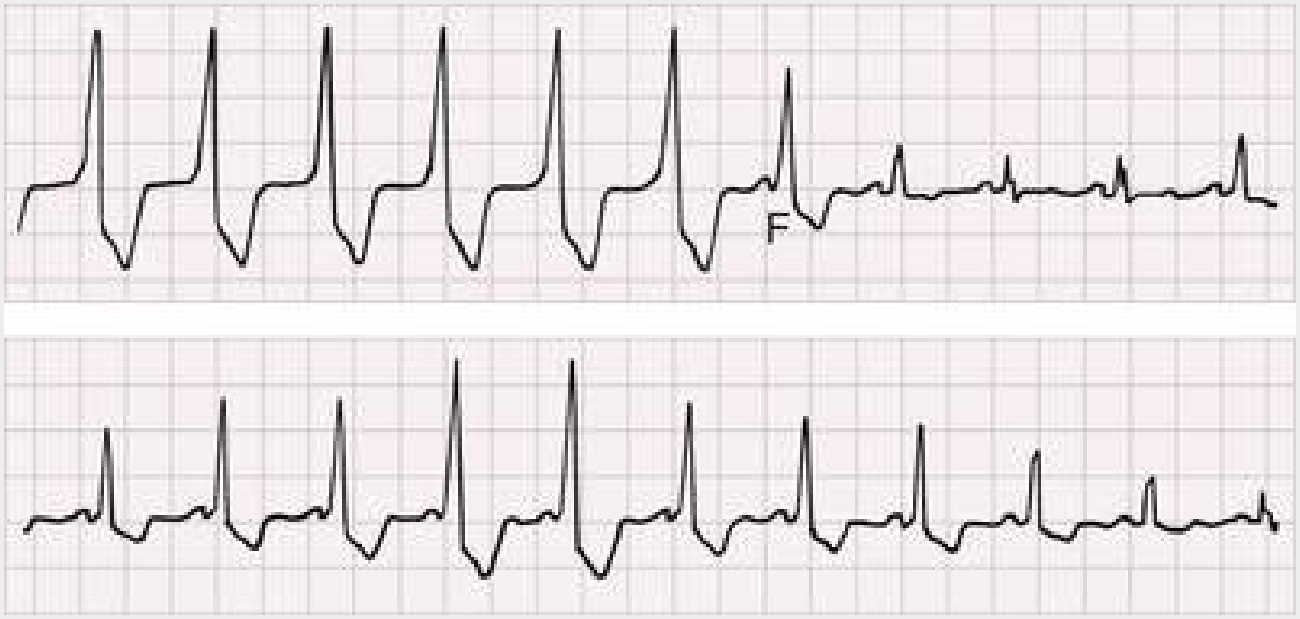

FIGURE 39.3 Accelerated idioventricular rhythm. In this continuous monitor lead recording, an accelerated idioventricular rhythm competes with the sinus rhythm. Wide QRS complexes at a rate of 110 beats/min fuse (*F*) with the sinus rhythm, which takes control briefly, generates the narrow QRS complexes, and then yields once again to the accelerated idioventricular rhythm as the P waves move “in and out” of the QRS complex. This example of isorhythmic AV dissociation may be caused by hemodynamic modulation of the sinus rate via the autonomic nervous system.

The arrhythmia occurs as a rule in patients who have heart disease, such as those with AMI or digitalis toxicity. It is transient and intermittent, with episodes lasting a few seconds to a minute, and does not appear to affect seriously the patient's clinical course or the prognosis. The arrhythmia usually occurs at the moment of reperfusion of a previously occluded coronary artery and can be found during resuscitation.

Management.

Suppressive therapy is rarely necessary because the ventricular rate is generally less than 100 beats/min. Such therapy may be considered, however, when (1) AV dissociation results in loss of sequential AV contraction, (2) an accelerated idioventricular rhythm occurs together with a more rapid VT, (3) an accelerated idioventricular rhythm begins with a PVC discharging in the vulnerable period of the

preceding T wave, (4) the ventricular rate is too rapid and produces symptoms, or (5) ventricular fibrillation (VF) develops as a result of the accelerated idioventricular rhythm. This last event appears to be rare. Therapy, when indicated, should be as noted earlier for VT. Frequently, simply increasing the sinus rate with atropine or atrial pacing suppresses the accelerated idioventricular rhythm.

Ventricular Tachycardia

Ventricular tachycardia can be caused by disorders of impulse formation (enhanced automaticity or triggered activity) and conduction (reentry), considered earlier (**see Chapter 34**). In general, the specific type, prognosis, and management of VT depend on the presence of underlying structural heart disease. With the exception of patients with inherited VT–sudden cardiac death syndromes (**see Chapter 33**), if structural heart disease is absent, the prognosis in patients with VT and PVCs is generally very good,[4] whereas in those with structural heart disease, the subsequent risk for sudden cardiac death (SCD) is increased.

Electrocardiographic Recognition

The electrocardiographic diagnosis of VT is suggested by the occurrence of a series of three or more consecutive, abnormally shaped QRS complexes longer than 120 milliseconds, with the ST-T vector pointing opposite the major QRS deflection. The R-R interval can be regular or varying. Patients can have VTs with multiple morphologies originating at the same or closely adjacent sites with different exits. Others have multiple sites of origin. Atrial activity can be independent of ventricular activity (AV dissociation), or the atria can be depolarized retrogradely (ventriculoatrial [VA] association). Depending on the particular type of VT, rates range from 70 to 250 beats/min, and the onset can be paroxysmal (sudden) or nonparoxysmal. QRS contours during the VT can be unchanging (uniform, monomorphic) or can vary randomly (multiform, polymorphic, or pleomorphic) in a more or less repetitive manner (torsades de pointes), in alternate complexes (bidirectional VT), or in a stable but changing contour (i.e., right bundle branch contour changing to a left bundle branch contour). VT can be *sustained*, defined arbitrarily as lasting longer than 30 seconds or requiring termination because of hemodynamic collapse, or *nonsustained*, when it stops spontaneously in less than 30 seconds. Most often, very premature stimulation is required to initiate VT electrically, whereas late-coupled ventricular complexes usually initiate its spontaneous onset (**Fig. 39.4**).

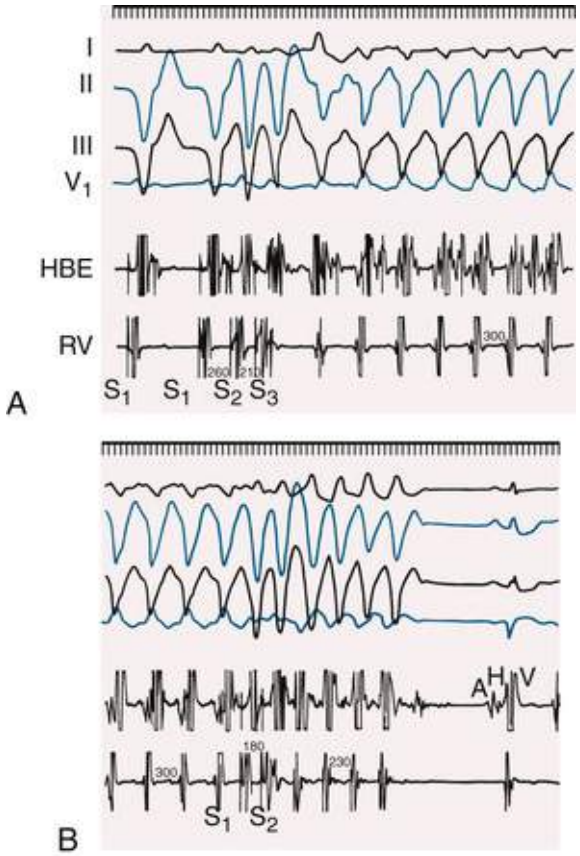

FIGURE 39.4 Initiation and termination of ventricular tachycardia (VT) by means of programmed ventricular stimulation. The last two ventricular-paced beats at a cycle length of 600 milliseconds are shown in **A.** A premature stimulus (S_2) at an S_1-S_2 interval of 260 milliseconds and another premature stimulus (S_3) at a cycle length of 210 milliseconds initiate sustained monomorphic VT at a cycle length of 300 milliseconds. **B,** Two premature ventricular stimuli (S_1-S_2) create an unstable VT that persists for several beats at a shorter cycle length (230 msec) and then terminates, followed by sinus rhythm. *HBE,* His bundle electrogram; *RV,* right ventricle.

It is important to distinguish supraventricular tachycardia (SVT) with aberrancy from VT. When the QRS during tachycardia is narrow (≤120 msec), SVT is easily diagnosed. However, when the QRS during tachycardia is wide (>120 msec), electrocardiographic distinction can be difficult because features of both arrhythmias overlap. Ventricular complexes with an abnormal and prolonged configuration indicate only that conduction through the ventricle is abnormal, and such complexes can occur in supraventricular rhythms as a result of preexisting bundle branch block, aberrant conduction during incomplete recovery of repolarization, conduction over accessory pathways, and several other conditions. These complexes do not necessarily indicate the origin of impulse formation or the reason for the abnormal conduction. Conversely, ectopic beats originating in the ventricle can infrequently have a fairly normal duration and shape. However, VT is the most common cause of tachycardia with a wide QRS complex in patients with a past history of MI or heart failure.

During the course of a tachycardia characterized by wide QRS complexes, the presence of fusion beats and capture beats provides maximum support for the diagnosis of VT but occurs relatively infrequently (**Fig. 39.5**; **see Table 37.2**). Fusion beats indicate activation of the ventricle from two different foci, with the implication that one of the foci had a ventricular origin. Capture of the ventricle by the supraventricular rhythm with a normal configuration of the captured QRS complex at an interval shorter than the tachycardia in question indicates that the impulse has a supraventricular origin and thus excludes a supraventricular origin of the tachycardia. AV dissociation has long been considered a hallmark of VT. However, retrograde VA conduction to the atria from ventricular beats occurs in at least 25% of patients, and therefore VT may not exhibit AV dissociation. AV dissociation can occur infrequently during SVTs.

Even if a P wave appears to be related to each QRS complex, it is at times difficult to determine whether the P wave is conducted anterogradely to the next QRS complex (i.e., SVT with aberrancy and a long PR interval) or retrogradely from the preceding QRS complex (i.e., a VT). As a general rule, however, AV dissociation during tachycardia with a wide QRS complex is strong presumptive evidence that the tachycardia is of ventricular origin.

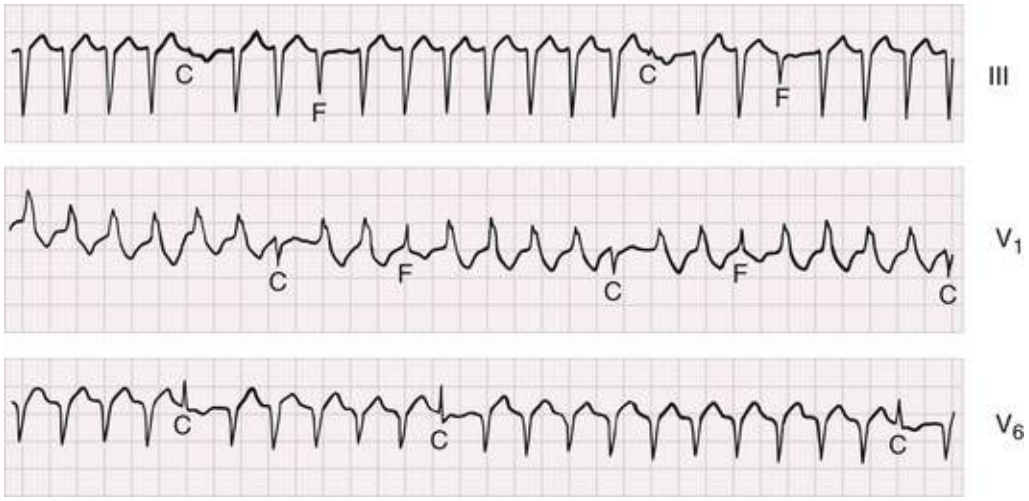

FIGURE 39.5 Fusion and capture beats during VT. The QRS complex is prolonged, and the R-R interval is regular except for occasional capture beats (*C*) that have a normal contour and are slightly premature. Complexes intermediate in contour represent fusion beats (*F*). Thus, even though atrial activity is not clearly apparent, AV dissociation is present during VT and produces intermittent capture and fusion beats.

Differentiation Between Ventricular and Supraventricular Tachycardia

Although fusion and capture beats and AV dissociation provide the strongest electrocardiographic evidence for differentiation of VT from SVT with aberrant conduction, these features are not always present. Other clues characterizing supraventricular arrhythmia with aberrancy include (1) consistent onset of the tachycardia with a premature P wave; (2) very short RP interval (0.1 second), which often requires an esophageal recording or invasive electrophysiologic study (EPS) to visualize the P waves; (3) QRS configuration the same as that occurring from known supraventricular conduction at similar rates; (4) P wave and QRS rate and rhythm linked to suggest that ventricular activation depends on atrial discharge (e.g., P-P interval changes preceding and therefore causing subsequent R-R intervals); and (5) slowing or termination of the tachycardia by vagal maneuvers, although vagal maneuvers can terminate right ventricular outflow tract VTs.

Analysis of specific QRS contours can also be helpful in the diagnosis of VT and localization of its site of origin. For example, QRS contours suggesting VT include left axis deviation in the frontal plane and a QRS duration exceeding 140 milliseconds with normal duration during sinus rhythm. In precordial leads with an RS pattern, the duration of the onset of the R to the nadir of the S exceeding 100 milliseconds suggests VT as the diagnosis. During VT with an RBBB appearance, (1) the QRS complex is monophasic or biphasic in V_1, with an initial deflection different from that of the sinus-initiated QRS complex; (2) the amplitude of the R wave in V_1 exceeds that of R′; and (3) a small R and large S wave or a QS pattern in V_6 may be present. With a VT having an LBBB contour, (1) the axis can be rightward, with negative deflections deeper in V_1 than in V_6; (2) a broad prolonged (>40 msec) R wave can be noted

in V_1; and (3) a small Q–large R wave or QS pattern in V_6 can exist. A QRS complex that is similar in V_1 through V_6, either all negative or all positive, favors a ventricular origin, as does the presence of a 2 : 1 VA block. (An upright QRS complex in V_1 through V_6 can also occur as a result of conduction over a left-sided accessory pathway.) Supraventricular beats with aberration often have a triphasic RSR′ pattern in V_1, an initial vector of the abnormal complex similar to that of the normally conducted beats, and a wide QRS complex that terminates a short cycle length after a long cycle (long-short cycle sequence).

During atrial fibrillation (AF), fixed coupling, short coupling intervals, a long pause after the abnormal beat, and runs of bigeminy rather than a consecutive series of abnormal complexes all favor a ventricular origin of the premature complex rather than a supraventricular origin with aberration. A grossly irregular, wide-QRS tachycardia with ventricular rates exceeding 200 beats/min should suggest AF with conduction over an accessory pathway (**see Fig. 37.22**).

In the presence of a preexisting bundle branch block, a wide-QRS tachycardia with a contour different from the contour during sinus rhythm is most likely a VT. On the basis of these criteria, several algorithms to distinguish VT from SVT with aberrancy have been suggested (**Table 39.2 and Fig. 39.6**). Exceptions exist to all the aforementioned criteria, especially in patients with preexisting conduction disturbances or preexcitation syndrome; when in doubt, one must rely on sound clinical judgment and consider the ECG as only one of several helpful ancillary tests.

TABLE 39.2

Stepwise Criteria Favoring Ventricular Tachycardia in Patients with Wide-Complex Tachycardias Using Different Algorithms*

KINDWALL CRITERIA†	WELLENS CRITERIA‡	BRUGADA CRITERIA§	MILLER CRITERIA‖
R >30 msec in V_1 or V_2 → VT	AV dissociation → VT	Absence of RS complex in all precordial leads → VT	Initial R wave in aVR → VT
Any Q in V_6 → VT	QRS width >140 msec → VT	Longest R/S interval >100 msec in any precordial lead → VT	aVR with initial r or q >40 msec in duration → VT
>60 msec to S wave nadir in V_1 or V_2 → VT	Left axis deviation >−30 degrees → VT	AV dissociation → VT	aVR with a notch on the descending limb of a negative-onset and predominantly negative QRS in aVR → VT
Notched downstroke S wave in V_1 or V_2 → VT	If RBBB morphology, monophasic or biphasic QRS in V_1 → SVT or R-to-S ratio of <1 in V_6 → VT	If RBBB morphology, monophasic R or qR in V_1 → VT R taller than R′ → VT rS in V_6 → VT	In aVR, mV of initial 40 msec divided by terminal 40 msec ($v_i/v_t \leq 1$) → VT
	If LBBB morphology, S in V_1-V_2 → VT	If LBBB morphology, initial R >40 msec in duration → VT Slurred or notched S in V_1 or V_2 → VT Beginning Q or QS in V_6 → VT

The VT origin or exit site can often be determined on the surface ECG. VTs from the left ventricular free wall typically exhibit an RBBB contour, whereas those from the right ventricle or septum have an LBBB contour (**Fig. 39.7A**). Septal VTs typically have narrower QRS complexes than free wall VTs. Apical VTs exhibit negative precordial lead concordance, whereas more basal sites typically have positive concordance. VTs from the posterior (inferior) left or right ventricle often have predominantly negative QRS complexes in leads II, III, and aVF (**Fig. 39.7B**), whereas outflow tract VTs frequently exhibit predominantly positive QRS complexes in these leads. Epicardial VTs have a delayed *intrinsicoid* (initial) deflection that slurs the early portion of the QRS complex; an intrinsicoid deflection exceeding 55% of the QRS duration is likely to be epicardial (**Fig. 39.7B**).

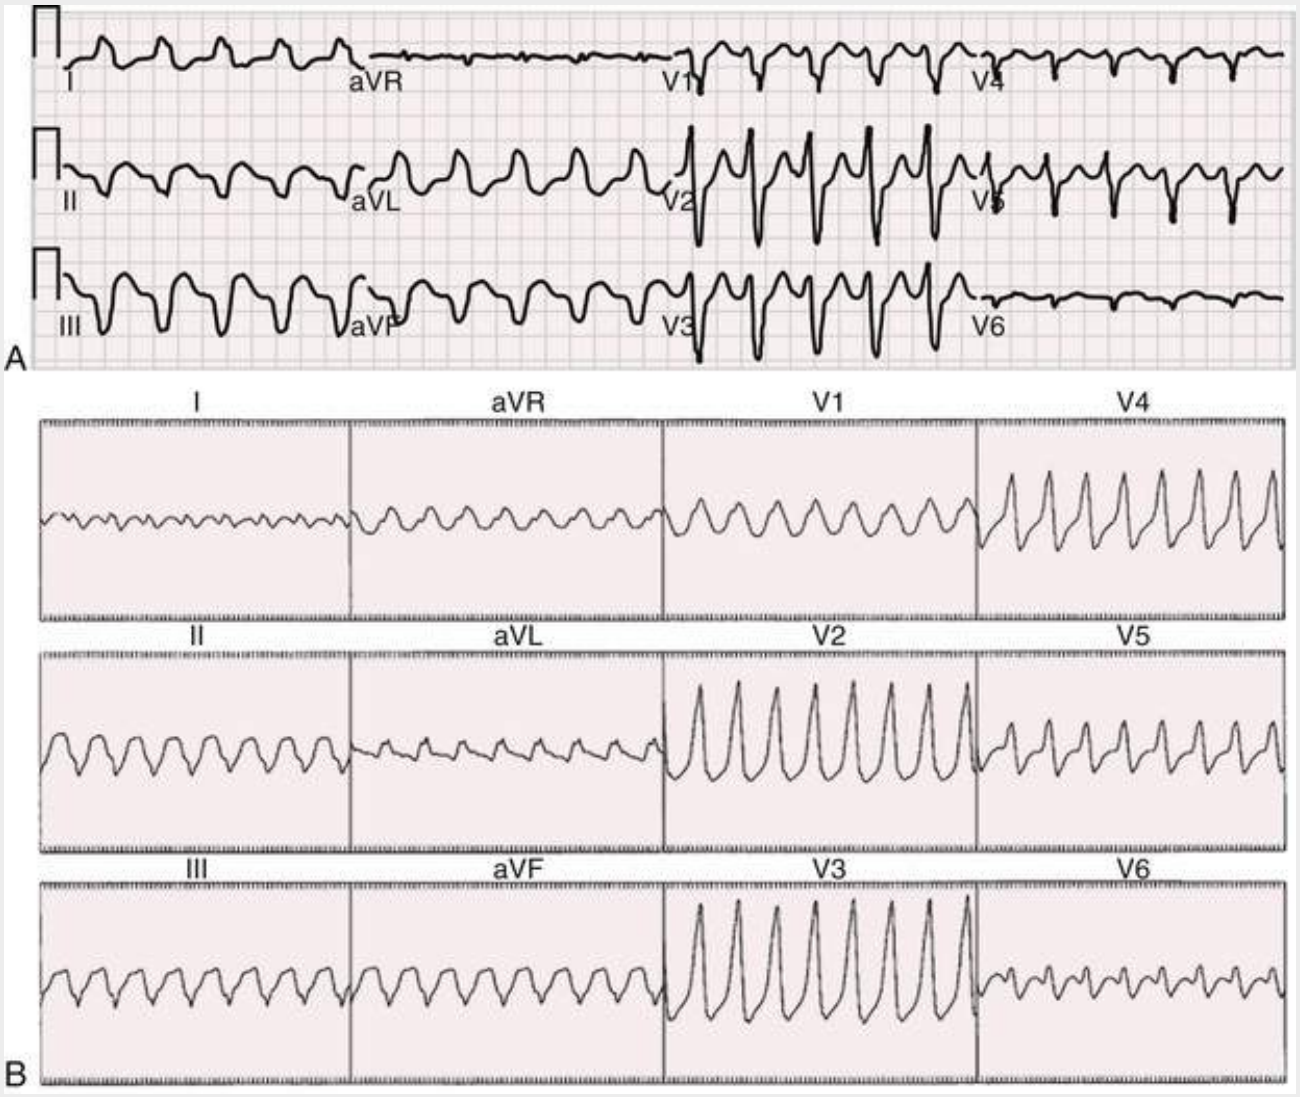

FIGURE 39.7 **A,** Ventricular tachycardia in a patient with a previous myocardial infarction. The VT exit is in the left ventricular septum (left bundle branch block morphology), inferiorly (QS in II, III, and aVF) close to the apex (QS in V_6). **B,** Epicardial ventricular tachycardia in a patient with Chagas disease. The VT has shortest intrinsicoid deflection, greater than 55% of the QRS in the precordium, and is therefore of epicardial origin. Because it has right bundle branch block morphology in V_1 and QS in leads II, III, and aVF, the origin is in the inferior left ventricle.

Electrophysiologic Features.

VT can be distinguished electrophysiologically by a short or negative H-V interval (i.e., H begins after the onset of ventricular depolarization) because of retrograde activation from the ventricles (**see Chapters 34 and 35**). His bundle deflections are usually obscured by simultaneous ventricular septal depolarization or inadequate catheter position. The latter must be determined during supraventricular rhythm before the onset or after the termination of VT (**see Fig. 39.4**). His bundle deflections dissociated from more rapid ventricular activation are diagnostic of VT, with rare exceptions.

Successful electrical induction of VT by premature ventricular stimulation depends on the characteristics of the VT and the anatomic substrate (**see Fig. 39.4**). Patients with sustained, hemodynamically stable VT and VT secondary to prior myocardial infarction (MI) have monomorphic VT induced more frequently (90%) than patients with nonsustained VT, VT from non–coronary-related causes or acute ischemia, and cardiac arrest (40% to 75%). In general, it is more difficult to induce VT with late premature ventricular stimuli than with early premature stimuli, during sinus rhythm than during ventricular pacing, with one premature stimulus than with two or three, and in normal hearts without drugs on board. The specificity of VT induction using more than two premature ventricular stimuli begins

to decrease, whereas the sensitivity increases; nonsustained polymorphic VT or VF can be induced in patients with no history of VT. On occasion, VT can be initiated only from the left ventricle or from specific sites in the right ventricle when they are closer to the reentrant circuit. Multiple premature stimuli can reduce the need for LV stimulation. Drugs such as isoproterenol can facilitate the induction of VT, as can alcohol.

Termination by pacing depends on the mechanism (reentrant VT can be pace-terminated), rate of the VT, and the site of pacing. Slower VTs are terminated more easily and with fewer stimuli. An increasing number of stimuli are required to terminate more rapid VTs, which increases the risks associated with pacing-induced VT acceleration.

Clinical Features

Symptoms during VT depend on the ventricular rate, duration of the tachycardia, and the presence and extent of the underlying heart disease and peripheral vascular disease. VT can occur in several forms: short, asymptomatic, nonsustained episodes; sustained, hemodynamically stable events (generally occurring at slower rates or in otherwise normal hearts); or unstable runs, often resulting in hemodynamic collapse and degenerating into VF. VTs initially nonsustained can later become sustained. Physical findings depend in part on the P-to-QRS relationship. If atrial activity is dissociated from the ventricular contractions, the findings of AV dissociation are present. If the atria are captured retrogradely, regularly occurring cannon *a* waves appear when atrial and ventricular contractions occur simultaneously, and signs of AV dissociation are absent.

Most patients treated for symptomatic recurrent VT have ischemic heart disease. The next largest group has cardiomyopathy (both congestive and hypertrophic; **see Chapters 77 and 78**), with lesser percentages divided among those with primary electrical disease such as inherited ion channel abnormalities (**Chapter 33**), idiopathic VT, congenital heart disease (**Chapter 75**), and miscellaneous causes. LV hypertrophy can lead to ventricular arrhythmias, as can areas of fibrosis detected by gadolinium magnetic resonance imaging (MRI; **Chapter 17**). Coronary artery spasm can cause transient myocardial ischemia with ventricular arrhythmias in some patients, during ischemia as well as during the apparent reperfusion period (**Chapter 59**). Many patients resuscitated from SCD (**Chapter 42**) have CAD or cardiomyopathy. When VT occurs in an ambulatory patient, it is infrequently induced by R-on-T PVCs. Patients with sustained VT are more likely to have a reduced EF, slowed intraventricular conduction and electrographic abnormalities (e.g., wide QRS), LV aneurysm, and previous MI. In patients with CAD, sustained VT displays a circadian variation, with the peak frequency occurring in the morning.

Many approaches have been used to assess prognosis in patients with ventricular arrhythmias, although none has sufficient positive or negative predictive value (**see Chapter 35**). Inducibility of VT during an EPS, reduced LV function, spontaneous ventricular arrhythmias, late potentials on a signal-averaged ECG, QT-interval dispersion, T wave alternans, prolonged QRS duration, heart rate turbulence, decreased heart rate variability, and reduced baroreceptor sensitivity all carry increased risk for total mortality and sudden death. Currently, however, no technique reliably predicts outcome better than assessment of LV function. LV function and inducibility of VT during EPS are the two strongest predictors of a poor outcome. In general, the prognosis for patients with idiopathic VT (see later) in the absence of structural heart disease is good, and less aggressive treatment is warranted than for patients with structural heart disease. Patients with inherited arrhythmia syndromes are an exception to this statement (**see Chapter 33**).

Management

Multiple large clinical trials have led to alterations of the management of VT and aborted sudden death (**Table 39.3**). Management decisions can be stratified into those involved in acute management (or termination) and those involved in long-term therapy (or prevention of recurrence or sudden death; **see Chapters 36 and 42**).

TABLE 39.3

Clinical Trials on the Treatment of Ventricular Tachycardia and Prevention of Cardiac Arrest

STUDY	PATIENT INCLUSION	ENDPOINTS	TREATMENT ARMS	KEY RESULTS
Primary Prevention Studies				
BHAT[a]	Post-MI	Total mortality SCD	Propranolol Placebo	Total mortality, sudden cardiac death reduced in the treatment arm
CAST[b,c]	Post-MI ≥6 PVCs/hr LVEF ≤40%	Arrhythmic death	Flecainide Encainide Moricizine Placebo	Arrhythmic death increased in all treatment arms
SWORD[d]	Post-MI LVEF <40% *or* Remote MI NYHA Class II-III	Total mortality	*d*-Sotalol Placebo	Increased mortality in the treatment arm
EMIAT[e]	Post-MI LVEF <40%	Total mortality Arrhythmic death	Amiodarone Placebo	Amiodarone reduced arrhythmic death but not total mortality
CAMIAT[f]	Post-MI ≥10 PVCs/hr or NSVT	Arrhythmic death Total mortality	Amiodarone Placebo	Amiodarone reduced arrhythmic death but not total mortality
GESICA[g]	CHF LVEF ≤35%	Total mortality	Amiodarone Best therapy	Amiodarone reduced mortality; patients with NSVT had higher mortality
CHF-STAT[h]	CHF LVEF ≤40% ≥10 PVCs/hr (asymptomatic)	Total mortality	Amiodarone Placebo	No effect on ischemic cardiomyopathy but trend toward reduced mortality in nonischemic cardiomyopathy
CABG-PATCH[i]	CAD undergoing CABG LVEF <36% Positive SAECG	Total mortality	CABG CABG + ICD	No difference in total mortality
MADIT[j]	Post-MI NSVT LVEF ≤35% NYHA Class I-III Inducible VT not suppressed by procainamide	Total mortality	ICD AAD (80% amiodarone)	ICD reduced mortality
MUSTT[k]	Post-MI LVEF <40% NSVT	Arrhythmic death or cardiac arrest	ICD in nonsuppressible group AAD in suppressible group No therapy	Improved survival in ICD group; no difference between no therapy and AAD group
MADIT II[l]	Post-MI EF ≤30% >10 PVCs/hr or couplets	Total mortality	ICD No ICD	Improved survival in ICD arm
DINAMIT[m]	Immediately post-MI EF ≤35%	Total mortality Arrhythmic mortality	ICD No ICD	No improvement in survival with ICD
IRIS[n]	Immediately post-MI EF ≤40%	Total mortality	ICD No ICD	No improvement in survival with ICD
COMPANION[o]	Ischemic or nonischemic CM NYHA Class III-IV QRS ≥120 msec	Total mortality	Medical therapy PM-CRT ICD-CRT	Improved survival in ICD-CRT group > PM-CRT > medical therapy
DEFINITE[p]	Nonischemic CM EF ≤36% PVCs or NSVT	Total mortality Arrhythmic	ICD No ICD	Improved survival in the ICD arm

		mortality		
SCD-HeFT[q]	CHF LVEF ≤35% NYHA Class II-III	Total mortality Arrhythmic mortality Cost Quality of life	ICD Amiodarone Placebo	Improved survival with ICD; no effect of amiodarone on survival
Secondary Prevention Studies				
ESVEM[r,s]	Cardiac arrest, sustained VT, or syncope ≥10 PVCs/hr Inducible VT	Recurrence of arrhythmia	EPS-guided AADs (imipramine, mexiletine, procainamide, quinidine, sotalol, pirmenol, propafenone) Holter-guided AADs	No difference between Holter- and EPS-guided groups; sotalol group had the lowest recurrence rate of VT, arrhythmic death, and total death
CASCADE[t]	Cardiac arrest Not associated with acute MI	Cardiac mortality Aborted cardiac arrest	EPS- or Holter-guided conventional drug therapy Empiric amiodarone	Survival with amiodarone better than with conventional guided drug therapy
CASH[u]	Cardiac arrest Not associated with acute MI	Total mortality	Empiric amiodarone Metoprolol Propafenone ICD	SCD mortality lowest in ICD arm; increased mortality in propafenone arm
AVID[v]	Cardiac arrest or sustained VT	Total mortality Cost Quality of life	ICD Drug therapy (empiric amiodarone or EPS- or Holter-guided sotalol)	Survival better in ICD group, with most benefit occurring in first 9 mo; benefit most pronounced in patients with EF <35%
CIDS[w,x]	Cardiac arrest or sustained VT	Total mortality	ICD Amiodarone	Survival trended better in ICD group

Acute Management of Sustained Ventricular Tachycardia

VT that does not cause hemodynamic decompensation can be treated medically to achieve acute termination by IV administration of amiodarone, lidocaine, or procainamide, followed by an infusion of the successful drug. Lidocaine is often ineffective; amiodarone and procainamide appear to be superior. However, in a randomized trial of out-of-hospital cardiac arrest, neither amiodarone nor lidocaine improved survival to hospital discharge.[5] In patients in whom procainamide is ineffective or may be problematic (severe heart failure, renal failure), IV amiodarone is frequently effective. In general, an initial amiodarone loading dose of 15 mg/min is given during a 10-minute period. This dose is followed by an infusion of 1 mg/min for 6 hours and then a maintenance dose of 0.5 mg/min for the remaining 18 hours and for the next several days, as necessary. If the VT does not terminate or if it recurs, a repeated loading dose can be given. Rarely, sinus bradycardia or AV block can be seen with IV amiodarone. The hypotension associated with IV amiodarone does not seem to be a frequent problem and is usually related to the rate of infusion.

If the arrhythmia does not respond to medical therapy, electrical direct-current (DC) cardioversion can be used. VT that precipitates hypotension, shock, angina, congestive heart failure, or symptoms of cerebral hypoperfusion should be treated promptly with DC cardioversion (**see Chapters 36 and 42**). Very low energies can terminate monomorphic VT, beginning with a synchronized shock of 10 to 50 J. After conversion of the arrhythmia to a normal rhythm, it is essential to institute measures to prevent recurrence.

When a defibrillator is not readily available, striking the patient's chest can infrequently terminate the VT. However, chest stimulation at the vulnerable period during the arrhythmia can accelerate the VT or possibly provoke VF, so backup defibrillation may be necessary.

In some cases, such as VT associated with a remote MI (which is caused by reentry), ventricular pacing via a pacing catheter inserted into the right ventricle or transcutaneously at rates faster than the tachycardia can terminate the tachycardia. This procedure incurs the risk of accelerating the VT to ventricular flutter or VF. In patients with recurrent VT, overdrive ventricular pacing can be used to prevent recurrences. Intermittent VT, interrupted by several supraventricular beats, generally is best treated pharmacologically.

A search for reversible conditions contributing to the initiation and maintenance of VT should corrected, if present. For example, VT related to ischemia, hypotension, or hypokalemia can at times be terminated by antianginal treatment, vasopressors, or potassium, respectively. Correction of heart failure can reduce the frequency of ventricular arrhythmias. Slow ventricular rates caused by sinus bradycardia or AV block can permit the occurrence of PVCs and ventricular tachyarrhythmias, which is corrected by transvenous pacing. Rarely, SVT can initiate ventricular tachyarrhythmias and should be prevented if this is the observed mechanism of VT initiation.

Long-Term Therapy for Prevention of Recurrences

Because the goal of long-term therapy is to prevent SCD and recurrence of symptomatic VT, asymptomatic nonsustained ventricular arrhythmias in low-risk populations (i.e., preserved LV function) often need not be treated. In patients with symptomatic nonsustained tachycardia, beta blockers may prevent recurrences. In patients refractory to beta blockers, class IC agents, sotalol, or amiodarone can be effective. However, class IC agents should be avoided in patients with structural heart disease, especially those with CAD, because of the increased mortality associated with these drugs secondary to their proarrhythmic effects. Sotalol should be used cautiously because of its potential for prolonging the QT interval and producing torsades de pointes. Patients with nonsustained VT after MI and poor LV function are at significant risk for sudden death. The major multicenter, randomized implantable cardioverter-defibrillator (ICD) trials are summarized in **Table 39.3**.

For secondary prevention of sustained VT or cardiac arrest in patients with structural heart disease, class I antiarrhythmic drugs (AADs) produce a worse outcome than do class III AADs, empiric amiodarone results in better survival than does EPS-guided AADs, and ICDs provide better survival than amiodarone, particularly in patients with an LVEF less than 0.35 (**see Table 39.3 and Chapters 36 and 42**). Therefore, in patients who have survived cardiac arrest or who have sustained VT resulting in hemodynamic compromise and poor LV function, an ICD is the treatment of choice.[6] In patients who refuse an ICD, empiric amiodarone may be the next best therapy, although no reduction in mortality was found in SCD-HeFT. The optimal therapy for patients with CAD who have preserved LV function with *sustained* VT is not currently known. Empiric amiodarone appears to be the safest therapy, although Holter-guided sotalol has been advocated, and ablation of monomorphic VT may be effective and preferable long-term.[7] Some patients who receive ICDs experience frequent shocks because of recurrent VT. In these patients, concomitant therapy with amiodarone or VT ablation may be required to reduce the frequency of VT or to slow the rate of the VT so that it can be pace-terminated. Other drugs, such as sotalol, procainamide, mexiletine, and flecainide, may be required if amiodarone is not effective. On occasion, a combination of drugs can be effective when a single drug is not. Ablation can also be considered in this situation. Although RF ablation of certain types of idiopathic VT (see later) is very effective (**see Chapter 36**), ablation for postinfarction VT or that associated with dilated cardiomyopathy is somewhat less effective. In addition, because of the significant mortality associated with these arrhythmias in patients with structural heart disease and depressed LV function, ablation is generally used as an adjunct to ICD placement to reduce the frequency of VT and ICD shocks.[8] However, in patients with

well-tolerated postinfarction VT and well-preserved LV function, or in patients refractory to drugs, ablation can be used as first-line therapy. In patients with VT or VF, prophylactic ablation of the VT substrate can reduce future shocks.[7]

Specific Types of Ventricular Tachycardia

A number of fairly specific types of VT have been identified, and distinction is based on a constellation of electrocardiographic and electrophysiologic features, a specific set of clinical events, and genetics (**see Chapter 33**). These different types of VT often have different prognoses and responses to different therapy.

Ventricular Arrhythmias in Patients with Cardiomyopathies

See **Chapters 61, 77, and 78**.

Ischemic Cardiomyopathy

Patients with previous MI are at risk for developing VT.[9] In the setting of a remote MI, the mechanism of VT is reentry and involves the infarct scar, in particular the border zone or other areas of the scar with deranged conduction (**see Chapter 34**). As a result, the VT in this setting is typically monomorphic, sometimes with more than one morphology because of different exit sites, reversal of the direction of reentry using the same circuit, or other circuits in the infarct scar. Polymorphic VT or VF in the setting of ischemic heart disease usually occurs during active ischemia or infarction.

Treatment of VT in the patient with ischemic heart disease follows the recommendations described earlier. In general, ICDs are indicated to prevent SCD from VT, especially in those with depressed LV function. Monomorphic VT in this setting is often amenable to pace termination from the ICD. In patients with preserved LV function and no hemodynamic compromise, optimal long-term treatment is still controversial. Primary suppression with AADs (e.g., amiodarone), implantation with an ICD, antitachycardia pacing, and ablation are options. Newer approaches to ablation of VT caused by a previous infarct scar have increased the efficacy,[10] but the recurrence rate is high because of multiple circuits, and ablation is in general reserved for refractory VT or well-tolerated VT (**see Chapter 36**). Surgical endocardial resection of the scarred area is also an effective treatment of refractory VT caused by previous MI. For recurrent VT or VT storm refractory to medications or ablation, cardiac sympathetic denervation has been effective in limited studies.

Nonischemic Cardiomyopathy

Both dilated and hypertrophic cardiomyopathy can be associated with VTs and an increased risk for SCD (**see Chapter 77**). Induction of VT by programmed stimulation does not reliably identify high-risk patients. Because it is difficult to predict patients at risk for SCD or those who might respond favorably to an AAD, ICDs have been advocated for patients with life-threatening ventricular arrhythmias and dilated cardiomyopathy (**see Table 39.3**). Bundle branch reentry can be the basis of some VTs in this population and can be treated by ablation of the right bundle branch. In patients with refractory or recurrent VT, ablation is an effective adjunct to an ICD, but ablation from the epicardial surface is often required.[10]

Hypertrophic Cardiomyopathy

The risk for SCD in patients with hypertrophic cardiomyopathy is increased by the presence of syncope, a

family history of SCD in first-degree relatives, septal thickness greater than 3 cm, or the presence of nonsustained VT on 24-hour electrocardiographic recordings (**see Chapter 78**). Asymptomatic or mildly symptomatic patients with brief and infrequent episodes of nonsustained VT have low mortality. Electrophysiologic testing to risk-stratify for ventricular arrhythmias and SCD is controversial and has not been shown to reliably identify patients at increased risk. Amiodarone has been useful in some patients with mildly symptomatic, nonsustained VT, but not in improving survival. Septal alcohol ablation and myotomy/myectomy have been useful in reducing the outflow gradient, but their role in reducing ventricular arrhythmias has not been established. Currently, no totally acceptable way to risk-stratify patients with hypertrophic cardiomyopathy in terms of VT has been identified. In patients believed to be at high risk for SCD or those with sustained VT or frequent nonsustained VT, an ICD may be indicated.[11]

Arrhythmogenic Right Ventricular Cardiomyopathy

Arrhythmogenic right ventricular cardiomyopathy (ARVC), also called arrhythmogenic right ventricular dysplasia (ARVD), is a heterogeneous inherited disease that results in fibrofatty infiltration of predominantly the right ventricle, although the disease can also affect the left ventricle, typically the posterior portion (**see Chapters 33 and 77**). Mutations in genes that encode various proteins of the desmosome (plakoglobin, desmoplakin, plakophilin, desmoglein, and desmocollin) have been found to cause the disease but are present in only approximately 50% of patients.[12] Right-sided heart failure or asymptomatic right ventricular (RV) enlargement can be present. Male patients predominate, and most are usually found to have an abnormal right ventricle on echocardiography, RV angiography, or MRI, although this abnormality may not be apparent on initial evaluation. Patients with ARVC have VT that generally has an LBBB contour (because the tachycardia arises in right ventricle) and can have several morphologies (including those consistent with outflow tract VT). The ECG during sinus rhythm can exhibit complete or incomplete RBBB and T wave inversions in V_1 to V_3. A terminal notch in the QRS, called an *epsilon wave,* can be present as a result of slowed intraventricular conduction. Findings on the signal-averaged ECG can be abnormal because of delayed conduction in the right ventricle (**Fig. 39.8A**).

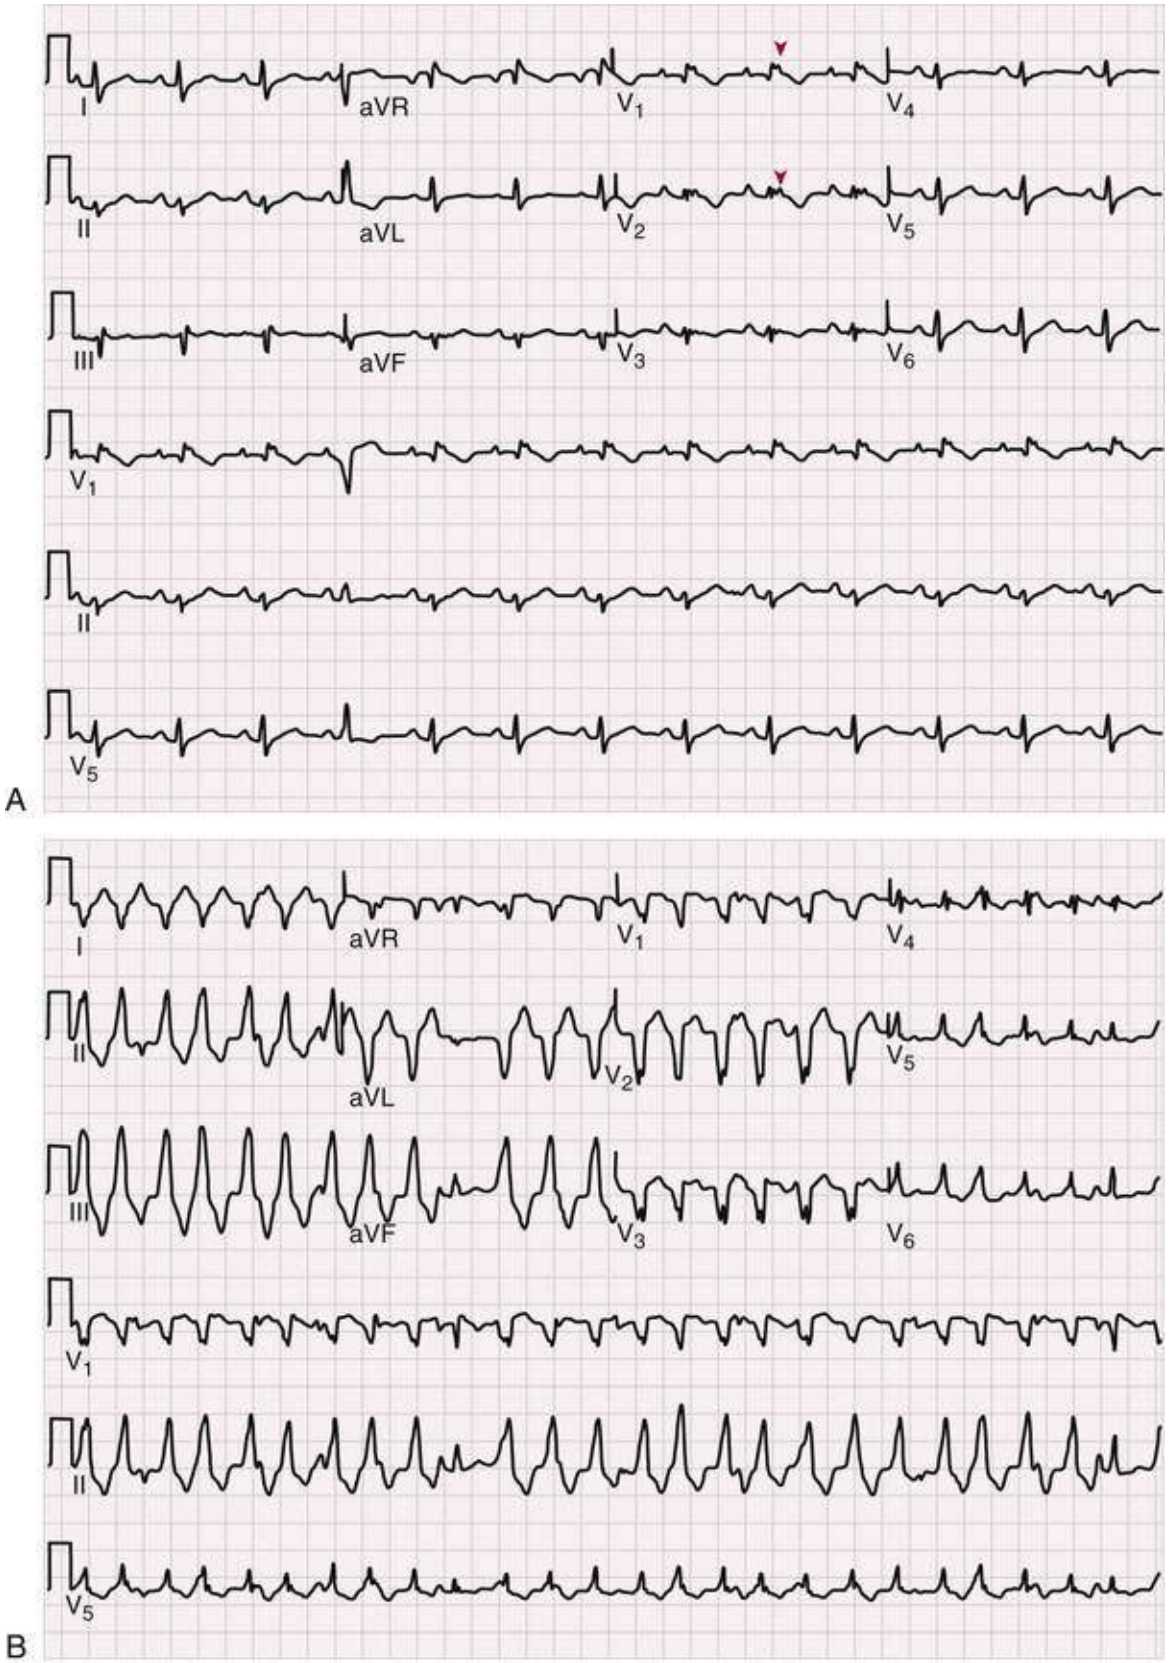

FIGURE 39.8 **A,** Normal sinus rhythm in a patient with arrhythmogenic right ventricular (RV) cardiomyopathy (dysplasia). The *arrowheads* in V_1 and V_2 point to late RV activation called an epsilon wave. **B,** VT in the same patient with RV dysplasia.

ARVC can be an important cause of ventricular arrhythmia in children and young adults with apparently normal hearts, as well as in older patients. The initial findings can be subtle and often mimic those of outflow tract VT, manifested only by tachycardia and no symptoms of right-sided heart failure. Diagnosis of ARVD can be elusive because of nonspecific findings on several tests depending on the stage and severity of the disease, desmosomal mutations present in only approximately 50% of cases, and low

penetrance of the inherited trait. Therefore the diagnosis of ARVD is based on fulfilling the diagnostic criteria established by the ARVD Task Force to provide guidance on the role of diagnostic tests and specificity[13] (**Table 39.4**). ICDs are generally preferable to pharmacologic approaches because of the progressive nature of the disease and poor prognosis, particularly if the patient has poorly tolerated VT resulting in syncope or SCD. RF catheter ablation can be tried but often requires ablation of multiple morphologies, as well as extensive substrate ablation to eliminate all potential reentrant circuits.[7,13] Because most of the circuits and scarring are located on the epicardial surface, epicardial ablation is often required.

TABLE 39.4

Diagnostic Criteria for Arrhythmogenic Right Ventricular (RV) Cardiomyopathy

Definite diagnosis	2 major criteria *or*
	1 major and 2 minor criteria *or*
	4 minor criteria from different categories
Borderline	1 major and 1 minor criteria *or*
	3 minor criteria from different categories
Possible	1 major *or*
	2 minor criteria from different categories
	CRITERIA
I. Global or Regional Dysfunction and Structural Alterations	
Major criteria	*By two-dimensional echocardiography*: Regional RV akinesia, dyskinesia,* or aneurysm *and* 1 of the following (end diastole): PLAX RVOT ≥32 mm (corrected for body size—PLAX/BSA ≥19 mm^2) PSAX RVOT ≥36 mm (corrected for body size—PSAX/BSA ≥21 mm^2) Fractional area change ≤33%
	By MRI: Regional RV akinesia or dyskinesia or dyssynchronous RV contraction *and* 1 of the following: Ratio of RV end-diastolic volume to BSA ≥110 mL/m^2 (male) or ≥100 mL/m^2 (female) RV ejection fraction ≤40%
	By RV angiography: Regional RV akinesia, dyskinesia, or aneurysm
Minor criteria	*By two-dimensional echocardiography*: Regional RV akinesia or dyskinesia *and* 1 of the following (end diastole): PLAX RVOT ≥29 to <32 mm (corrected for body size—PLAX/BSA ≥16 to ≤19 mm/m^2) PSAX RVOT ≥32 to <36 mm (corrected for body size—PSAX/BSA ≥18 to <21 mm/m^2) Fractional area change >33% to ≤40%
	By MRI: Regional RV akinesia or dyskinesia or dyssynchronous RV contraction *and* 1 of the following: Ratio of RV end-diastolic volume to BSA ≥100 to <110 mL/m^2 (male) or ≥90 to <100 mL/m^2 (female) RV ejection fraction >40% to ≤45%
II. Tissue Characterization of Wall	
Major criteria	Residual myocytes <60% by morphometric analysis (or <50% if estimated), with fibrous replacement of the RV free wall myocardium in ≥1 sample, with or without fatty replacement of tissue on endomyocardial biopsy
Minor criteria	Residual myocytes 60% to 75% by morphometric analysis (or 50% to 65% if estimated), with fibrous replacement of the RV free wall myocardium in ≥1 sample, with or without fatty replacement of tissue on endomyocardial biopsy
III. Repolarization Abnormalities	
Major criteria	Inverted T waves in right precordial leads (V_1, V_2, and V_3) or beyond in individuals >14 yr (in the absence of complete RBBB QRS ≥120 msec)
Minor criteria	Inverted T waves in leads V_1 and V_2 in individuals >14 yr (in the absence of complete RBBB) or in V_4, V_5, or V_6
	Inverted T waves in leads V_1, V_2, V_3, and V_4 in individuals >14 yr in the presence of complete RBBB
IV. Depolarization/Conduction Abnormalities	
Major criteria	Epsilon wave (reproducible low-amplitude signals between end of QRS complex to onset of T wave) in right precordial leads (V_1 to V_3)
Minor criteria	Filtered QRS duration (fQRS) ≥114 msec
	Duration of terminal QRS ≤40 μV (low-amplitude signal duration) ≥38 msec
	Root-mean-square voltage of terminal 40 msec ≤20 μV
	Terminal activation duration of QRS ≥55 msec measured from nadir of S wave to end of QRS, including R′, in V_1, V_2, or V_3, in the absence of complete RBBB
V. Arrhythmias	
Major criteria	Nonsustained or sustained VT of LBBB morphology with superior axis (negative or indeterminate QRS in leads II, III, and aVF and positive in lead aVL)
Minor criteria	Nonsustained or sustained ventricular tachycardia of RV outflow configuration, LBBB morphology with inferior axis (positive QRS in leads II, III, and aVF and negative in lead aVL) or of unknown axis
	>500 ventricular extrasystoles per 24 hr (Holter)
VI. Family History/Genetics	
Major criteria	ARVC/D confirmed in a first-degree relative who meets the current task force criteria
	ARVC/D confirmed pathologically at autopsy or surgery in a first-degree relative
	Identification of a pathogenic mutation† categorized as associated or probably associated with ARVC/D in the patient under evaluation
Minor	History of ARVC/D in a first-degree relative in whom it is not possible or practical to determine whether the family member meets the current task force criteria

criteria	Premature sudden death (<35 yr) because of suspected ARVC/D in a first-degree relative
	ARVC/D confirmed pathologically or by current task force criteria in a second-degree relative

*Hypokinesis is not included in this or subsequent definitions of RV regional wall motion abnormalities for the proposed modified criteria.

†A pathogenic mutation is a DNA alteration associated with ARVC/D that alters or is expected to alter the encoded protein, is unobserved or rare in a large non-ARVC/D control population, and either alters or is predicted to alter the structure or function of the protein or has demonstrated linkage to the disease phenotype in a conclusive pedigree.

ARVC/D, Arrhythmogenic right ventricular cardiomyopathy/dysplasia; *aVF,* augmented voltage unipolar left foot lead; *aVL,* augmented voltage unipolar left arm lead; BSA, body surface area; *LBBB,* left bundle branch block; *PLAX,* parasternal long-axis view; *PSAX,* parasternal short-axis view; *RBBB,* right bundle branch block; *RVOT,* right ventricular outflow tract; *VT,* ventricular tachycardia.

From Marcus FI, McKenna WJ, Sherrill D, et al. Diagnosis of arrhythmogenic right ventricular cardiomyopathy/dysplasia: proposed modification of the task force criteria. Circulation 2010;121:1533.

Tetralogy of Fallot

Chronic serious ventricular arrhythmias can occur in patients years after repair of tetralogy of Fallot (**see Chapter 75**). Sustained VT after repair can be caused by reentry at the site of previous surgery in the RV outflow tract and can be cured by resection or catheter ablation of this area. Findings on the signal-averaged ECG can be abnormal. Decreased cardiac output can occur during VT and residual RV outflow obstruction and lead to VF. In some patients, worsening of pulmonary insufficiency and RV dilation can trigger the VT. Replacement of the pulmonic valve and concomitant cryoablation of the outflow tract may be required to eliminate the tachycardia.

Inherited Arrhythmia Syndromes (see Chapter 33)

Catecholaminergic Polymorphic Ventricular Tachycardia

Catecholaminergic polymorphic VT (CPVT) is an uncommon form of inherited VT that occurs in the absence of overt structural heart disease.[14-17] Mutations in genes encoding proteins responsible for intracellular calcium handling have been identified as causes of the disease.[18] Patients typically have syncope or aborted sudden death with highly reproducible, stress-induced VT that is often bidirectional. These patients have no structural heart disease and normal QT intervals. A family history of sudden death or stress-induced syncope is present in approximately 30% of cases. During exercise, typical responses include initial sinus tachycardia and ventricular extrasystoles, followed by salvoes of monomorphic or bidirectional VT, which eventually lead to polymorphic VT as exercise continues (**Fig. 39.9**). The treatment of choice is beta blockers[17] and an ICD, although breakthrough can occur despite beta blockade. Left-sided or bilateral sympathectomy has been reported to be effective in a few cases (**see Chapter 99**). In addition, flecainide inhibits ryanodine receptor–mediated calcium release and has had some clinical success.[17] Patients with CPVT should be instructed to avoid vigorous exercise.

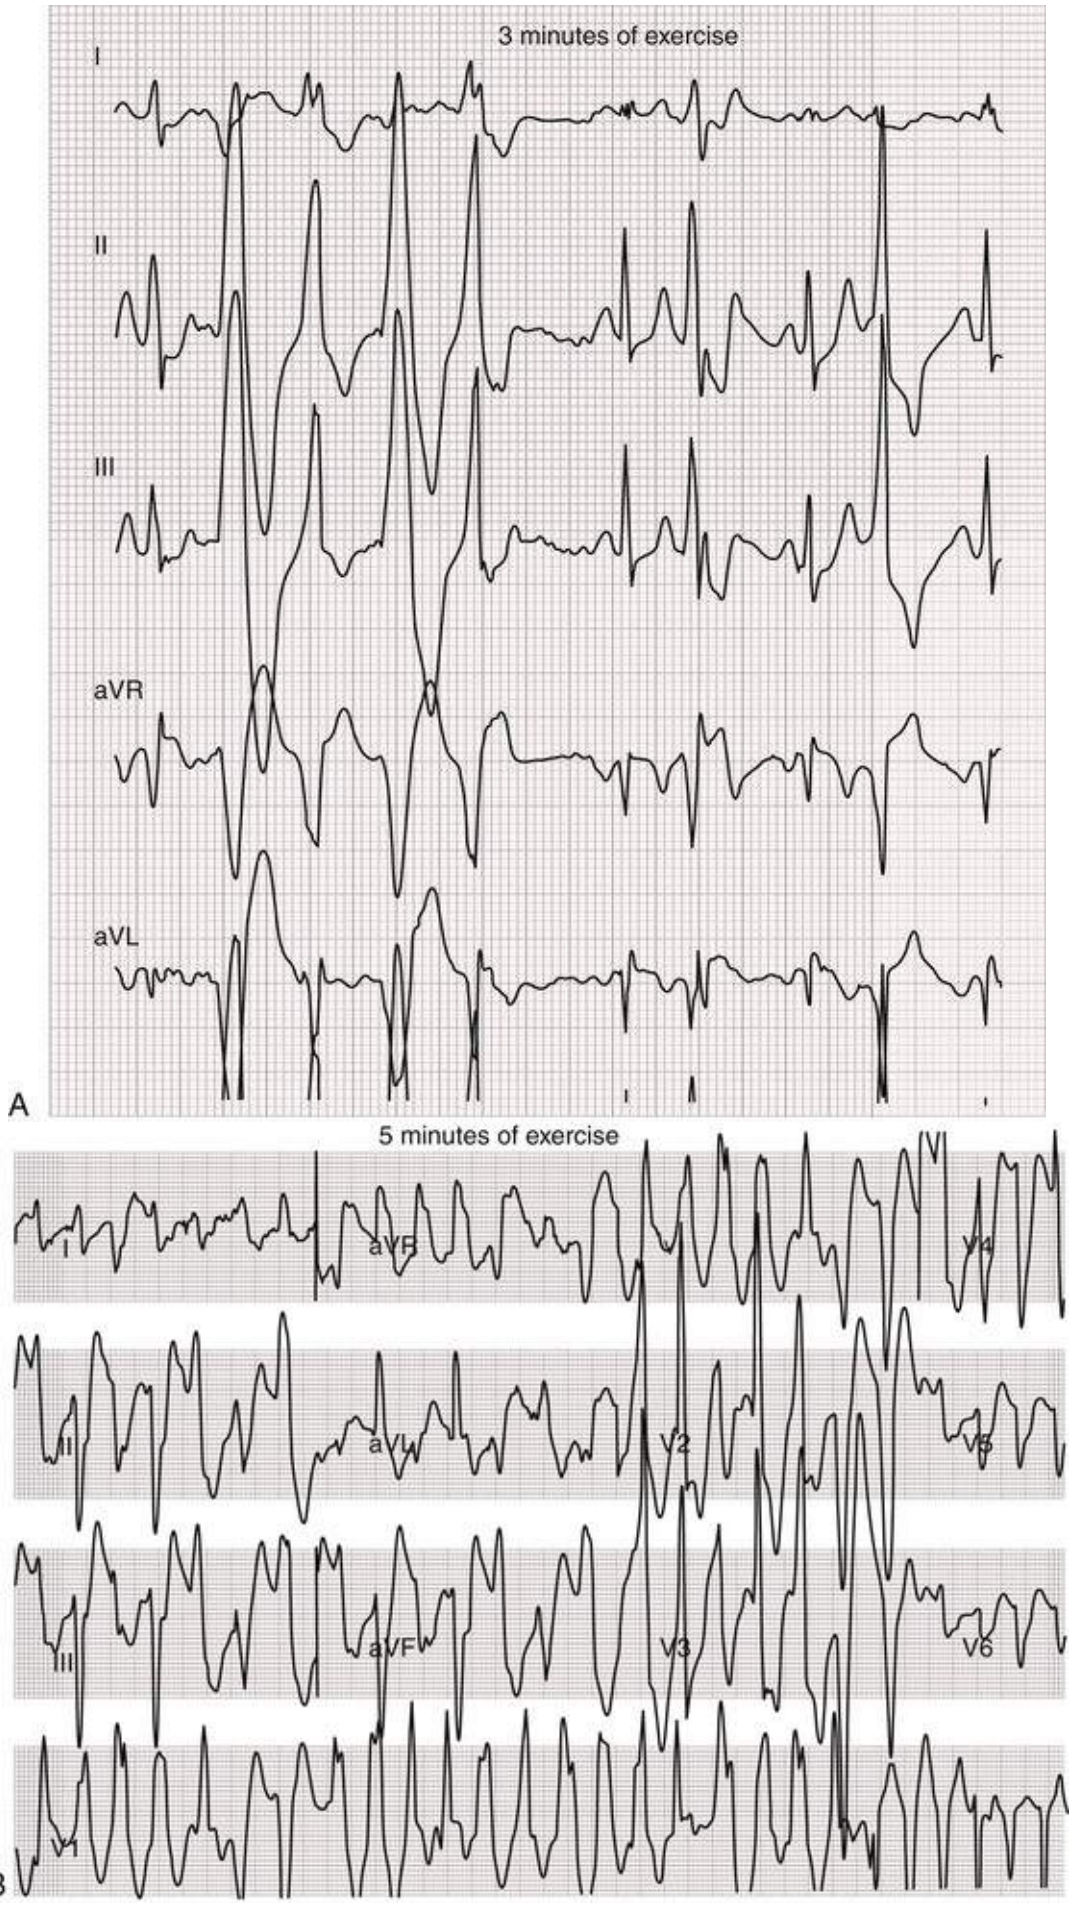

FIGURE 39.9 ECG obtained during an exercise treadmill test in a patient with catecholaminergic polymorphic VT. **A,** During the early phase of exercise, short runs of polymorphic VT and PVCs occur. **B,** With further exercise, bidirectional VT ensues.

Torsades de Pointes

Electrocardiographic Recognition

The term *torsades de pointes* (TdP) refers to a VT characterized by QRS complexes of changing amplitude that appear to twist around the isoelectric line and occur at rates of 200 to 250 per minute (**Fig. 39.10A**). Originally described in the setting of bradycardia caused by complete heart block, TdP usually connotes a syndrome, not simply an electrocardiographic description of the QRS complex of the tachycardia, characterized by prolonged ventricular repolarization with QT intervals generally exceeding 500 milliseconds. The U wave can also become prominent and merge with the T wave, but its role is not clear. The abnormal repolarization need not be present or at least prominent in all beats, but it may be apparent only on the beat before the onset of TdP (i.e., after a PVC). Long-short R-R cycle sequences usually precede the onset of TdP from acquired causes. Relatively late PVCs can discharge during termination of the long T wave and precipitate successive bursts of VT, during which the peaks of QRS complexes appear successively on one side and then on the other side of the isoelectric baseline; these peaks give the typical twisting appearance with continuous and progressive changes in QRS contour and amplitude. TdP can terminate with progressive prolongation of cycle length and larger and more distinctly formed QRS complexes and culminate in a return to the basal rhythm, a period of ventricular standstill, and a new attack of TdP or VF.

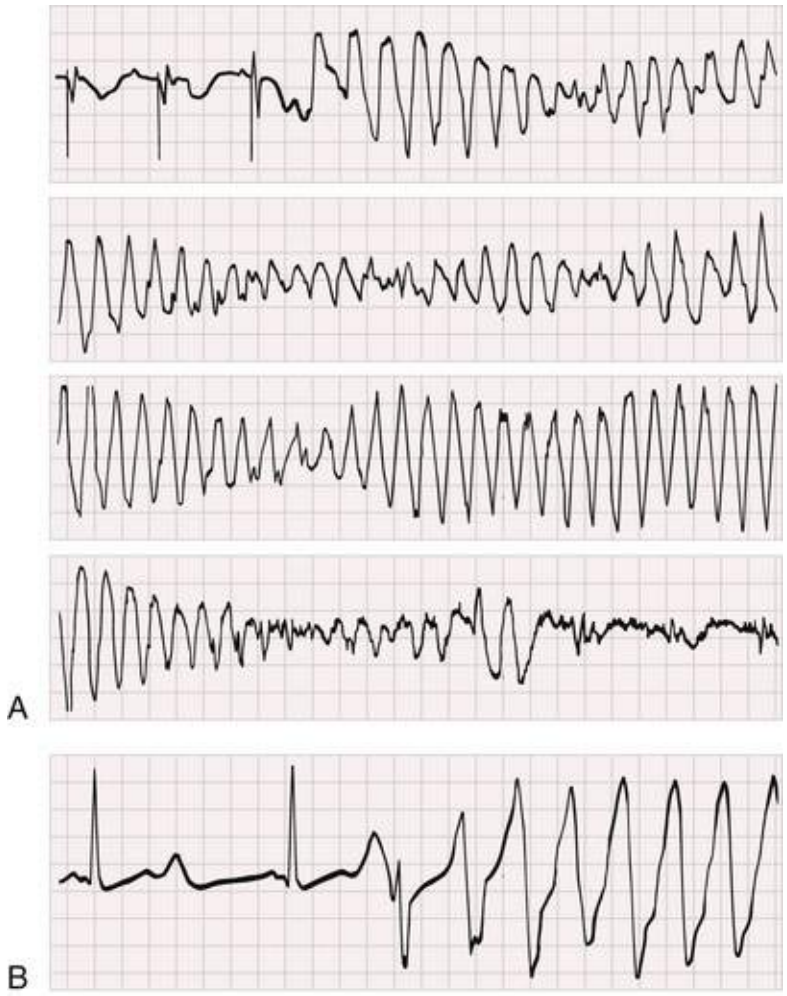

FIGURE 39.10 Torsades de pointes. **A,** Continuous monitor lead recording. A demand ventricular pacemaker (VVI) had been implanted because of a type II second-degree AV block. After treatment with amiodarone for recurrent VT, the QT interval became prolonged (approximately 640 msec during paced beats), and episodes of TdP developed. In this recording the tachycardia spontaneously terminates, and a paced ventricular rhythm is restored. Motion artifact is noted at the end of the recording as the patient lost consciousness. **B,** Tracing from a young boy with congenital long-QT syndrome. The QTU interval in the sinus beats is at least 600 milliseconds. Note the TU wave alternans in the first and second complexes. A late premature complex occurring in the downslope of the TU wave initiates an episode of VT.

A less common form, the short-coupled variant of TdP, is a malignant disease with a high mortality rate that shares several characteristics with idiopathic VF. The ventricular arrhythmia in this setting is initiated with a close-coupled PVC and does not usually involve preceding pauses or bradycardia.

VT that is similar morphologically to TdP and occurs in patients without QT prolongation, whether spontaneous or electrically induced, should generally be classified as polymorphic VT, not as TdP. The distinction has important therapeutic implications (see later).

Electrophysiologic Features

The electrophysiologic mechanisms responsible for TdP are not completely understood. Most data suggest that early afterdepolarizations (EADs) are responsible for both long-QT syndrome and TdP, or at least its initiation (**see Chapter 34**). Perpetuation can be caused by triggered activity, reentry resulting from dispersion of repolarization produced by the EADs, or abnormal automaticity. However, most data currently point to transmural reentry as the most likely mechanism of perpetuation.

Clinical Features

Although many predisposing factors have been cited for TdP, the most common causes are congenital

severe bradycardia, potassium depletion, and use of QT-prolonging medications, such as class IA or III AADs. More than 50 drugs have been noted to prolong the QT interval. Clinical features depend on whether the TdP is caused by acquired or congenital (idiopathic) long-QT syndrome (see later). Symptoms from the tachycardia depend on its rate and duration, as with other VTs, and range from palpitations to syncope and death. Women, perhaps because of a longer QT interval, are at greater risk than men for TdP.

Management

The approach to management of VT with a polymorphic pattern depends on whether it occurs in the setting of a prolonged QT interval. For this practical reason, and because the mechanism of the tachycardia can differ according to whether a long QT interval is present, it is important to restrict the definition of torsades de pointes to the typical polymorphic VT in the setting of a long QT or U wave in the basal complexes. In all patients with TdP, administration of class IA, possibly some class IC, and class III AADs (e.g., amiodarone, dofetilide, sotalol) can increase the abnormal QT interval and worsen the arrhythmia. IV magnesium is the initial treatment of choice for TdP from an acquired cause, followed by temporary ventricular or atrial pacing. Isoproterenol, given cautiously because it may exacerbate the arrhythmia, can be used to increase the rate until pacing is instituted. Lidocaine, mexiletine, or phenytoin can be tried. The cause of the long QT should be determined and corrected, if possible. When the QT interval is normal, polymorphic VT resembling TdP is diagnosed, and standard AADs can be prescribed. In borderline cases the clinical context may help determine whether treatment should be initiated with AADs. Torsades de pointes resulting from congenital long-QT syndrome is treated with beta blockade, pacing, and ICDs (see later). ECGs obtained from close relatives can help secure the diagnosis of long-QT syndrome in borderline cases.

Long-QT Syndrome

Electrocardiographic Recognition

The upper limit for duration of the normal QT interval corrected for heart rate (QTc) is often given as 0.44 second (**see Fig. 39.10B**). However, the normal QTc interval may actually be longer (0.46 second in men and 0.47 second in women), with a normal range of ±15% of the mean value. The nature of the U wave abnormality and its relationship to long-QT syndrome (LQTS) are not clear. The probable risk for development of life-threatening ventricular arrhythmias in patients with idiopathic LQTS is related to the length of the QTc interval, with risk increasing at values of 500 milliseconds or longer. T wave “humps” on the ECG can suggest the presence of LQTS and can be caused by EADs. Unique T wave contours have been ascribed to specific genotypes causing LQTS.

Clinical Features

Long-QT syndrome can be divided into congenital and acquired forms. The congenital form is a familial disorder that can be associated with sensorineural deafness (Jervell and Lange-Nielsen syndrome, autosomal recessive) or normal hearing (Romano-Ward syndrome, autosomal dominant). Congenital LQTS is caused by inherited channelopathies created by mutations in one or more genes[19,20] (**see Chapter 33**).

Patients with the acquired form may also have an underlying genetic predisposition, with a long QT interval developing from various drugs, such as quinidine, procainamide, *N*-acetylprocainamide, sotalol,

amiodarone, disopyramide, phenothiazines, tricyclic antidepressants, erythromycin, pentamidine, some antimalarials, cisapride, and probucol. Other causes are electrolyte abnormalities (e.g., hypokalemia, hypomagnesemia), effects of a liquid protein diet and starvation, central nervous system lesions, significant bradyarrhythmias, cardiac ganglionitis, and mitral valve prolapse. A more comprehensive list that is regularly updated can be found at https://www.crediblemeds.org.

Patients with congenital LQTS can initially have syncope, at times misdiagnosed as epilepsy, as a result of TdP. Sudden death can occur in this group of patients; it develops in approximately 10% of pediatric patients without preceding symptoms. In some patients the ventricular arrhythmia becomes sustained and probably transitions to VF to cause SCD. Patients with LQTS at increased risk for SCD include those with family members who died suddenly at an early age and those who have experienced syncope. Exercise, particularly swimming, and emotional stress appear to be triggers in LQT1, with lethal cardiac events occurring more frequently at rest or during sleep in LQT3. Patients with LQT2 have many events occurring during emotional stress or a sudden loud noise (e.g., telephone or alarm clock) (**see Chapter 33**).

Stress testing can prolong the QT interval and produce T wave alternans, the latter indicative of electrical instability. ECGs should be obtained for all family members when the proband has symptoms. Premature ventricular stimulation electrically does not generally induce arrhythmias in this syndrome, and EPSs are not usually helpful in making the diagnosis.

Management

For patients who have LQTS but not syncope, complex ventricular arrhythmias, a family history of SCD, or a QTc interval of 500 milliseconds or more, no therapy or treatment with a beta blocker is generally recommended. In asymptomatic patients with complex ventricular arrhythmias, a family history of early SCD, or a QTc interval of 500 milliseconds or more, beta adrenoceptor blockers such as nadolol at maximally tolerated doses are recommended. Implantation of a permanent pacemaker to prevent the bradycardia or pauses that may predispose to the development of TdP may be indicated. In patients with syncope or aborted sudden death, an ICD is warranted. These patients should also be treated with concomitant beta blockers. An ICD is beneficial in these patients not simply because of its shocking capabilities, but also because of the ability to pace continually for prevention of bradycardia-induced TdP and algorithms to prevent post-PVC pauses. Use of an ICD in patients without syncope but with a long QT interval and a strong family history of SCD is still controversial but may be warranted in select high-risk patients (**see Chapter 36**).

Left-sided cervicothoracic sympathetic ganglionectomy that interrupts the stellate ganglion and the first three or four thoracic ganglia may be helpful and can be done thorascopically. Participation in competitive sports, previously contraindicated for patients with congenital LQTS, has been liberalized.[21,22] For patients with the acquired form and TdP, IV magnesium and atrial or ventricular pacing are initial choices. Avoidance of precipitating drugs is mandatory.

Short-QT Syndrome

An inherited syndrome resulting in a short QT interval carries an increased risk for sudden death because of VF[23] and may be one of the syndromes responsible for “idiopathic VF.” Patients with short-QT syndrome (SQTS) are also prone to the development of AF. Several genetic abnormalities have been identified, many of which are gain-of-function mutations in the same genes that cause LQTS (**see Chapter 33**). Diagnostic criteria proposed by an expert consensus recommendation[14] includes QTc of 330

milliseconds or less or QTc of 360 milliseconds or less *and* at least one clinical criterion: pathogenic mutation, family history of SQTS or SCD before or at age 40, or survival of VT/VF arrest without heart disease. In many patients with SQTS, the QT does not change with the heart rate, and thus the conventional formulas for QT correction may not apply to these patients. A short QT interval on an ECG without a family history of SCD or a history of syncope, palpitations, or AF may not necessarily indicate an increased risk for SCD, and similarly, some patients with known SQTS mutations have QT intervals in the lower range of normal. Patients often have persistently short QT intervals, short or absent ST segments, and tall and narrow T waves in the precordial leads. Other causes of SQTS, such as hyperkalemia, hypercalcemia, hyperthermia, acidosis, and digitalis, should be excluded.

ICDs are considered the treatment of choice in symptomatic patients with SQTS to prevent SCD. AADs that prolong refractoriness have reportedly been effective in some patients. In particular, quinidine was effective in patients with a gain-of-function mutation in the *HERG* (*KCNH2*) gene.

J Wave Syndromes

The J wave, also referred to as the Osborn wave, is the junction of the QRS complex and the ST segment on a surface ECG. The J wave can be accentuated in hypothermia and hypercalcemia. It is now recognized that spontaneous accentuation of the J wave (previously thought to be benign), may predispose to ventricular arrhythmias (polymorphic VT and VF).[24] The J wave syndromes—a spectrum of pathologic early repolarization predisposing to ventricular arrhythmias—includes Brugada syndrome (BrS) and early repolarization syndrome (ERS). BrS and ERS share several features: male predominance (70% to 80%); average age of first event in fourth to sixth decade; ECG abnormalities are often dynamic and can be augmented by sodium channel blockers and fever; VF often occurs in sleep and can be triggered by short-coupled PVCs; and association with $I_{K.ATP}$ gain-of-function or I_{Na} or I_{Ca} loss-of-function mutations (**see Chapter 33**). The main differences between the syndromes lie in the region of the myocardium most affected and thus the ECG leads in which the J wave abnormalities are seen. BrS predominantly affects the RV outflow tract and thus ECG leads V_1 to V_3. ERS affects the inferior LV wall and thus ECG leads I, II, III, aVF, aVL, and V_4 to V_6. In addition, there is a higher prevalence of AF, structural abnormalities (primarily RV) and late potentials on signal-averaged ECG in BrS (sometimes making the differential between BrS and ARVC difficult).

The precise mechanisms of the J wave syndromes are not entirely clear. The majority of evidence points to abnormalities in the transmural gradient of the action potential notch (caused by I_{to}) present in the epicardium but not endocardium because of an abnormal transmural distribution of I_{to} (**see Chapter 35**). The mechanism of VT/VF in these patients likely results from phase 2 reentry because of this repolarization gradient. However, at least in BrS, conduction slowing may also play a role.

Brugada Syndrome

Brugada syndrome is characterized by an RBBB and ST-segment elevation in the anterior precordial leads, often without evidence of structural heart disease[24,25] (**Fig. 39.11**) (**see Chapter 33**). BrS is more common in apparently healthy young Southeast Asians but also exists in other areas of the world and ethnicities. Findings on the ECG are characterized as type 1, type 2, or type 3 patterns (**Table 39.5** and **eFig. 39.1**), seen in leads V_1 to V_3. Placing the right precordial leads in the second or third intercostal space (“high leads”) can increase the sensitivity of detecting a type 1 pattern. Only type 1 is diagnostic of BrS. Signature findings on the ECG can be transient, and subtle similar ECG changes can be found in

patients without BrS, making the diagnosis difficult in patient without spontaneous type 1 patterns captured at presentation. The 2013 consensus statement on inherited arrhythmias[14] and the 2015 European Society of Cardiology (ESC) guidelines for management of ventricular arrhythmias[7] proposed diagnostic criteria for BrS as 2 mm or more of ST-segment elevation in one or more right precordial leads placed in the second, third, or fourth intercostal space, occurring spontaneously or provoked by a class I drug. According to these guidelines, a type 2 or 3 pattern is only diagnostic when it converts to a type 1 pattern with drug provocation. However, since the population with the drug-provoked type 1 pattern is at relatively low risk, the 2016 consensus report on J wave syndromes[24] proposes a modification to the diagnostic criteria: when type 1 ST-segment elevation is only provoked by a class I drug, diagnosis of BrS is made only with one additional clinical feature: documented VF or VT, syncope of probable arrhythmic cause, family history of SCD before age 45, family history of Brugada type 1 pattern, or nocturnal agonal respirations.

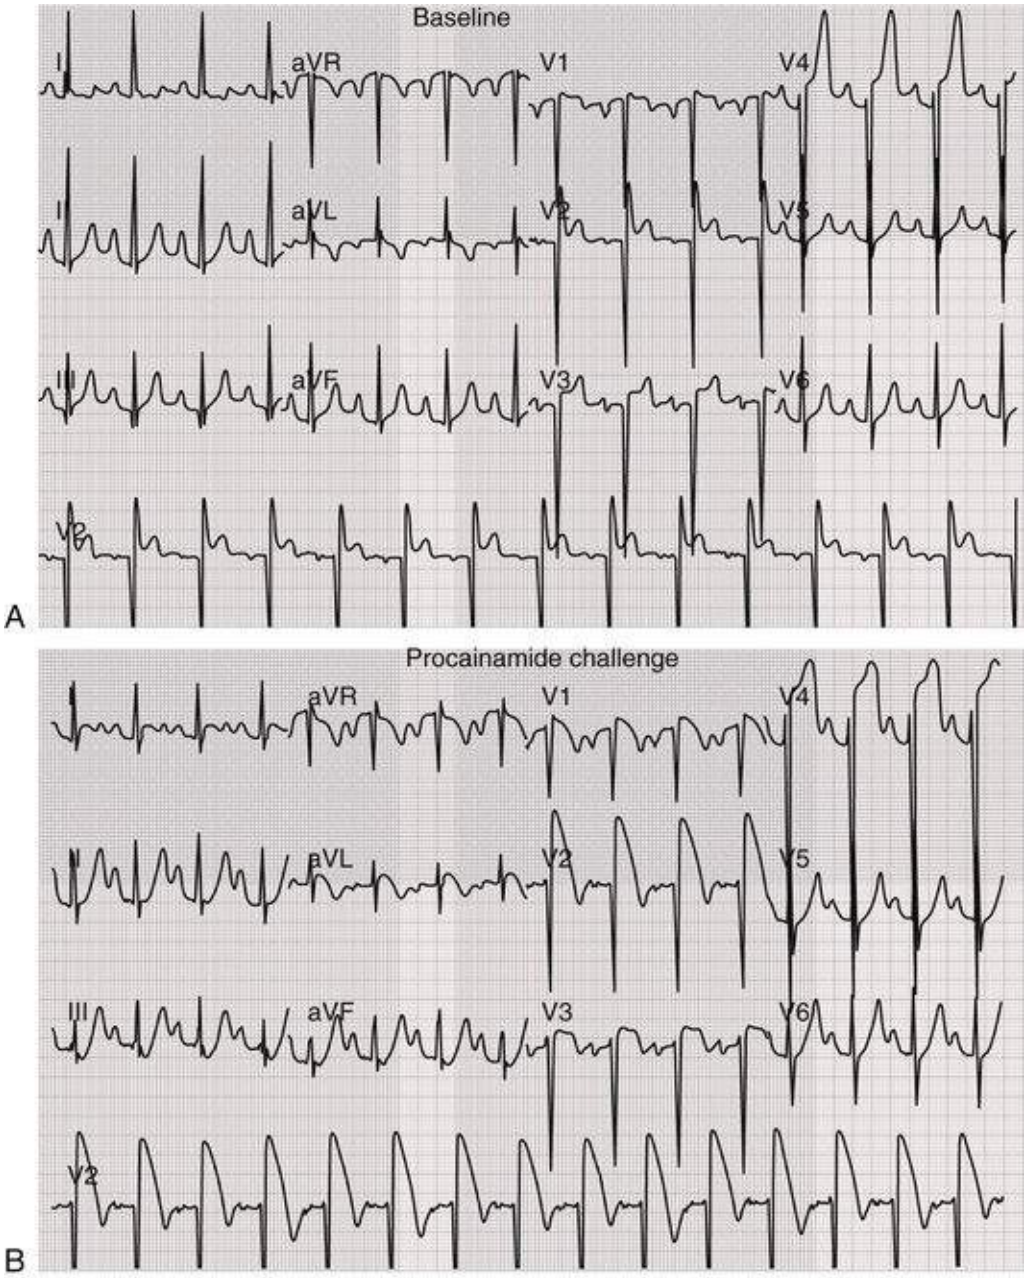

FIGURE 39.11 **A,** Twelve-lead ECG of a patient with Brugada syndrome. The ECG is characterized by a right bundle branch block pattern and persistent ST elevation in leads V_1 through V_3. This ECG shows a type 2 Brugada pattern with a "saddleback" ST-segment elevation greater than 1 mm and a biphasic T wave in V_1 (positive in V_2-V_3). **B,** After procainamide challenge, the prototypic changes on the ECG are exaggerated, with an increase in ST elevation, and the ECG shows a type 1 pattern with a downward-sloping coved ST elevation and negative T waves in V_1 to V_3.

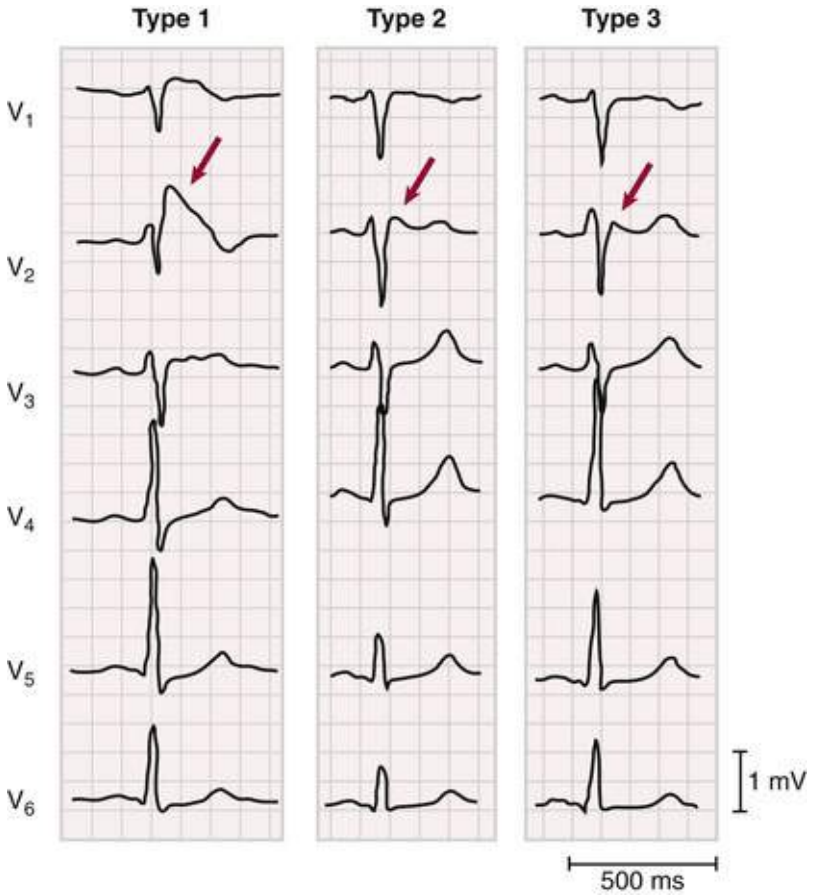
TABLE 39.5

Characteristics of Brugada-Pattern Electrocardiograms

	TYPE 1	TYPE 2	TYPE 3
J wave amplitude	≥2 mm	≥2 mm	≥2 mm
T wave	Negative	Positive or biphasic	Positive
ST-T configuration	Coved	Saddleback	Saddleback
ST segment (terminal portion)	Gradually descending	Elevated ≥1 mm	Elevated <1 mm

From Wilde AAM, Antzelevitch C, Borggrefe M, et al. Proposed diagnostic criteria for the Brugada syndrome: consensus report. Circulation 2002;106:2514.



EFIGURE 39.1 Precordial leads of a patient with Brugada syndrome showing dynamic changes on the ECG over several days. The second two ECGs (types 2 and 3) were obtained from the same patient as the first ECG (type 1), just 13 days later. *Arrows* denote the J wave. (From Wilde AAM, Antzelevitch C, Borggrefs M, et al. Proposed diagnostic criteria for the Brugada syndrome: consensus report. Circulation 2002;106:2514.)

Controversy remains as to whether additional risk stratification is useful in BrS.[26] Drug challenge with a class I AAD (procainamide, flecainide, ajmaline, or pilsicainide) to provoke ECG changes should be considered when there is a clinical suspicion of BrS in the absence of a diagnostic type 1 ECG pattern. Drug challenge is not indicated in patients with spontaneous type 1 Brugada pattern (whether the patient is symptomatic or not) since there is no additional diagnostic value. Other causes of ST elevation mimicking Brugada type 1 pattern (RBBB, pectus excavatum, occlusion of left anterior descending or conus branch, ARVC) should be excluded. EPSs to risk-stratify patients remain controversial, with some suggesting that VT/VF inducibility is unable to identify high-risk patients with BrS and others demonstrating an increased risk (especially with fewer extrastimuli).[27,28] However, a negative EPS does not predict low risk in patients with clinical risk factors (aborted SCD, spontaneous VT/VF or syncope), and the most recent consensus statement proposes that EPS may be considered in asymptomatic patients with type 1 Brugada pattern.[24] An ICD should be considered if such a patient has inducible VT/VF with two or less extrastimuli. A spontaneous ECG pattern of BrS (type 1), a history of syncope, ventricular refractoriness less than 200 milliseconds, and QRS fragmentation were the best predictors of a high-risk group.[28] Mutations in *SCN5A* account for 18% to 28% of BrS cases, with mutations in the voltage-gated calcium channel (*CACNA1C, CACNB2b, CACNA2D1*) accounting for about another 13%. A variety of mutations in other genes involved in regulation of I_{Na} (loss of function), I_{Ca} (loss of function), I_{to} (gain of function), or $I_{K.ATP}$ (gain of function) have been rarely reported. Genetic testing may not be helpful in risk stratification, although it can be helpful in family screening if there is an identifiable causative mutation (**see Chapter 33**).

ICD implantation is warranted in patients with BrS with aborted SCD or spontaneous VT/VF (class I

indication) or with a history of syncope (class IIa).[7] ICD implantation may be considered in patients with a type 1 ECG pattern and inducible VT/VF with two or less extrastimuli.[24] Ablation in the epicardium of the anterior RV outflow tract can normalize the ECG and suppress VT, perhaps by eliminating the I_{to}-rich area of the RV outflow tract.[29] Ablation may be considered in patients with frequent ICD shocks (class IIb).[7,24] Quinidine can normalize the ECG and suppress the VT, presumably by blocking the calcium-independent transient outward potassium current (I_{to}), or perhaps a late sodium current. Quinidine has been effective in patients with frequent or storms of VT/VF on ICD (Class IIb).[7,24,30] and may also be useful in patients who qualify for an ICD but either refuse or are otherwise contraindicated (class IIa).[7,24] In patients with VT storm secondary to Brugada syndrome, low-dose isoproterenol can also be effective in suppressing the arrhythmia. In patients with diagnosed or suspected Brugada syndrome, fevers should be aggressively treated and drugs that can provoke Brugada syndrome should be avoided (see http://www.brugadadrugs.org/avoid/).

Early Repolarization Syndrome

Most patients with early repolarization are not at risk for ventricular arrhythmias. However, ERS is diagnosed in patients presenting with aborted sudden cardiac death or documented VT/VF and early repolarization pattern in the inferior and/or lateral ECG leads. This early repolarization pattern is identified as the presence of a J wave (terminal QRS notch) or J point elevation (slurred downslope of a prominent R wave) of 0.1 mV or more in two or more contiguous leads (excluding V_1 to V_3) in the setting of a narrow QRS (QRSd <120 msec), with or without ST-segment elevation.[24,31] The differential diagnosis of this pattern overlaps with BrS and includes juvenile ST patterns, stress (takotsubo) cardiomyopathy, hypothermia, hypocalcemia, pericardial disease, hypertrophy, and myocardial ischemia. ERS shares many of the same features as BrS, and although fewer mutations have been identified for ERS, these appear to be in similar genes as BrS (**see Chapter 33**).

There is currently no risk stratification strategy of patients with early repolarization ECG pattern. Electrophysiologic testing does not appear to be helpful in risk stratification. Symptoms (aborted SCD, spontaneous VT/VF, syncope), family history of SCD, and coexistence of Brugada pattern or short QT appear to be the strongest predictors of risk. Treatment is similar to that of BrS. Symptomatic patients (aborted SCD, spontaneous VT/VF, or syncope of presumed arrhythmic origin) should undergo ICD implantation. Quinidine and isoproterenol can be used to treat recurrent, frequent VT/VF. Treatment of the asymptomatic patient with an ECG pattern suggestive of ERS and a family history of SCD at an early age could be considered for ICD implantation.[24]

Idiopathic Ventricular Tachycardias

Idiopathic VT is defined as monomorphic VT in patients without structural heart disease or coronary disease. When more than one morphology of VT is present, one should suspect other disease entities, such as ARVD. Idiopathic VTs have any one of several characteristic electrocardiographic morphologies representing three distinct entities based on the location of the VT—outflow tract tachycardias, annular tachycardias, and fascicular tachycardias. The prognosis for all forms of idiopathic monomorphic VT without structural heart disease is good. They are amenable to ablation and frequently respond well to drug therapy. Idiopathic VTs with monomorphic contours can be divided into several types, based largely on anatomic location of origin.[32] Location of idiopathic VT can often be deduced from the QRS pattern on 12-lead ECG (**see Table 39.1**).

Outflow Tract Tachycardias

Right ventricular outflow tract (RVOT) VT accounts for about 70% of idiopathic VTs, while 10% to 15% originate from the LVOT. Two types, paroxysmal VT and repetitive monomorphic VT, appear to originate from the region of the RVOT (**Figs. 39.12 and 39.13**) or the LVOT; occasionally, however, outflow tract VT can also be sustained, although infrequently. Rarely the VT can originate from the proximal pulmonary artery (just beyond the pulmonic valve) or from the cusps of the aortic valve. Outflow tract VTs have a characteristic electrocardiographic appearance of an LBBB contour in V_1 and an inferior axis in the frontal plane. Distinguishing ECG features indicating RVOT origin of the VT include later precordial transition (V_3 or later) and narrower R wave duration in V_1 and V_2. Distinguishing ECG features indicating LVOT origin include the presence of an S wave in lead I, an early precordial R wave transition (V_1 to V_2), notched qrS in V_1 or V_2, and broader R wave duration in V_1 and V_2.

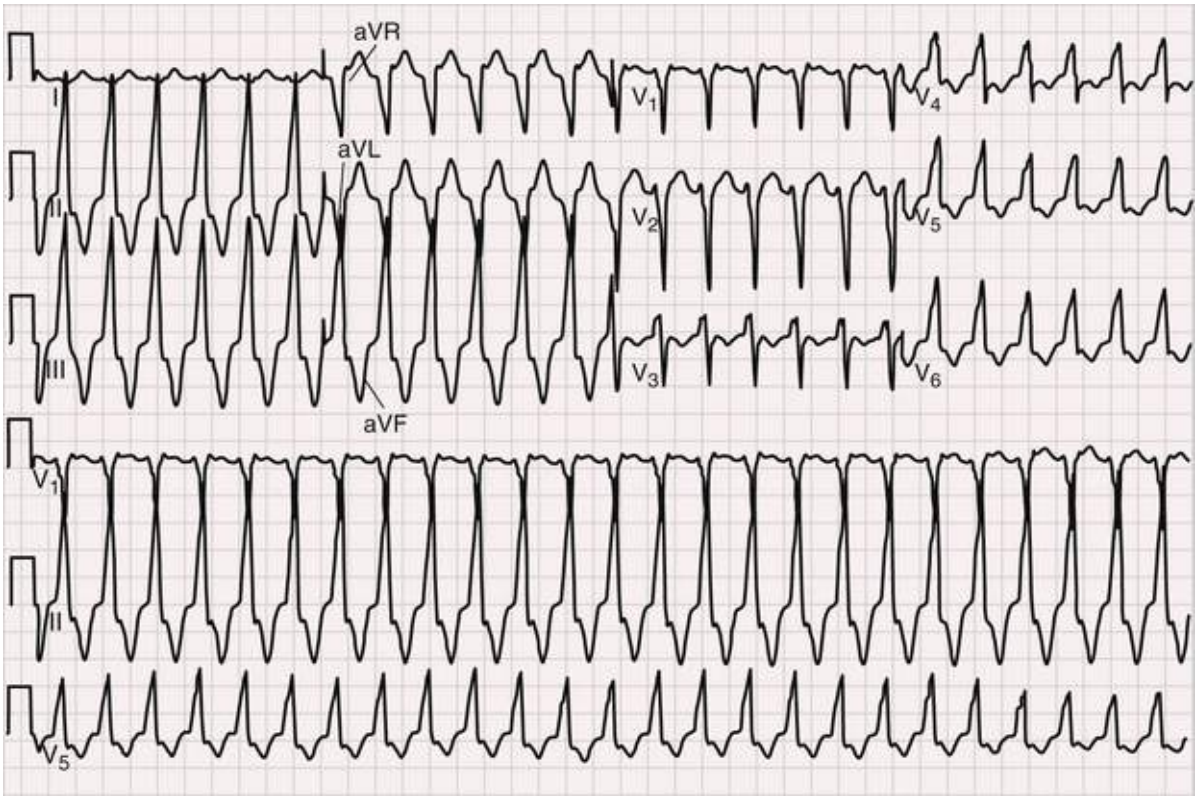


FIGURE 39.12 VT originating from the RV outflow tract. This tachycardia is characterized by a left bundle branch block contour in lead V_1 and an inferior axis.

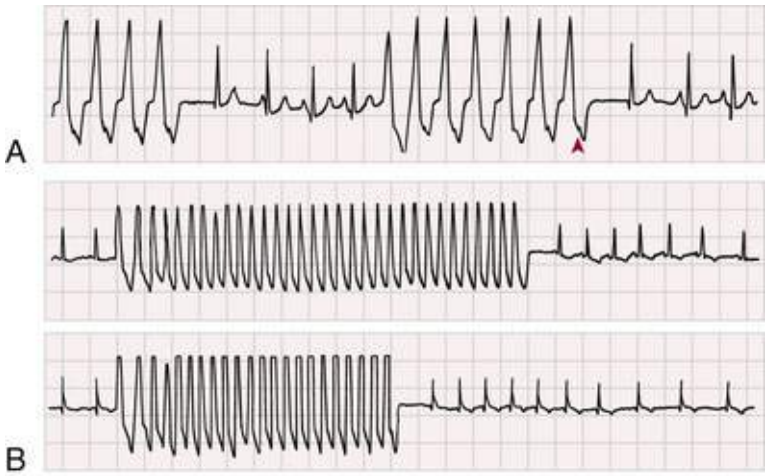

FIGURE 39.13 **A,** Repetitive monomorphic VT. Short episodes of a monomorphic VT at a rate of 160 beats/min repeatedly interrupt the normal sinus rhythm. Retrograde atrial capture probably occurs (*arrowhead* points to deflection in ST segment), and the retrograde P wave of the last complex of the repetitive monomorphic VT conducts over the normal pathway to produce a QRS complex with a normal contour. **B,** Short runs of a very rapid (260 beats/min) VT of uniform contour. They probably provoke a compensatory sympathetic response because each is followed by a brief period of sinus tachycardia. The sinus pacemaker appears to be unstable because of the resultant changes in P wave morphology.

Vagal maneuvers, including adenosine, can terminate outflow tract VT, whereas exercise, stress, isoproterenol infusion, and rapid or premature stimulation often initiate or perpetuate the tachycardia. Beta blockers and verapamil can suppress this tachycardia as well. The paroxysmal form is induced by exercise or stress, whereas the repetitive monomorphic type occurs at rest, with sinus beats interposed between runs of nonsustained VT that may be precipitated by transient increases in sympathetic activity unrelated to exertion. In a small number of patients, the tachycardia seems to arise in the inflow tract or apex of the right ventricle. The prognosis for most patients with outflow tract (RV or LV) VT is good. RF catheter ablation effectively eliminates this focal tachycardia in symptomatic patients. In others, AADs can be effective.

Annular Ventricular Tachycardias.

VTs arising from the mitral or tricuspid annulus account for 5% to 8% of idiopathic VTs, with a relative similar distribution between mitral and tricuspid. Most often these are of the repetitive monomorphic type. For mitral annular VT, the ECG morphology is typically an RBBB pattern (transition in V_1 or V_2), S wave in V_6, and monophasic R or Rs in leads V_2 through V_6. For tricuspid annular VT, the foci generally originate in the septal region, and thus the typical finding on the ECG is an LBBB pattern (Qs in lead V_1), an early transition in precordial leads (V_3), and narrower QRS complexes. These VTs behave similar to outflow tract VT, both in prognosis and in drug response. Annular VTs are amenable to ablation.

Fascicular Ventricular Tachycardia (Left Septal Ventricular Tachycardia).

A left septal VT has been described as most often arising in the left posterior septum, frequently preceded by a fascicular potential, and is sometimes called a *fascicular tachycardia* (**Fig. 39.14**). The tachycardias most often arise from the left posterior fascicle but can also arise (or exit) from the anterior fascicle. Because they arise from the fascicle, the VT appearance on an ECG typically has a rapid initial component and resembles either a typical left anterior fascicular block (for those arising from the posterior fascicle) or less frequently a typical left posterior fascicular block (for those arising from the anterior fascicle). Entrainment has been demonstrated, which suggests reentry as a cause of some of the

tachycardias. Verapamil or diltiazem often suppresses left septal VT, whereas adenosine does so only rarely, thus suggesting that I_{Ca} current may be important. Several mechanisms may be operative, and the group may not be homogeneous. Once initiated, the tachycardia is paroxysmal and sustained. Left septal VT can be started by rapid atrial or ventricular pacing and sometimes by exercise or isoproterenol. The prognosis is generally good. RF catheter ablation is effective in symptomatic patients.

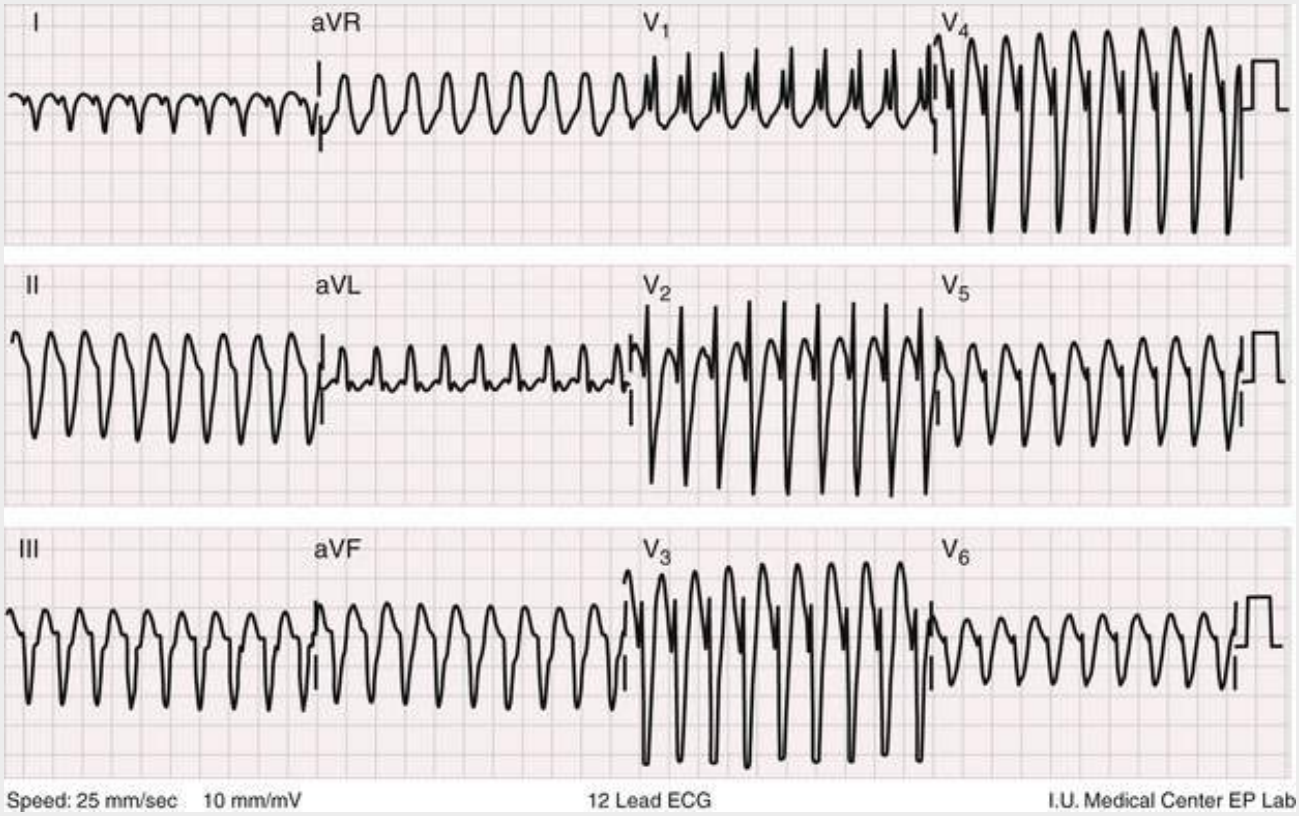

FIGURE 39.14 Left septal VT. This tachycardia is characterized by a right bundle branch block contour. In this instance the axis was rightward. The site of the VT was established to be in the left posterior septum by electrophysiologic mapping and ablation.

Other Forms of Idiopathic VT.

Several other, less common forms of idiopathic VT have also been reported. VT originating from the papillary muscle (origin from posterior papillary muscle is more common than from anterior muscle) is typically focal in origin, can have multiple morphologies, and is often exercise induced (catecholamine sensitive) and can mimic fascicular VT on ECG. In general, however, papillary muscle VT has wider a wider QRS. Papillary muscle VT is amenable to ablation.

Idiopathic VT can also arise from the crux of the heart. Anatomically, this area is an epicardial location near the junction of the middle cardiac vein and the coronary sinus. For this VT, ablation usually requires percutaneous epicardial access and can be attempted from within the coronary sinus or middle cardiac vein; however, the origin can be near the posterior descending artery.

Idiopathic Ventricular Fibrillation.

Idiopathic VF can occur in approximately 1% to 8% of individuals with out-of-hospital VF. Findings on cardiovascular evaluation are normal, except for the arrhythmia. Monomorphic VT is rarely induced at EPS. Its natural history is incompletely known, but recurrences are reported. It is important to remember that in this entity, as well as in idiopathic VT, the arrhythmia may be an early manifestation of a developing cardiomyopathy, at least in some patients. There is overlap of idiopathic VF with SQTS and J

wave syndromes (see earlier). In some cases, short-coupled PVCs can trigger VF (**Fig. 39.15**). In patients with idiopathic VF, ICDs are a useful therapeutic choice. Ablation of short-coupled PVCs that trigger VF, often from Purkinje fibers, has also been effective in reducing recurrence.

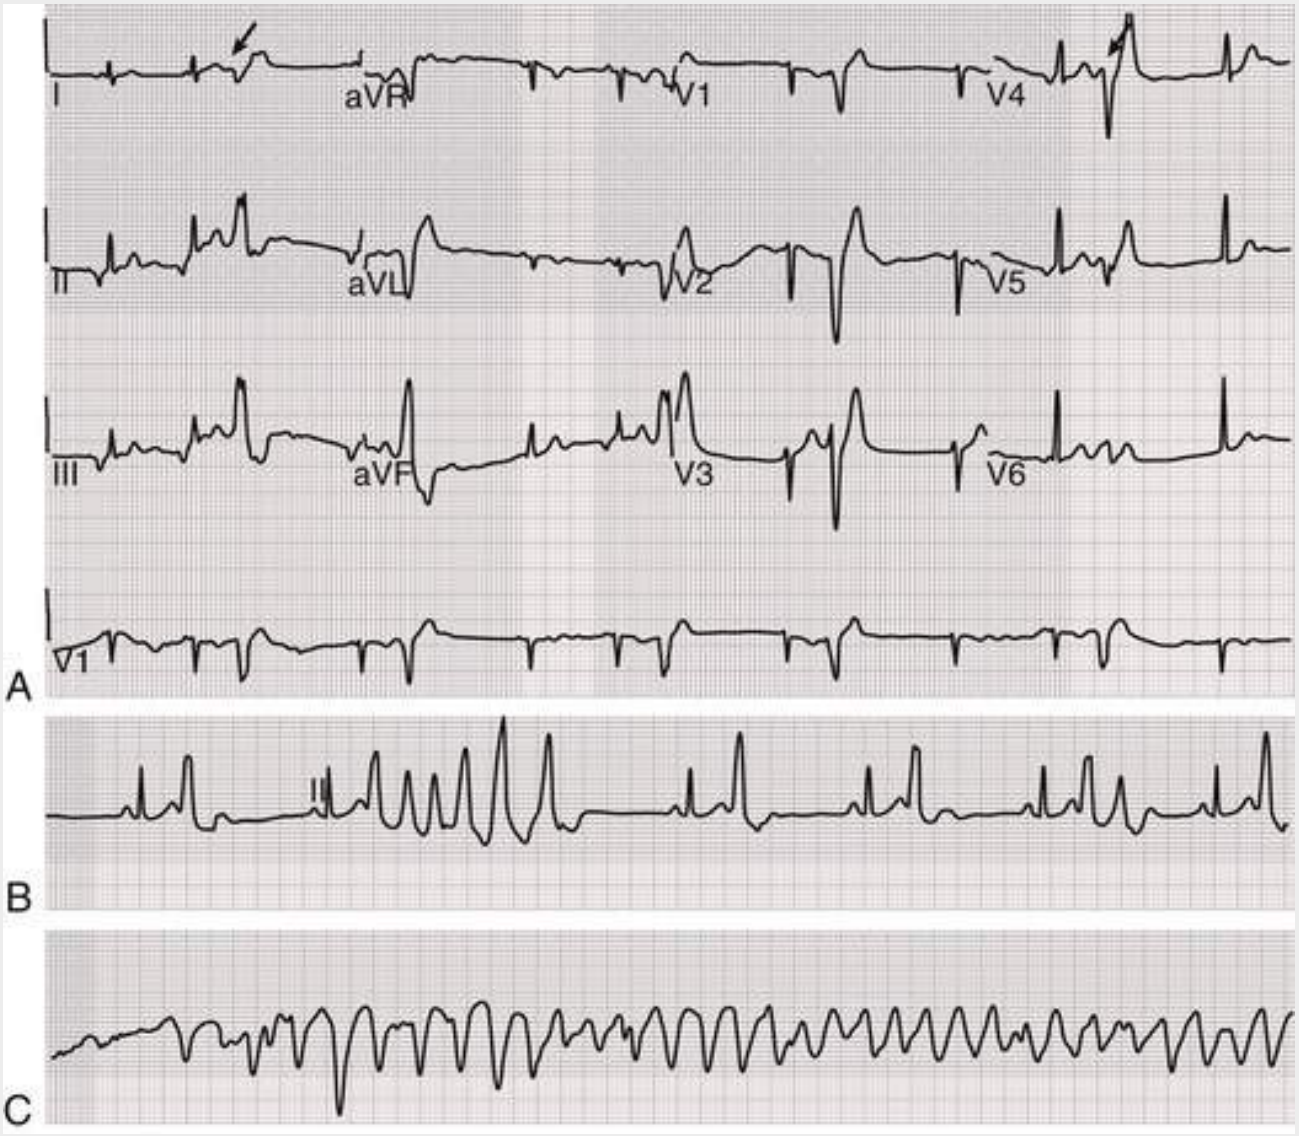

FIGURE 39.15 Tracings from a patient with idiopathic VF as a result of short-coupled premature ventricular complexes. **A,** ECG showing frequent, spontaneous short-coupled PVCs occurring on the late phase of the T wave. **B,** When occurring during bradycardia, the PVCs occur in the early phase of the T wave and produce a short run of VF. **C,** Spontaneous VF in the same patient after another short-coupled spontaneous PVC.

Bidirectional Ventricular Tachycardia.

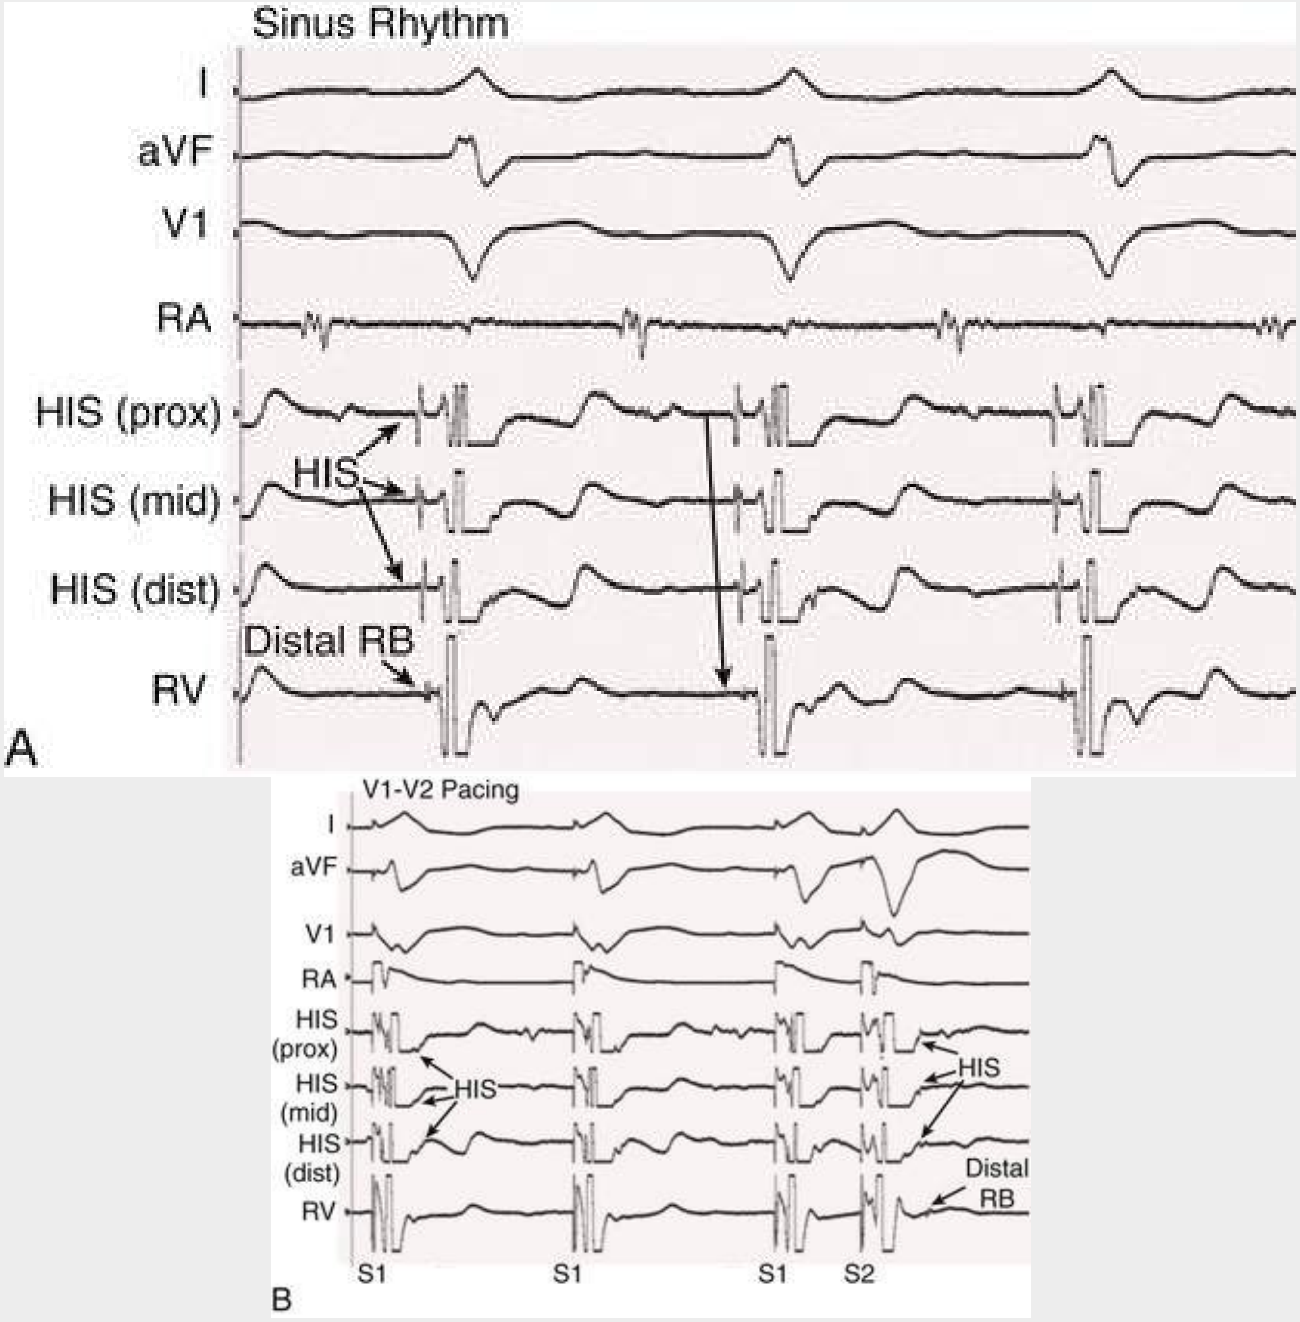
Bidirectional VT is an uncommon type of VT characterized by QRS complexes with RBBB pattern, polarity in the frontal plane alternating from −60 to −90 degrees to +120 to +130 degrees, and a regular rhythm. The ventricular rate is between 140 and 200 beats/min. Although the mechanism and site of origin of this tachycardia have remained somewhat controversial, most evidence supports a ventricular origin.

Bidirectional VT can be a manifestation of digitalis excess, typically in older patients and those with severe myocardial disease. When the tachycardia is caused by digitalis, the extent of toxicity is frequently advanced, and the prognosis is poor. As the use of digitalis has decreased, this form of VT has become very uncommon. When seen in the absence of digitalis, a diagnosis of CPVT should be

considered (**see Fig. 39.9**).

Bundle Branch Reentrant Ventricular Tachycardia.

VT secondary to bundle branch reentry is characterized by a QRS morphology determined by the circuit established over the bundle branches or fascicles. Retrograde conduction over the left bundle branch system and anterograde conduction over the right bundle branch create a QRS complex with LBBB contour and constitute the most common form. The frontal plane axis may be approximately +30 degrees. Conduction in the opposite direction produces RBBB contour. Reentry can also occur over the anterior and posterior fascicles. Electrophysiologically, bundle branch reentrant complexes are started after a critical S_2-H_2 or S_3-H_3 delay. The H-V interval of the bundle branch reentrant complex equals or exceeds the H-V interval of the spontaneous, normally conducted QRS complex (**Fig. 39.16**).



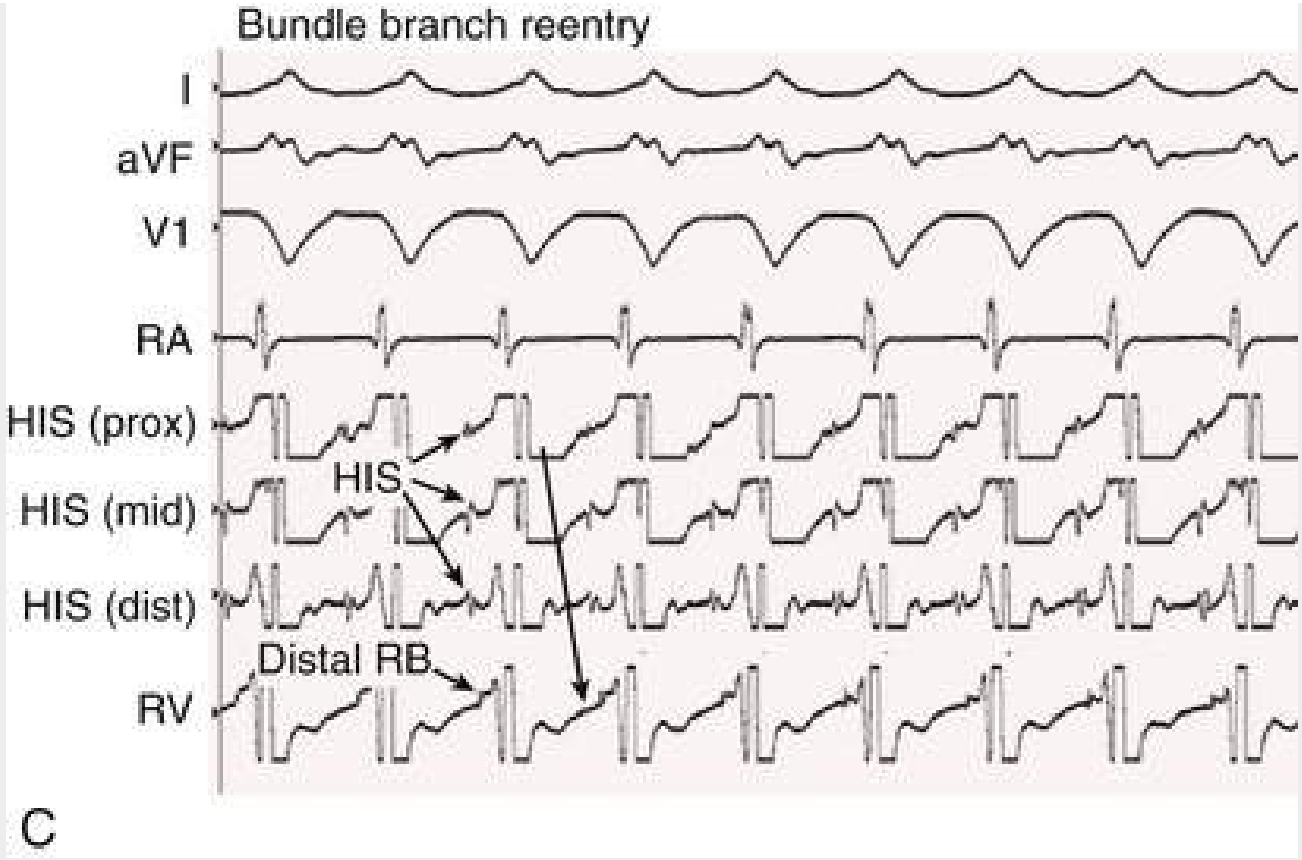


FIGURE 39.16 Surface and intracardiac recordings in a patient with inducible bundle branch reentry. Catheter position is labeled on the left. The His catheter is somewhat distal in its recording position, and the RV catheter is positioned in the right ventricle to record a distal right bundle potential. **A,** His bundle recordings and distal right bundle branch recording (on the RV catheter) during sinus rhythm. Notice that the right bundle potential (*RB*) is normally activated after the His bundle. **B,** Delay in S_2-H_2 and reversal of activation between His and right bundle during premature stimulation. During S_1 pacing, the RB is not visible because it is buried in the complex immediately after the pacing artifact (simultaneous with local ventricular activation). Following the premature beat (S_2), the His moves out (is prolonged), and the right bundle is activated after the His potential, demonstrating that with the S_2, there was unidirectional block in the retrograde right bundle, transmural conduction, retrograde up the left bundle (not recorded), and then anterograde down the distal His to the right bundle. **C,** Bundle branch reentry induced with the S_1-S_2. The distal His bundle and right bundle are activated anterogradely, and the H-V interval during bundle branch reentry is slightly longer that in sinus rhythm **(A).** *prox,* Proximal; *dist,* distal; *RA,* right atrium; *RV,* right ventricle.

Bundle branch reentry is a form of monomorphic sustained VT that is usually seen in patients with structural heart disease, such as dilated cardiomyopathy, and generally in the setting of a wide QRS during sinus rhythm because of an intraventricular conduction delay. Infrequently, bundle branch reentry can occur in the absence of myocardial disease.

The therapeutic approach is as for other types of VT; however, ablation is very effective. In the acute setting, pace termination is frequently effective.

Ventricular Flutter and Fibrillation

Electrocardiographic Recognition

Ventricular flutter and ventricular fibrillation (VF) are arrhythmias that represent severe derangements of the heartbeat that can terminate fatally or produce significant brain damage within 3 to 5 minutes unless corrective measures are undertaken promptly (**see Chapter 42**). Ventricular flutter is manifested as a sine

wave in appearance—regular large oscillations occurring at a rate of 150 to 300 beats/min (usually about 200) (**Fig. 39.17A**). Distinction between rapid VT and ventricular flutter can be difficult and is usually of academic interest only. Hemodynamic collapse is present with both. VF is recognized by the presence of irregular undulations of varying contour and amplitude (**Fig. 39.17B**). Distinct QRS complexes, ST segments, and T waves are absent. Fine-amplitude fibrillatory waves (0.2 mV) are present with prolonged VF. These fine waves identify patients with worse survival rates and are sometimes confused with asystole.

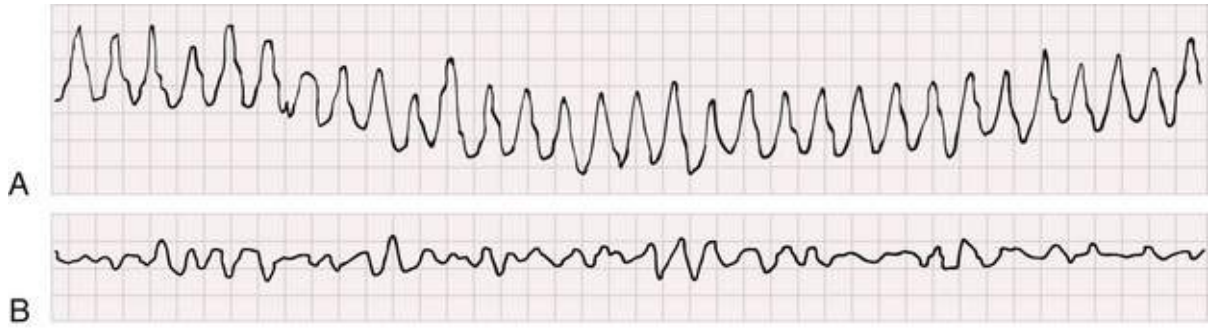

FIGURE 39.17 Ventricular flutter and VF. **A,** The sine wave appearance of the complexes occurring at a rate of 300 beats/min is characteristic of ventricular flutter. **B,** The irregular undulating baseline typifies VF.

Mechanisms

Ventricular fibrillation occurs in various clinical situations but most often in association with CAD and as a terminal event (**see Chapters 42, 58, and 59**). Cardiovascular events, including SCD from VF, occur most frequently in the morning. VF can occur during AAD administration, hypoxia, ischemia, or AF that results in very rapid ventricular rates in patients with preexcitation syndrome; after electrical shock administered during cardioversion (**see Chapters 36 and 41**) or accidentally by improperly grounded equipment; and during competitive ventricular pacing to terminate VT.

Clinical Features

Ventricular flutter or VF results in faintness, followed by loss of consciousness, seizures, apnea, and eventually, if the rhythm continues untreated, death. Blood pressure is unobtainable, and heart sounds are usually absent. The atria can continue to beat at an independent rhythm for a time or in response to impulses from the fibrillating ventricles. Eventually, electrical activity of the heart ceases (**see Chapter 42**).

Management

Management should follow basic life support and advanced cardiac life support guidelines (**see Chapter 42**). Immediate nonsynchronized DC electrical shock using 200 to 400 J is mandatory therapy for VF, ventricular flutter, and pulseless VT. Cardiopulmonary resuscitation is performed only until the defibrillation equipment is ready or if the “downtime” has been long. Defibrillation requires fewer joules if it is done early. If the circulation is markedly inadequate despite return to sinus rhythm, closed-chest massage should be instituted. The use of anesthesia during electrical shock is dictated by the patient's condition but is not generally required. After conversion of the arrhythmia to a normal rhythm, it is essential to monitor the rhythm continuously and to institute measures to prevent recurrence. Metabolic

acidosis quickly follows cardiovascular collapse. If the arrhythmia is terminated within 30 to 60 seconds, significant acidosis does not occur.

Bradyarrhythmias and Atrioventricular Block

Jeffrey E. Olgin, Douglas P. Zipes

Bradyarrhythmias

Bradyarrhythmia is arbitrarily defined as a heart rate less than 60 beats/min. Frequently, bradyarrhythmias are physiologic, as in well-conditioned athletes with low resting heart rates or in type I atrioventricular (AV) block during sleep. In other cases, bradyarrhythmias can be pathologic. Similar to tachyarrhythmias, bradyarrhythmias can be categorized on the basis of the level of disturbance in the hierarchy of the normal impulse generation and conduction system (from sinus node to AV node to His-Purkinje system) (**see Chapter 37 and Table 37.1**).

Sinus Bradycardia

Electrocardiographic Recognition

Sinus bradycardia is diagnosed in an adult when the sinus node discharges at a rate less than 60 beats/min (**Fig. 40.1A**). P waves have a normal contour and occur before each QRS complex, usually with a constant PR interval longer than 120 milliseconds. Sinus arrhythmia often coexists.

FIGURE 40.1 **A,** Sinus bradycardia at a rate of 40 to 48 beats/min. The second and third QRS complexes (*arrowheads*) represent junctional escape beats. Note the P waves at the onset of the QRS complex. **B,** Nonrespiratory sinus arrhythmia occurring as a consequence of digitalis toxicity. Monitor leads were used.

Clinical Features

Sinus bradycardia can result from excessive vagal or decreased sympathetic tone, as an effect of medications, or from anatomic changes in the sinus node. In most cases, symptomatic sinus bradycardia is caused by the effects of medication. Asymptomatic sinus bradycardia frequently occurs in healthy young adults, particularly well-trained athletes, and decreases in prevalence with advancing age. During sleep, the normal heart rate can fall to 35 to 40 beats/min, especially in adolescents and young adults, with marked sinus arrhythmia sometimes producing pauses of 2 seconds or longer. Eye surgery, coronary arteriography, meningitis, intracranial tumors, increased intracranial pressure, cervical and mediastinal tumors, and certain disease states (e.g., severe hypoxia, myxedema, hypothermia, fibrodegenerative changes, convalescence from some infections, gram-negative sepsis, mental depression) can produce sinus bradycardia. Sinus bradycardia also occurs during vomiting or vasovagal syncope (**see Chapter 43**) and can be produced by carotid sinus stimulation or by the administration of parasympathomimetic drugs, lithium, amiodarone, beta adrenoceptor–blocking drugs, clonidine, propafenone, ivabradine (a specific I_f pacemaker current blocker; **see Chapters 34 and 37**), or calcium antagonists. Conjunctival instillation of beta blockers for glaucoma can produce sinus or AV nodal abnormalities, especially in elderly patients.

In most cases, sinus bradycardia is a benign arrhythmia and can actually be beneficial by producing a longer period of diastole and increasing ventricular filling time, especially for heart failure patients. It can be associated with syncope caused by an abnormal autonomic reflex (cardioinhibitory; **see Chapter 43**). Sinus bradycardia occurs in 10% to 15% of patients with acute myocardial infarction (MI) and may be even more prevalent when patients are seen in the early hours of infarction. Unless it is accompanied by hemodynamic decompensation or arrhythmias, sinus bradycardia is generally associated with a more favorable outcome after MI than sinus tachycardia. It is usually transient and occurs more commonly during inferior than during anterior MI; it has also been noted during reperfusion with thrombolytic agents (**see Chapter 62**). Bradycardia that follows resuscitation from cardiac arrest is associated with a poor prognosis.

Management

Treatment of sinus bradycardia is not usually necessary unless cardiac output is inadequate or arrhythmias result from the slow rate. Atropine (0.5 mg intravenously as an initial dose, repeated if necessary) is generally effective acutely; lower doses, particularly given subcutaneously or intramuscularly, can exert an initial parasympathomimetic effect, possibly by a central action. For recurrent symptomatic episodes, temporary or permanent pacing may be needed (**see Chapters 36 and 41**). As a general rule, no drugs are

available that increase the heart rate reliably and safely during long periods without important side effects.

Sinus Arrhythmia

Sinus arrhythmia is characterized by a phasic variation in sinus cycle length during which the maximum sinus cycle length minus the minimum sinus cycle length exceeds 120 milliseconds or the maximum sinus cycle length minus the minimum sinus cycle length divided by the minimum sinus cycle length exceeds 10% (**Fig. 40.1B**). It is the most frequent form of arrhythmia and is considered a normal event. P wave morphology does not usually vary, and the PR interval exceeds 120 milliseconds and remains unchanged because the focus of discharge remains relatively fixed within the sinus node. On occasion, the pacemaker focus can wander within the sinus node, or its exit to the atrium may change and produce P waves of a slightly different contour (but not retrograde) and a slightly changing PR interval that exceeds 120 milliseconds.

Sinus arrhythmia usually occurs in the young, especially those with slower heart rates or after enhanced vagal tone, such as following the administration of digitalis or morphine or athletic training, and decreases with age or with autonomic dysfunction, such as in diabetic neuropathy. Sinus arrhythmia appears in two basic forms. In the respiratory form the P-P interval cyclically shortens during inspiration, primarily as a result of reflex inhibition of vagal tone, and slows during expiration; breath-holding eliminates the variation in cycle length (**see Chapter 35**). Nonrespiratory sinus arrhythmia is characterized by a phasic variation in the P-P interval unrelated to the respiratory cycle and can be the result of digitalis intoxication. Loss of sinus rhythm variability is a risk factor for sudden cardiac death (**see Chapter 42**).

Symptoms produced by sinus arrhythmia are uncommon, but on occasion, if the pauses are excessively long, palpitations or dizziness can result. Marked sinus arrhythmia can produce a sinus pause sufficiently long to cause syncope if it is not accompanied by an escape rhythm.

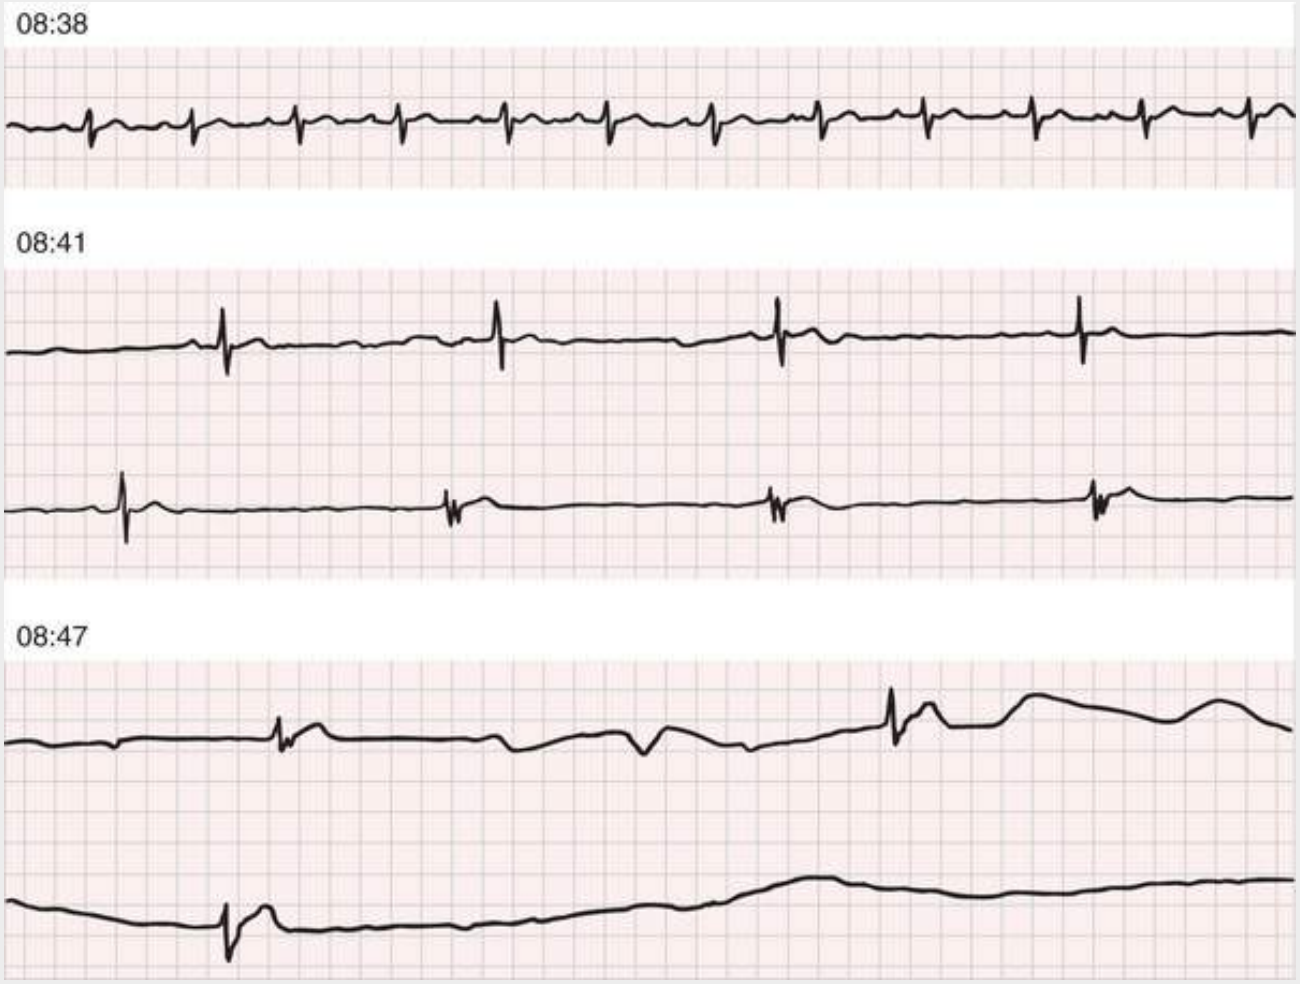
Treatment is usually unnecessary. Increasing the heart rate by exercise or drugs generally abolishes sinus arrhythmia. Symptomatic individuals may experience relief from palpitations with sedatives, tranquilizers, atropine, ephedrine, or isoproterenol administration, as for the treatment of sinus bradycardia.

Ventriculophasic Sinus Arrhythmia.

The most common example of ventriculophasic sinus arrhythmia occurs during complete AV block and a slow ventricular rate, when P-P cycles that contain a QRS complex are shorter than P-P cycles without a QRS complex. Similar lengthening can be present in the P-P cycle that follows a PVC with a compensatory pause. Alterations in the P-P interval are probably caused by the influence of the autonomic nervous system responding to changes in ventricular stroke volume.

Sinus Pause or Sinus Arrest.

Sinus pause or sinus arrest is recognized by a pause in the sinus rhythm (**eFig. 40.1**). The P-P interval delimiting the pause does not equal a multiple of the basic P-P interval. Differentiation of sinus arrest, which is thought to be caused by slowing or cessation of spontaneous sinus node automaticity and therefore a disorder of impulse formation, from sinoatrial (SA) exit block in patients with sinus arrhythmia can be difficult without direct recordings of sinus node discharge.



EFIGURE 40.1 Sinus arrest. The patient had a long-term electrocardiographic recorder connected when he died suddenly of cardiac standstill. The rhythms demonstrate progressive sinus bradycardia and sinus arrest at 8:41 AM. The rhythm then becomes a ventricular escape rhythm, which progressively slows and finally ceases at 8:47 AM. The paired electrocardiographic strips are continuous recordings.

Failure of sinus nodal discharge results in the absence of atrial depolarization and in periods of ventricular asystole if escape beats initiated by latent pacemakers do not occur (**eFig. 40.1**). Involvement of the sinus node by acute MI, degenerative fibrotic changes, effects of digitalis toxicity, stroke, or excessive vagal tone can produce sinus arrest. Transient sinus arrest (especially while sleeping) may have no clinical significance by itself if latent pacemakers promptly escape to prevent ventricular asystole or the genesis of other arrhythmias precipitated by the slow rates. Sinus arrest and AV block have been demonstrated in many patients with sleep apnea (**see Chapter 87**).

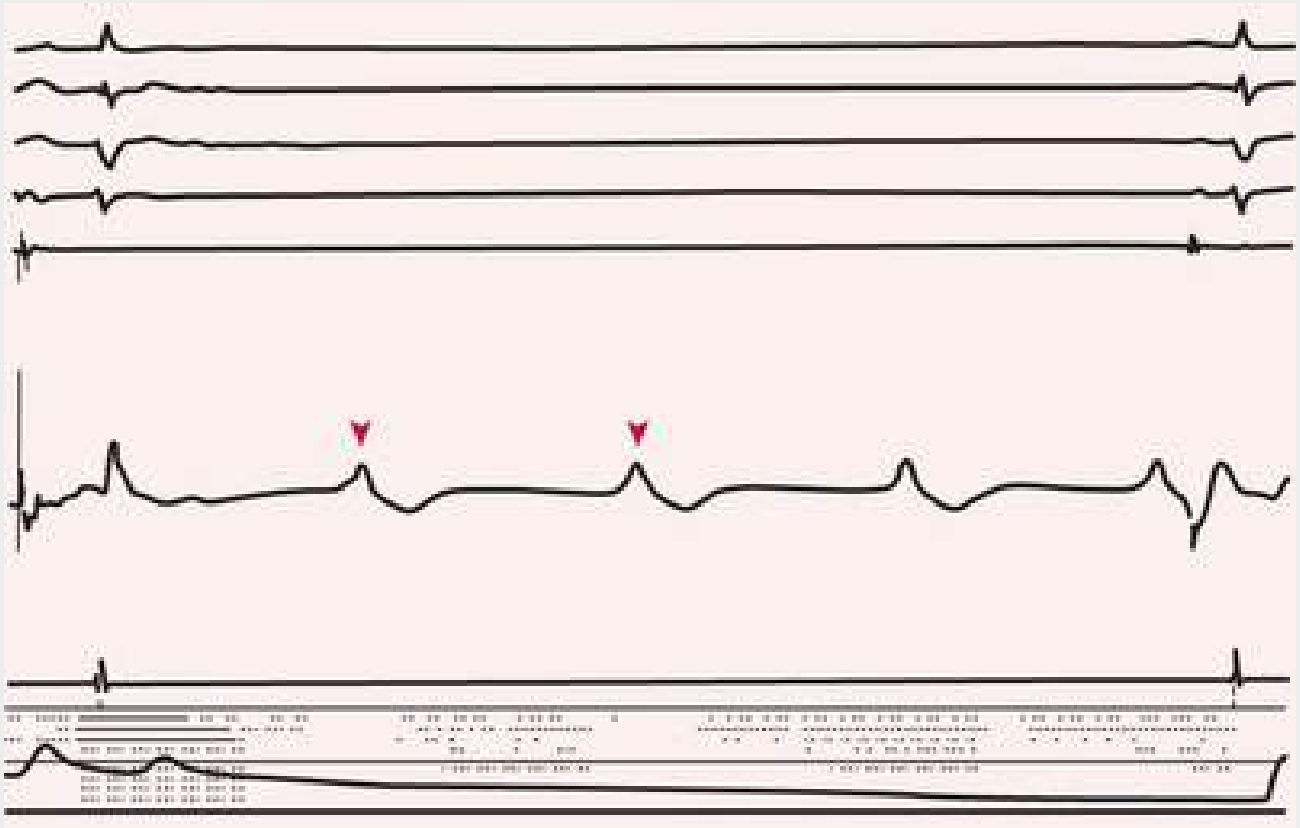
Treatment is as outlined earlier for sinus bradycardia. In patients who have a chronic form of sinus node disease characterized by marked sinus bradycardia or sinus arrest, permanent pacing is often necessary. However, as a general rule, chronic pacing for sinus bradycardia is indicated only in symptomatic patients or those with a sinus pause exceeding 3 seconds while awake.

Sinoatrial Exit Block.

SA exit block is an arrhythmia that is recognized electrocardiographically by a pause resulting from absence of the normally expected P wave (**eFig. 40.2**). The duration of the pause is a multiple of the basic P-P interval. SA exit block is caused by a conduction disturbance during which an impulse formed within the sinus node fails to depolarize the atria or does so with delay (**eFig. 40.3**). An interval without P waves that equals approximately two, three, or four times the normal P-P cycle characterizes type II second-degree SA exit block. During type I (Wenckebach) second-degree SA exit block, the P-P interval progressively shortens before the pause, and the duration of the pause is less than two P-P cycles. (**See**

Chapter 35 for further discussion of Wenckebach intervals.) First-degree SA exit block cannot be recognized on the electrocardiogram (ECG) because SA nodal discharge is not recorded. Third-degree SA exit block can be manifested as a complete absence of P waves and is difficult to diagnose with certainty without sinus node electrograms.

EFIGURE 40.2 Sinus nodal exit block. **A,** Type I SA nodal exit block has the following features. The P-P interval shortens from the first to the second cycle in each grouping, followed by a pause. The duration of the pause is less than twice the shortest cycle length, and the cycle after the pause exceeds the cycle before the pause. The PR interval is normal and constant. Lead V_1 is shown. **B,** The P-P interval varies slightly because of sinus arrhythmia. The two pauses in sinus nodal activity equal twice the basic P-P interval and are consistent with a type II 2 : 1 SA nodal exit block. The PR interval is normal and constant. Lead III recording is shown.



EFIGURE 40.3 Sinus node exit block. After a period of atrial pacing (only the last paced cycle is shown), a sinus node exit block developed. The tracing demonstrates sinus node potentials (*arrowheads*), recorded with a catheter electrode, not conducting to the atrium until the last complex. Recordings are leads I, II, III, and V_1, right atrial recording, sinus node recording, and RV apical recording. The bottom tracing is femoral artery blood pressure.

Excessive vagal stimulation, acute myocarditis, MI, or fibrosis involving the atrium, as well as drugs such as quinidine, procainamide, flecainide and digitalis, can produce SA exit block. SA exit block is usually transient. It may be of no clinical importance except to prompt a search for the underlying cause. On occasion, syncope can result if the SA block is prolonged and unaccompanied by an escape rhythm. SA exit block can occur in well-trained athletes.

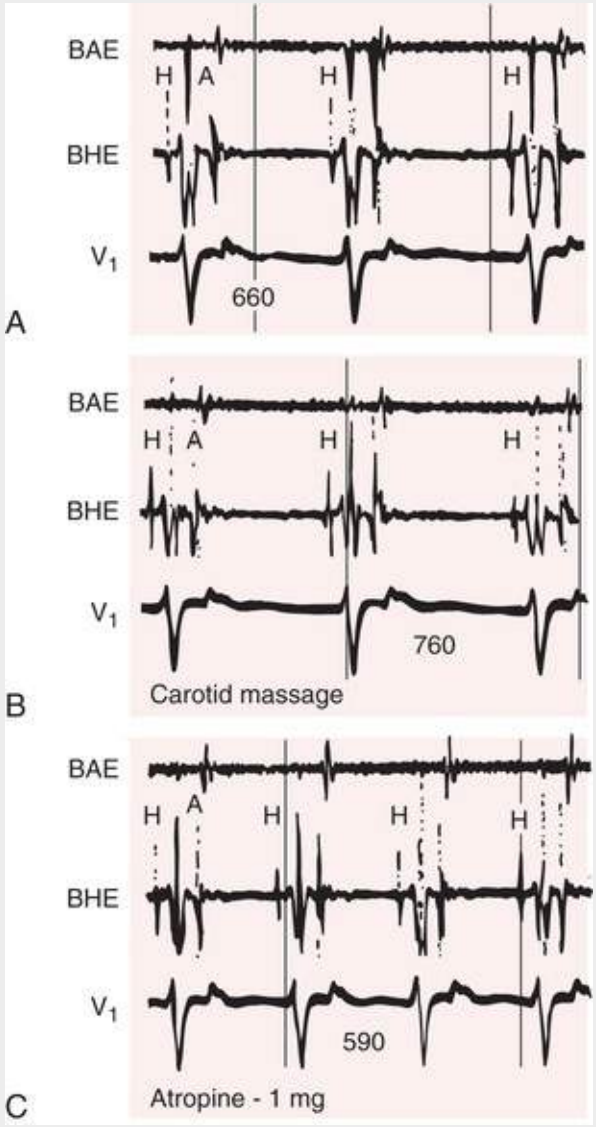
Therapy for patients who have symptomatic SA exit block is as outlined earlier for sinus bradycardia.

Wandering Pacemaker.

This variant of sinus arrhythmia involves passive transfer of the dominant pacemaker focus from the sinus node to latent pacemakers that have the next highest degree of automaticity located in other atrial sites (usually lower in the crista terminalis) or in AV junctional tissue. The change occurs in a gradual fashion over the duration of several beats; thus only one pacemaker at a time controls the rhythm, in sharp contrast to AV dissociation. The ECG displays a cyclic increase in the R-R interval: a PR interval that gradually shortens and can become less than 120 milliseconds, and a change in the P wave contour that becomes negative in lead I or II (depending on the site of discharge) or is lost within the QRS complex (**eFig. 40.4**). In general, these changes occur in reverse as the pacemaker shifts back to the sinus node. Wandering pacemaker is a normal phenomenon that often occurs in very young persons and particularly in athletes, presumably because of augmented vagal tone. Persistence of an AV junctional rhythm for long periods, however, may indicate underlying heart disease (**eFigs. 40.5 and 40.6**). Treatment is not usually indicated but, if necessary, is the same as that for sinus bradycardia (see earlier).

EFIGURE 40.4 Wandering atrial pacemaker. As the heart rate slows, the P waves become inverted and then gradually revert toward normal when the heart rate speeds up again. The PR interval shortens to 0.14 second with the inverted P wave and is 0.16 second with the upright P wave. This phasic variation in cycle length with varying P wave contour suggests a shift in pacemaker site and is characteristic of a wandering atrial pacemaker.

EFIGURE 40.5 AV junctional rhythm. **Top,** AV junctional discharge occurs fairly regularly at a rate of approximately 50 beats/min. Retrograde atrial activity follows each junctional discharge. **Bottom,** Recording made on a different day in the same patient. The AV junctional rate is slightly more variable, and retrograde P waves precede onset of the QRS complex. The positive terminal portion of the P wave gives the appearance of AV dissociation, which was not present.



EFIGURE 40.6 Nonparoxysmal AV junctional tachycardia. **A,** Control. **B,** Response to carotid sinus massage. **C,** Response to atropine, 1 mg intravenously. Note that His bundle depolarization is the earliest recordable electrical activity in each cycle. The atria are depolarized retrogradely; low right atrial activity recorded in the bipolar His electrogram (*BHE*) precedes high right atrial activity recorded in the bipolar atrial electrogram (*BAE*). Note also that carotid sinus massage slows the junctional discharge rate, whereas atropine speeds it up. From these tracings alone, one could not distinguish the rhythm from some other types of supraventricular tachycardia. However, the onset and termination of this tachycardia were typical of nonparoxysmal AV junctional tachycardia.

Hypersensitive Carotid Sinus Syndrome

Electrocardiographic Recognition

Hypersensitive carotid sinus syndrome is characterized most frequently by ventricular asystole caused by cessation of atrial activity as a result of sinus arrest or SA exit block (**Fig. 40.2**). AV block is observed less frequently, probably in part because the absence of atrial activity from sinus arrest precludes the manifestations of AV block. However, if an atrial pacemaker maintained an atrial rhythm during the episodes, a higher prevalence of AV block would probably be noted. In symptomatic patients, AV junctional or ventricular escapes generally do not occur or are present at very slow rates, suggesting that heightened vagal tone and sympathetic withdrawal can suppress subsidiary pacemakers located in the ventricles, as well as in supraventricular structures.

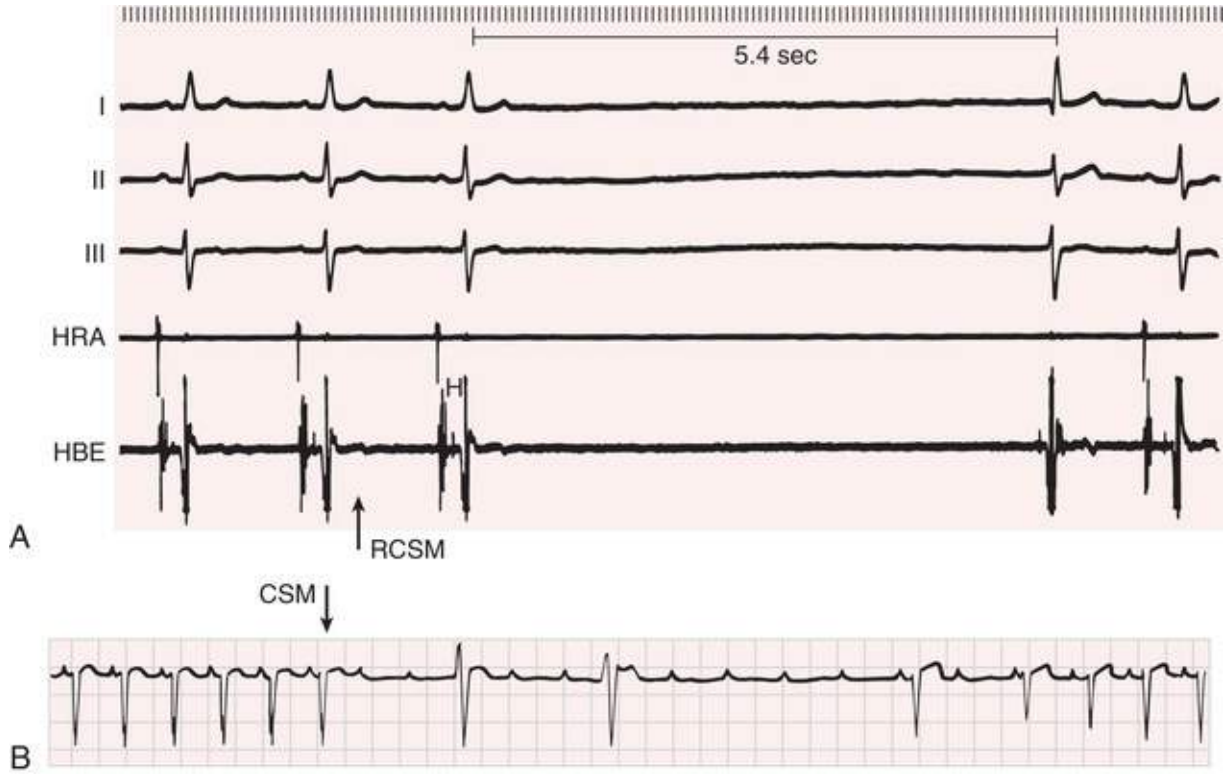


FIGURE 40.2 **A,** Right carotid sinus massage (RCSM, *arrow*) results in sinus arrest and a ventricular escape beat (probably fascicular) 5.4 seconds later. Sinus discharge then resumes. **B,** Carotid sinus massage (CSM, *arrow;* monitor lead) results in slight sinus slowing but, more important, advanced AV block. Obviously, an atrial pacemaker without ventricular pacing would be inappropriate for this patient. *HBE,* His bundle electrogram; *HRA,* high right atrial electrogram.

Clinical Features

Hypersensitive carotid sinus syndrome is a reflex or neutrally mediated cause of bradycardia and syncope.[1] Two types of hypersensitive carotid sinus responses are noted. *Cardioinhibitory* carotid sinus hypersensitivity is generally defined as ventricular asystole exceeding 3 seconds during carotid sinus stimulation, although normal limits have not been definitively established. In fact, asystole exceeding 3 seconds during carotid sinus massage is not common but can occur in asymptomatic subjects (**Fig. 40.2**). *Vasodepressor* carotid sinus hypersensitivity is usually defined as a decrease in systolic blood pressure (SBP) of 50 mm Hg or more without associated cardiac slowing or a decrease in SBP exceeding 30 mm Hg when the patient's symptoms are reproduced.

Even if a hyperactive carotid sinus reflex is elicited in patients, particularly in older patients who complain of syncope or presyncope, the hyperactive reflex elicited with carotid sinus massage may not necessarily be responsible for these symptoms. Direct pressure or extension of the carotid sinus as a result of head turning, neck tension, and tight collars can also be a source of syncope by reducing blood flow through the cerebral arteries. Hypersensitive carotid sinus reflex is most often associated with coronary artery disease. The mechanism responsible for hypersensitive carotid sinus reflex is not known.

Management

Atropine acutely abolishes cardioinhibitory carotid sinus hypersensitivity. However, most symptomatic patients require pacemaker implantation. Because AV block can occur during periods of hypersensitive carotid reflex, some form of ventricular pacing, with or without atrial pacing, is generally required. Atropine and pacing do not prevent the SBP decrease in the vasodepressor form of carotid sinus hypersensitivity, which may result from inhibition of sympathetic vasoconstrictor nerves and possibly

from activation of cholinergic sympathetic vasodilator fibers. Combinations of vasodepressor and cardioinhibitory types can occur, and vasodepression can account for continued syncope after pacemaker implantation in some patients. Patients who have a hyperactive carotid sinus reflex that does not cause symptoms require no treatment. Drugs such as digitalis, methyldopa, clonidine, and propranolol can enhance the response to carotid sinus massage and be responsible for symptoms in some patients. Elastic support hose and sodium-retaining drugs may be helpful in patients with vasodepressor responses.

Sick Sinus Syndrome

Electrocardiographic Recognition

Sick sinus syndrome is a term applied to a syndrome encompassing several sinus nodal abnormalities, including (1) persistent spontaneous sinus bradycardia not caused by drugs and inappropriate for the physiologic circumstance, (2) sinus arrest or exit block (**Fig. 40.3**), (3) combinations of SA and AV conduction disturbances, and (4) alternation of paroxysms of rapid regular or irregular atrial tachyarrhythmias and periods of slow atrial and ventricular rates (bradycardia-tachycardia syndrome; **Fig. 40.4**). More than one of these conditions can be recorded in the same patient on different occasions, and their mechanisms can often be shown to be causally interrelated and combined with an abnormal state of AV conduction or automaticity.

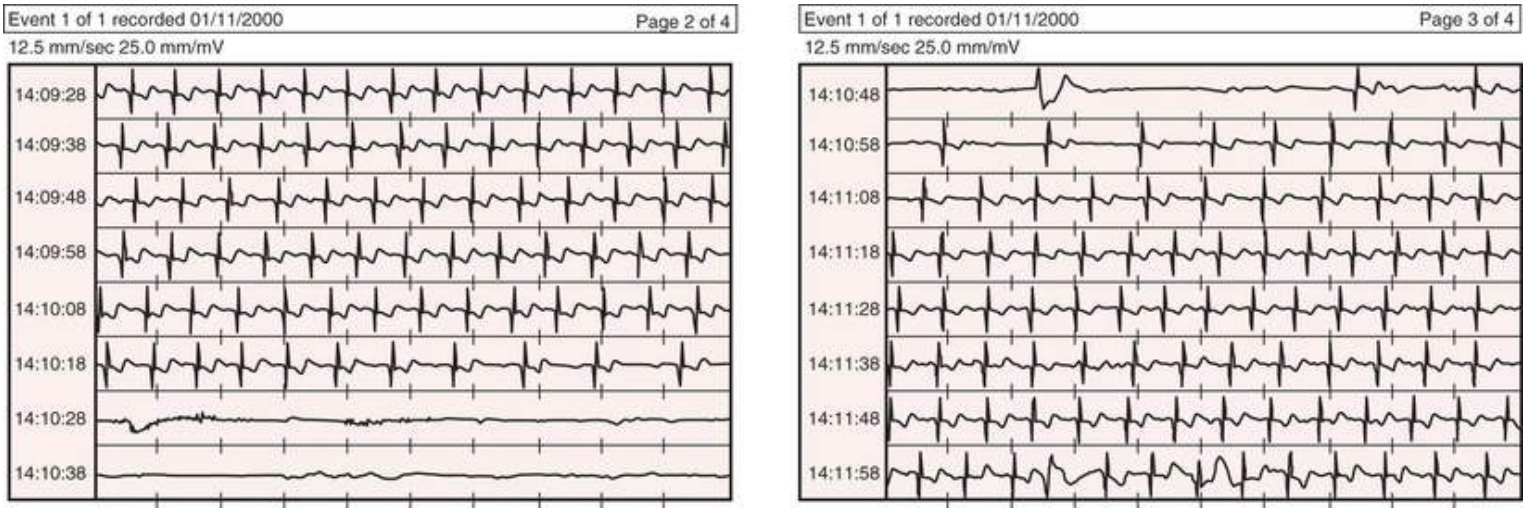

FIGURE 40.3 Continuous recording from an implanted loop recorder in a patient with syncope. The tracing shows paroxysmal sinus node arrest and a sinus pause of nearly 30 seconds. The preceding sinus cycle length appears to lengthen just before the pause, which suggests an autonomic component of the pause. There is also a single ventricular escape complex at 14 : 10 : 48.

FIGURE 40.4 Sick sinus syndrome with bradycardia-tachycardia. **Top,** Intermittent sinus arrest is apparent with junctional escape beats at irregular intervals (*red circles*). **Bottom,** In this continuous monitor lead recording, a short episode of atrial flutter is followed by almost 5 seconds of asystole before a junctional escape rhythm resumes. The patient became presyncopal at this point.

Patients with sinus node disease can be categorized as having intrinsic disease unrelated to autonomic abnormalities or combinations of intrinsic and autonomic abnormalities. Symptomatic patients with sinus pauses or SA exit block frequently show abnormal responses on electrophysiologic testing and can have a relatively high incidence of atrial fibrillation. In children, sinus node dysfunction most frequently occurs in those with congenital or acquired heart disease, particularly after corrective cardiac surgery. Sick sinus syndrome can occur in the absence of other cardiac abnormalities. The course of the disease is frequently intermittent and unpredictable because it is influenced by the severity of the underlying heart disease. Excessive physical training can heighten vagal tone and produce syncope related to sinus bradycardia or AV conduction abnormalities in otherwise normal individuals.

The anatomic basis of sick sinus syndrome can involve total or subtotal destruction of the sinus node, areas of nodal-atrial discontinuity, inflammatory or degenerative changes in the nerves and ganglia surrounding the node, and pathologic changes in the atrial wall. Fibrosis and fatty infiltration occur, and the sclerodegenerative processes generally involve the sinus node and the AV node or the bundle of His and its branches or distal subdivisions. Occlusion of the sinus node artery may be important.

Management

For patients with sick sinus syndrome, treatment depends on the basic rhythm problem but usually involves permanent pacemaker implantation when symptoms are manifested (**see Chapter 41**). Pacing for the bradycardia, combined with drug therapy to treat the tachycardia, is required in those with bradycardia-tachycardia syndrome.

Atrioventricular Block (Heart Block)

Heart block is a disturbance of impulse conduction that can be permanent or transient, depending on the anatomic or functional impairment. It must be distinguished from *interference,* a normal phenomenon that is a disturbance of impulse conduction caused by physiologic refractoriness resulting from inexcitability secondary to a preceding impulse. Interference or block can occur at any site where impulses are conducted, but they are recognized most often between the sinus node and atrium (SA block), between the atria and ventricles (AV block), within the atria (intra-atrial block), or within the ventricles (intraventricular block). SA exit block was discussed earlier (see Sinus Bradycardia). An AV block exists if the atrial impulse is conducted with delay or is not conducted at all to the ventricle when the AV junction is not physiologically refractory. During AV block, the block can occur in the AV node, His bundle, or bundle branches. In some cases of bundle branch block (BBB), the impulse may only be delayed and not completely blocked in the bundle branch, yet the resulting QRS complex may be indistinguishable from a QRS complex generated by a complete BBB.

The conduction disturbance is classified by severity into three categories. During first-degree heart

block, conduction time is prolonged but all impulses are conducted. Second-degree heart block occurs in two forms, Mobitz type I (Wenckebach) and type II. Type I heart block is characterized by progressive lengthening of the conduction time until an impulse is not conducted. Type II heart block denotes an occasional or repetitive sudden block of conduction of an impulse, without prior measurable lengthening of conduction time. When no impulses are conducted, complete or third-degree block is present. The degree of block may depend in part on the direction of impulse propagation. For unknown reasons, normal retrograde conduction can occur in the presence of advanced anterograde AV block. The reverse can also occur. Some electrocardiographers use the term *advanced* or *high-grade heart block* to indicate blockage of two or more consecutive impulses.

First-Degree Atrioventricular Block

During first-degree AV block, every atrial impulse is conducted to the ventricles and a regular ventricular rate is produced, but the PR interval exceeds 0.20 second in adults. PR intervals as long as 1.0 second have been noted and can at times exceed the P-P interval, a phenomenon known as *skipped P waves*. Clinically important PR interval prolongation can result from a conduction delay in the AV node (A-H interval), in the His-Purkinje system (H-V interval), or at both sites. Equally delayed conduction over both bundle branches can infrequently produce PR prolongation without significant QRS complex aberration. On occasion, an intra-atrial conduction delay can result in PR prolongation. If the QRS complex on the scalar ECG is normal in contour and duration, the AV delay almost always resides in the AV node and rarely within the His bundle itself. If the QRS complex shows a BBB pattern, the conduction delay may be within the AV node or the His-Purkinje system (**Fig. 40.5**). In the latter case, a His bundle ECG is necessary to localize the site of conduction delay. Acceleration of the atrial rate or enhancement of vagal tone by carotid massage can cause first-degree AV nodal block to progress to type I second-degree AV block. Conversely, type I second-degree AV nodal block can revert to a first-degree block with deceleration of the sinus rate.

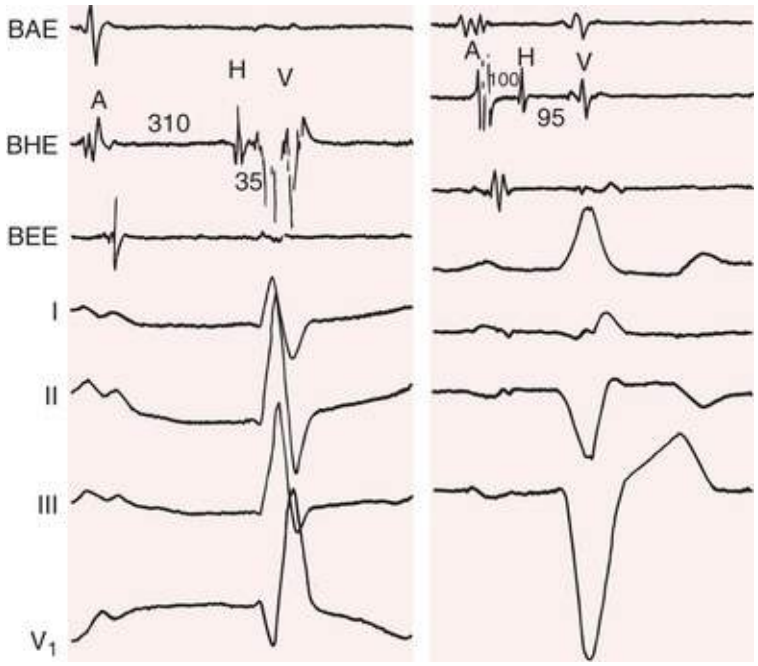

FIGURE 40.5 First-degree AV block. One complex during sinus rhythm is shown. **Left panel,** The PR interval measured 370 milliseconds (PA = 25 msec; A-H = 310 msec; H-V = 39 msec) during a right bundle branch block. Conduction delay in the AV node causes the first-degree AV block. **Right panel,** The PR interval is 230 milliseconds (PA = 39 msec; A-H = 100 msec; H-V = 95 msec) during a left bundle branch block. The conduction delay in the His-Purkinje system is causing the first-degree AV block. *BAE,* Bipolar atrial electrogram; *BEE,* bipolar esophageal electrogram; *BHE,* bipolar His electrogram.

Second-Degree Atrioventricular Block

Blocking of some atrial impulses conducted to the ventricle at a time when physiologic interference is not involved constitutes second-degree AV block (**Figs. 40.6, 40.7, and 40.8; eFig. 40.7**). The nonconducted P wave can be intermittent or frequent, can occur at regular or irregular intervals, and may be preceded by fixed or lengthening PR intervals. A distinguishing feature is that conducted P waves relate to the QRS complex with recurring PR intervals; that is, the association of P with QRS is not random. Electrocardiographically, typical type I second-degree AV block is characterized by progressive PR prolongation culminating in a nonconducted P wave (**Figs. 40.7 and 40.8B; eFig. 40.7**), whereas in type II second-degree AV block, the PR interval remains constant before the blocked P wave (**Fig. 40.8A**). In both cases the AV block is intermittent and generally repetitive and can block several P waves in a row. Frequently, the eponyms Mobitz type I and Mobitz type II are applied to the two types of block, whereas Wenckebach block refers to type I block only. A Wenckebach block in the His-Purkinje system in a patient with a BBB can closely resemble an AV nodal Wenckebach block (**Fig. 40.8B**).

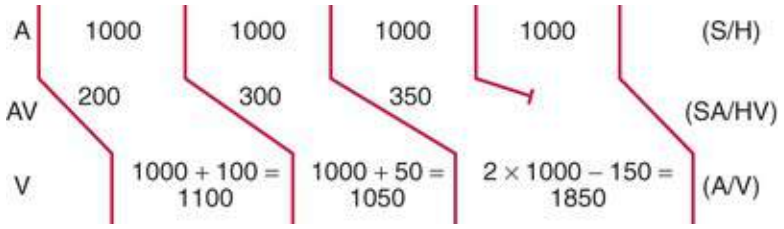

FIGURE 40.6 Typical 4 : 3 Wenckebach cycle. P waves (A tier) occur at a cycle length of 1000 milliseconds. The PR interval (AV tier) is 200 milliseconds for the first beat and generates a ventricular response (V tier). The PR interval increases by 100 milliseconds in the next complex, which results in an R-R interval of 1100 milliseconds (1000 + 100). The increment in the PR interval is only 50 milliseconds for the third cycle, and the PR interval becomes 350 milliseconds. The R-R interval shortens to 1050 milliseconds (1000 + 50). The next P wave is blocked, and an R-R interval is created that is less than twice the P-P interval by an amount equal to the increments in the PR interval. Thus the Wenckebach features explained in the text can be found in this diagram. If the increment in the PR interval of the last conducted complex increased rather than decreased (e.g., 150 msec rather than 50 msec), the last R-R interval before the block would increase (1150 msec) rather than decrease and thus become an example of an atypical Wenckebach cycle (**see Fig. 40.1**). If this were a Wenckebach exit block from the sinus node to the atrium, the sinus node cycle length (*S*) would be 1000 milliseconds, and the SA interval would increase from 200 to 300 to 350 milliseconds and culminate in a block. These events would be inapparent on a scalar ECG. However, the P-P interval on the ECG would shorten from 1100 to 1050 milliseconds, and finally, there would be a pause of 1850 milliseconds (*A*). If this rhythm were a junctional rhythm arising from the His bundle and conducting to the ventricle, the junctional rhythm cycle length would be 1000 milliseconds (*H*) and the H-V interval would progressively lengthen from 200 to 300 to 350 milliseconds, whereas the R-R interval would decrease from 1100 to 1050 milliseconds and then increase to 1850 milliseconds (*V*). The only clue to the Wenckebach exit block would be the changes in cycle length in the ventricular rhythm.

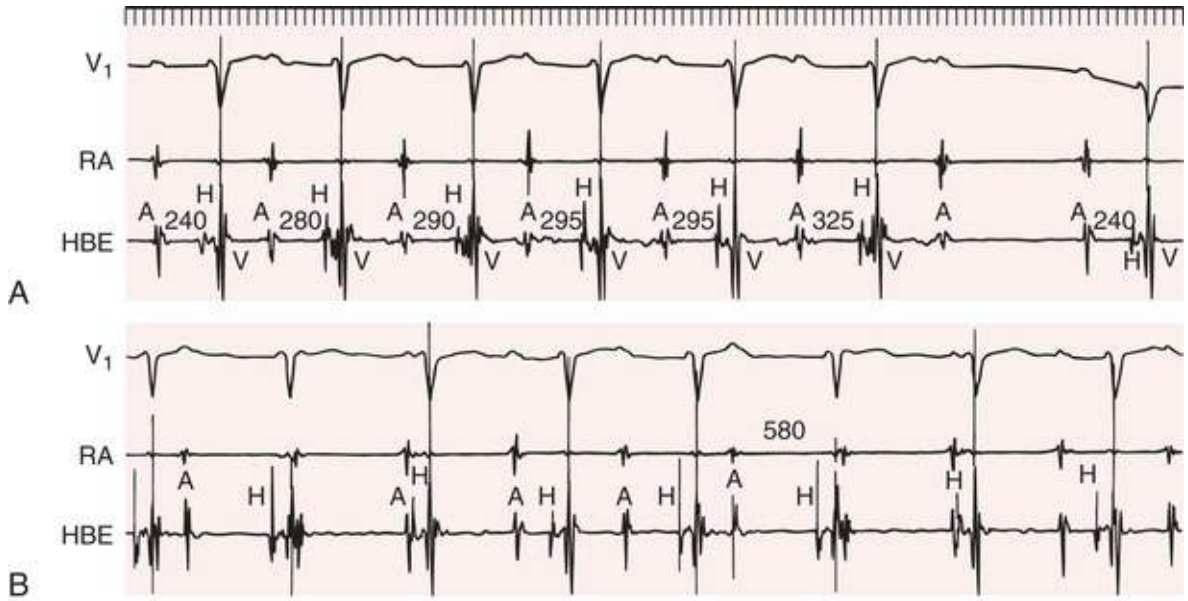

FIGURE 40.7 **A,** Type I (Wenckebach) AV nodal block. During spontaneous sinus rhythm, progressive PR prolongation occurs and culminates in a nonconducted P wave. From the His bundle recording (HBE), it is apparent that the conduction delay and subsequent block occur within the AV node. Because the increment in conduction delay does not consistently decrease, the R-R intervals do not reflect the classic Wenckebach structure. **B,** Recorded 5 minutes after the intravenous administration of atropine, 0.5 mg. Atropine has had its predominant effect on sinus and junctional automaticity by this time, with little improvement in AV conduction. Consequently, more P waves are blocked and AV dissociation is present, caused by a combination of AV block and an enhanced junctional discharge rate. At 8 minutes (not shown), when atropine finally improved AV conduction, 1 : 1 AV conduction occurred. *RA,* Right atrium.

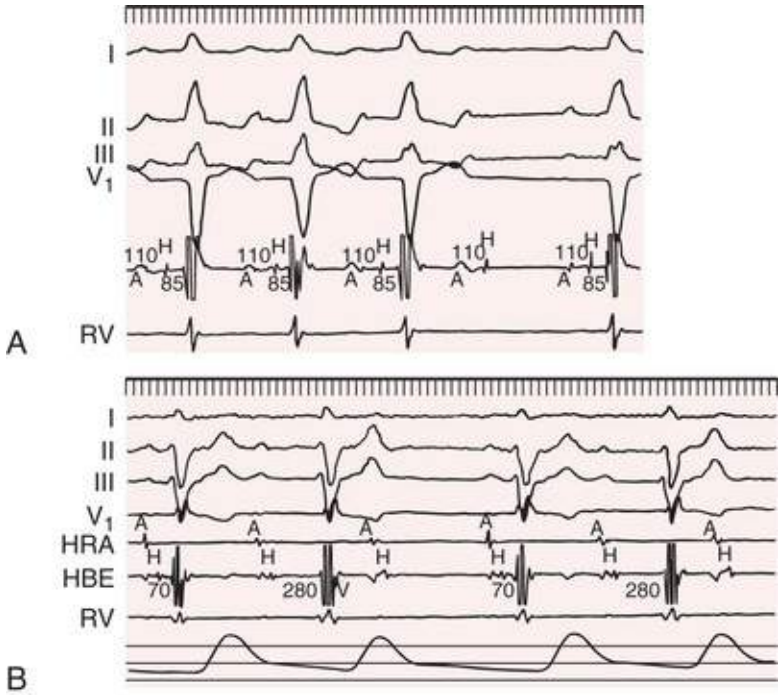

FIGURE 40.8 Type II AV block. **A,** The sudden development of a His-Purkinje block is apparent. The A-H and H-V intervals remain constant, as does the PR interval. A left bundle branch block is present. **B,** Wenckebach AV block in the His-Purkinje system. The QRS complex exhibits a right bundle branch block morphology. However, note that the second QRS complex in the 3 : 2 conduction exhibits a slightly different contour from the first QRS complex, particularly in V_1. This finding is the clue that the Wenckebach AV block might be in the His-Purkinje system. The H-V interval increases from 70 to 280 milliseconds, and then a block distal to the His bundle results. *HBE,* His bundle electrogram; *HRA,* high right atrium; *RV,* right ventricle.

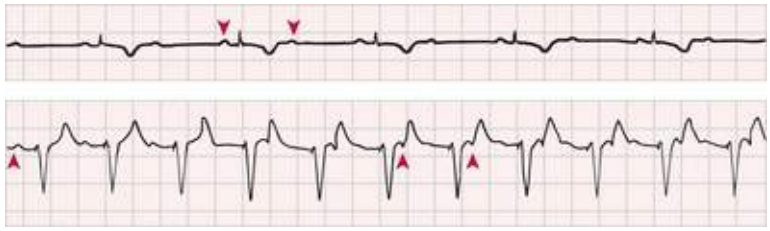

EFIGURE 40.7 Unidirectional block. **Top,** During spontaneous sinus rhythm at a rate of 68 beats/min, 2 : 1 anterograde AV conduction occurs. **Bottom,** 1 : 1 retrograde conduction is seen during ventricular pacing at a rate of 70 beats/min. P waves are indicated by *arrowheads*.

Certain features of type I second-degree block deserve special emphasis because when actual conduction times are not apparent on the ECG—for example, during SA, junctional, or ventricular exit block (**see Fig. 40.6**)—a type I conduction disturbance can be difficult to recognize. During a typical type I block, the increment in conduction time is greatest in the second beat of the Wenckebach group, and the absolute increase in conduction time decreases progressively over subsequent beats. These two features serve to establish the characteristics of classic Wenckebach group beats: (1) the interval between successive beats progressively decreases, although the conduction time increases (but by a decreasing function); (2) the duration of the pause produced by the nonconducted impulse is less than twice the interval preceding the blocked impulse (which is usually the shortest interval); and (3) the cycle that follows the nonconducted beat (beginning the Wenckebach group) is longer than the cycle preceding the blocked

impulse. Although much emphasis has been placed on this characteristic grouping of cycles, primarily to be able to diagnose a Wenckebach exit block, this typical grouping occurs in fewer than 50% of patients with a type I Wenckebach AV nodal block.

Differences in these cycle-length patterns can result from changes in pacemaker rate (e.g., sinus arrhythmia), in neurogenic control of conduction, and in the increment of conduction delay. For example, if the PR increment in the last cycle increases, the R-R cycle of the last conducted beat can lengthen rather than shorten. In addition, because the last conducted beat is often at a critical state of conduction, it can become blocked and produce a 5 : 3 or 3 : 1 conduction ratio instead of a 5 : 4 or 3 : 2 ratio. During a 3 : 2 Wenckebach structure, the duration of the cycle that follows the nonconducted beat will be the same as the duration of the cycle that precedes the nonconducted beat.

Although it has been suggested that type I and type II AV block are different manifestations of the same electrophysiologic mechanism that differ only quantitatively in the size of the increments, clinical separation of second-degree AV block into types I and II serves a useful function, and in most cases the differentiation can be made easily and reliably from the surface ECG. Type II AV block often antedates the development of Adams-Stokes syncope and complete AV block, whereas type I AV block with a normal QRS complex is generally more benign and does not progress to more advanced forms of AV conduction disturbance. In older people, type I AV block with or without BBB has been associated with a clinical picture similar to that seen in type II AV block.

In a patient with an acute MI, type I AV block usually accompanies inferior infarction (perhaps more often if an right ventricular infarction also occurs), is transient, and does not require temporary pacing, whereas type II AV block occurs in the setting of acute anterior MI, can require temporary or permanent pacing, and is associated with high mortality, generally as a result of pump failure. A high degree of AV block can occur in patients with acute inferior MI and is associated with more myocardial damage and a higher mortality rate than in those without AV block.

Although type I conduction disturbance is ubiquitous and can occur in any cardiac tissue in vivo as well as in vitro, the site of block for the usual forms of second-degree AV block can generally be determined from the surface ECG with sufficient reliability to permit clinical decisions without an invasive electrophysiologic study (EPS). Type I AV block with a normal QRS complex almost always takes place at the level of the AV node, proximal to the His bundle. An exception is the uncommon patient with type I intrahisian block. Type II AV block, particularly in association with a BBB, is localized to the His-Purkinje system. Type I AV block in a patient with a BBB can be caused by a block in the AV node or in the His-Purkinje system. Type II AV block in a patient with a normal QRS complex can be caused by an intrahisian AV block, but the block is likely to be a type I AV nodal block, which exhibits small increments in AV conduction time.

Differentiation of Type I from Type II Atrioventricular Block.

The preceding generalizations encompass most patients with second-degree AV block. However, certain caveats must be heeded to avoid misdiagnosis because of subtle electrocardiographic changes or exceptions.

1. A 2 : 1 AV block can be a form of type I or type II AV block (**Fig. 40.9**). If the QRS complex is normal, the block is more likely to be type I and located in the AV node, and one should search for

transition of the 2 : 1 block to a 3 : 2 block, during which the PR interval lengthens in the second cardiac cycle. If a BBB is present, the block can be located in the AV node or His-Purkinje system.

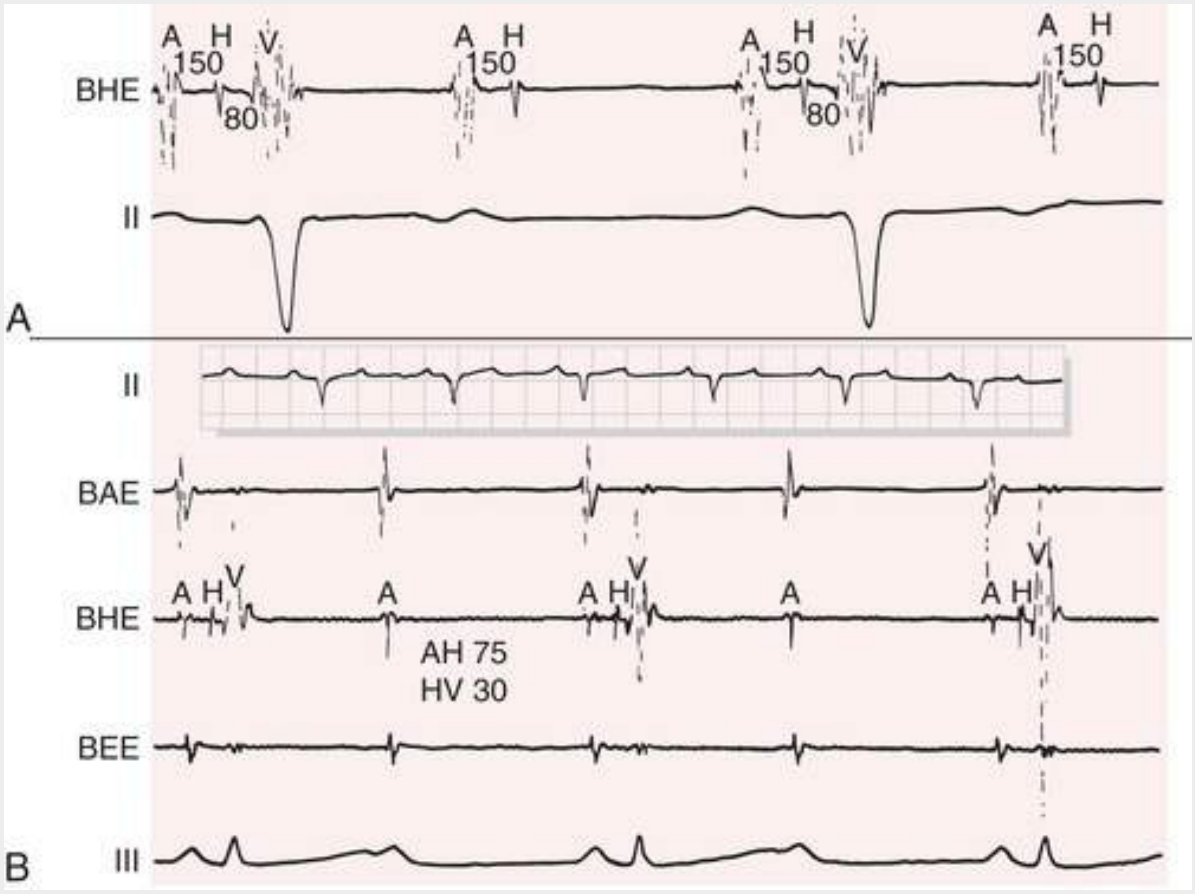

FIGURE 40.9 A 2 : 1 AV block proximal and distal to the His bundle deflection in two different patients. **A,** 2 : 1 AV block seen on the scalar ECG occurs distal to the His bundle recording site in a patient with a right bundle branch block and anterior hemiblock. The A-H interval (150 msec) and H-V interval (80 msec) are both prolonged. **B,** 2 : 1 AV block proximal to the bundle of His in a patient with a normal QRS complex. The A-H interval (75 msec) and the H-V interval (30 msec) remain constant and normal. *BAE,* Bipolar atrial electrogram; *BEE,* bipolar esophageal electrogram; *BHE,* bipolar His electrogram.

2. AV block can occur simultaneously at two or more levels and cause difficulty in distinguishing between types I and II.
3. If the atrial rate varies, it can alter conduction times and cause a type I AV block to stimulate a type II block or change a type II AV block into type I. For example, if the shortest atrial cycle length that has just achieved 1 : 1 AV nodal conduction at a constant PR interval is decreased by only 10 or 20 milliseconds, the P wave of the shortened cycle can block conduction at the level of the AV node without an apparent increase in the antecedent PR interval. An apparent type II AV block in the His-Purkinje system can be converted to type I in the His-Purkinje system in some patients by increasing the atrial rate.
4. Concealed premature His depolarizations can create electrocardiographic patterns that simulate those of type I or II AV block.
5. Abrupt transient alterations in autonomic tone can cause sudden block of one or more P waves without altering the PR interval of the conducted P wave before or after the block. Thus, an apparent type II AV block would be produced at the AV node. Clinically, a burst of vagal tone usually lengthens the P-P interval, as well as produces an AV block.

6. The response of the AV block to autonomic changes, either spontaneous or induced, to distinguish type I from type II AV block can be misleading. Although vagal stimulation generally increases and vagolytic agents decrease the extent of type I AV block, such conclusions are based on the assumption that the intervention acts primarily on the AV node and fail to consider rate changes. For example, atropine can minimally improve conduction in the AV node and greatly increase the sinus rate, which results in an increase in AV nodal conduction time and the degree of AV block as a result of the faster atrial rate (**see Fig. 40.7B**). Conversely, if an increase in vagal tone minimally prolongs AV conduction time but greatly slows the heart rate, the net effect on type I AV block may be to improve conduction. In general, however, carotid sinus massage improves and atropine worsens AV conduction in patients with His-Purkinje block, whereas the opposite results are to be expected in patients with AV nodal block. Similarly, exercise or isoproterenol is likely to increase the sinus rate and improve AV nodal block but worsen His-Purkinje block. These interventions can help differentiate the site of block without invasive study, although damaged His-Purkinje tissue may be influenced by changes in autonomic tone.
7. During type I AV block with high ratios of conducted beats, the increment in PR interval can be quite small and can suggest a type II AV block if only the last few PR intervals before the blocked P wave are measured. Comparing the PR interval of the first beat in the long Wenckebach cycle with that of the beats immediately preceding the blocked P wave readily reveals the increment in AV conduction.
8. The classic AV Wenckebach structure depends on a stable atrial rate and a maximal increment in AV conduction time for the second PR interval of the Wenckebach cycle along with a progressive decrease in subsequent beats. Unstable or unusual alterations in the increment of AV conduction time or in the atrial rate, often seen with long Wenckebach cycles, result in atypical forms of type I AV block in which the last R-R interval can lengthen because the PR increment increases; such alterations are common.
9. Finally, the PR interval on the scalar ECG consists of conduction through the atrium, AV node, and His-Purkinje system. An increment in H-V conduction, for example, can be masked on the scalar ECG by a reduction in the A-H interval, and the resulting PR interval will not reflect the entire increment in His-Purkinje conduction time. Very long PR intervals (200 msec) are more likely to result from AV nodal conduction delay (and block), with or without concomitant His-Purkinje conduction delay, although an H-V interval of 390 milliseconds is possible.

First-degree and type I second-degree AV block can occur in normal healthy children, and a Wenckebach AV block can be a normal phenomenon in well-trained athletes, as noted earlier, probably related to an increase in resting vagal tone. On occasion, progressive worsening of the Wenckebach AV conduction disorder can result, and the athlete becomes symptomatic and needs to decondition. In patients who have chronic second-degree AV nodal block (proximal to the His bundle) without structural heart disease, the course is relatively benign (except in older age-groups), whereas in those with structural heart disease, the prognosis is poor and related to the underlying heart disease.

Third-Degree (Complete) Atrioventricular Block

Third-degree or complete AV block occurs when no atrial activity is conducted to the ventricles and therefore the atria and ventricles are controlled by independent pacemakers. Thus, complete AV block is one type of complete AV dissociation. The atrial pacemaker can be sinus or ectopic (tachycardia, flutter,

or fibrillation) or can result from an AV junctional focus occurring above the block with retrograde atrial conduction. The ventricular focus is usually located just below the region of the block, which can be above or below the His bundle bifurcation. Sites of ventricular pacemaker activity that are in or closer to the His bundle appear to be more stable and can produce a faster escape rate than those located more distally in the ventricular conduction system. The ventricular rate in acquired complete heart block is less than 40 beats/min but can be faster with congenital complete AV block. The ventricular rhythm, usually regular, can vary in response to premature ventricular complexes (PVCs), a shift in the pacemaker site, an irregularly discharging pacemaker focus, or autonomic influences.

Complete AV block can result from a block at the level of the AV node (usually congenital; **Fig. 40.10**), within the bundle of His, or distal to it in the Purkinje system (usually acquired; **eFig. 40.8**).[2] Block proximal to the His bundle generally exhibits normal QRS complexes and rates of 40 to 60 beats/min because the escape focus that controls the ventricle arises in or near the His bundle. In complete AV nodal block, the P wave is not followed by a His deflection, but each ventricular complex is preceded by a His deflection (**Fig. 40.10**). His bundle recording can be useful to differentiate AV nodal from intrahisian block because the intrahisian may carry a more serious prognosis than the AV nodal block. Intrahisian block is recognized infrequently without invasive studies. In patients with AV nodal block, atropine generally speeds both the atrial and the ventricular rate. Exercise can reduce the extent of AV nodal block. Acquired complete AV block occurs most often distal to the bundle of His because of trifascicular conduction disturbance. Each P wave is followed by a His deflection, and the ventricular escape complexes are not preceded by a His deflection (**see eFig. 40.8**). The QRS complex is abnormal, and the ventricular rate is generally less than 40 beats/min. A hereditary form caused by degeneration of the His bundle and bundle branches has been linked to the *SCN5A* gene, which is also responsible for LQT3 (**see Chapter 33**).

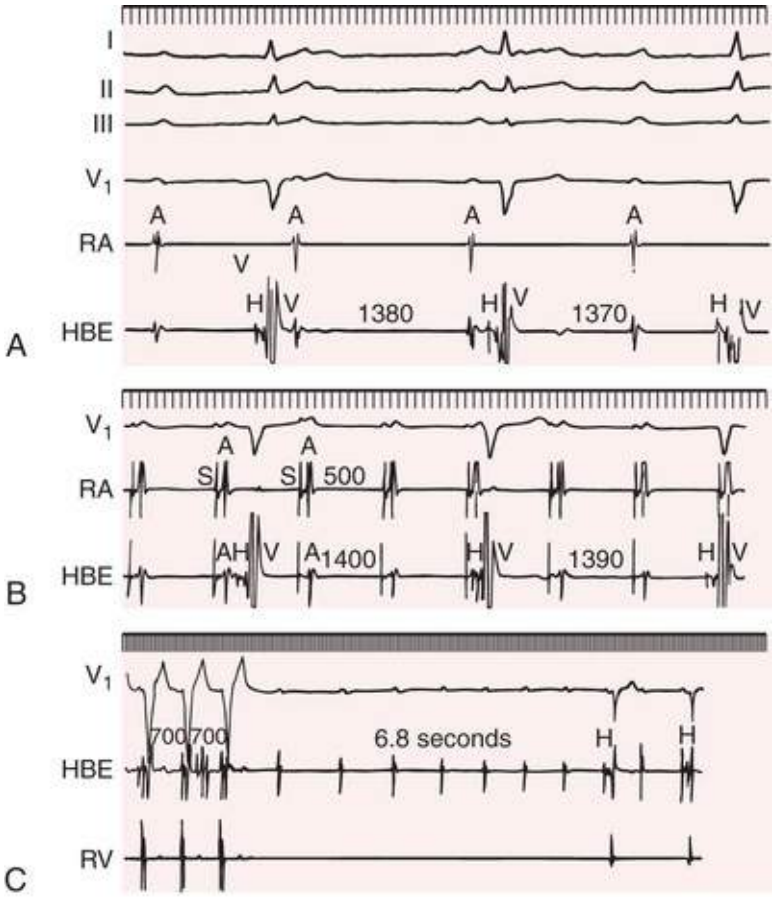

FIGURE 40.10 Congenital third-degree AV block. **A,** Complete AV nodal block is apparent. No P wave is followed by a His bundle potential, whereas each ventricular depolarization is preceded by a His bundle potential. **B,** Atrial pacing (cycle length of 500 msec) fails to alter the cycle length of the functional rhythm. Still, no P wave is followed by a His bundle potential. **C,** After 30 seconds of ventricular pacing (cycle length of 700 msec), suppression of the junctional focus results for almost 7 seconds (overdrive suppression of automaticity). *HBE,* His bundle electrogram; *RA,* right atrium; *RV,* right ventricle.

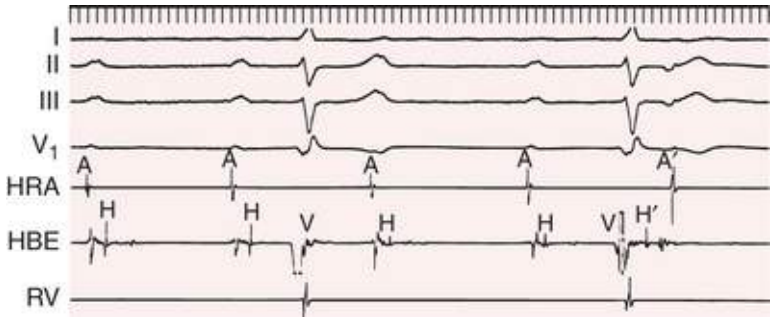


EFIGURE 40.8 Complete anterograde AV block with retrograde VA conduction. All the sinus P waves are blocked distal to the His bundle, consistent with acquired complete AV block. The ventricles escape at a cycle length of approximately 1800 milliseconds (33 beats/min) and are not preceded by His bundle activation. The ventricular escape rhythm produces a QRS contour with left axis deviation and a right bundle branch block, possibly caused by impulse origin in the posterior fascicle of the left bundle branch. Of interest is the fact that the second ventricular escape beat conducts retrogradely through His (*H*) and to the atrium (note the low-high atrial activation sequence and the negative P wave in leads II and III). The first ventricular complex does not conduct retrogradely, probably because the His bundle is still refractory from the immediately preceding atrial impulse. *HBE,* His bundle electrogram; *HRA,* high right atrium; *RV,* right ventricle.

Paroxysmal AV block in some cases can be caused by hyperresponsiveness of the AV node to vagotonic reflexes.[3] Surgery, electrolyte disturbances, myoendocarditis, tumors, Chagas disease, rheumatoid nodules, calcific aortic stenosis, myxedema, polymyositis, infiltrative processes (e.g., amyloidosis,

sarcoidosis, scleroderma), and an almost endless assortment of common and unusual conditions can produce AV block. In adults, rapid rates may be followed by block (called *tachycardia-dependent* AV block), which is thought to result from a phase 3 block (block caused by incomplete action potential recovery), postrepolarization refractoriness, and concealed conduction in the AV node. Less common than tachycardia-dependent AV block, *pause-dependent paroxysmal* AV block can also occur; it results in AV block after a pause or during relative bradycardia and thus can be difficult to distinguish from vagal AV block. This form of AV block is often referred to as a *phase 4 block* because it is thought that spontaneous depolarizations during the resting phase of the action potential result in an inability to depolarize, although other mechanisms may also play a role.

In children the most common cause of AV block is congenital (**see Chapter 75**). In such circumstances the AV block can be an isolated finding or associated with other lesions. Neonatal autoimmune disease, from maternal antibodies crossing the placenta, accounts for most cases of heart block in utero or in the immediate neonatal period but only for rare cases of congenital heart block occurring after this period. Anatomic disruption between the atrial musculature and peripheral parts of the conduction system and nodoventricular discontinuity are two common histologic findings. Children are most often asymptomatic; however, in some children, symptoms requiring pacemaker implantation develop. Mortality from congenital AV block is highest in the neonatal period, is much lower during childhood and adolescence, and increases slowly later in life. Adams-Stokes attacks can occur in patients with congenital heart block at any age. It is difficult to predict the prognosis in an individual patient. A persistent heart rate at rest of 50 beats/min or less correlates with the incidence of syncope, and extreme bradycardia can contribute to the frequency of Adams-Stokes attacks in children with congenital complete AV block. The site of block may not distinguish symptomatic children who have congenital or surgically induced complete heart block from those without symptoms. Prolonged recovery times of escape foci after rapid pacing (**see Fig. 40.10C**), slow heart rates on 24-hour electrocardiographic recordings, and the occurrence of paroxysmal tachycardias may be factors predisposing to the development of symptoms.

Clinical Features

Many of the signs of AV block are evident at the bedside. First-degree AV block can be recognized by a long *a* to *c* wave interval in the jugular venous pulse and by diminished intensity of the first heart sound (S_1) as the PR interval lengthens. In type I second-degree AV block, the heart rate may increase imperceptibly with gradually diminishing intensity of S_1; widening of the *a* to *c* interval, terminated by a pause; and an *a* wave not followed by a *v* wave. Intermittent ventricular pauses and *a* waves in the neck not followed by *v* waves characterize type II AV block. S_1 maintains a constant intensity. In complete AV block, the findings are the same as those in AV dissociation (see later).

Significant clinical manifestations of first- and second-degree AV block usually consist of palpitations or subjective feelings of the heart “missing a beat.” Persistent 2 : 1 AV block can produce symptoms of chronic bradycardia. Complete AV block can be accompanied by signs and symptoms of reduced cardiac output, syncope or presyncope, angina, or palpitations from ventricular tachyarrhythmias. It can occur in twins.

Management

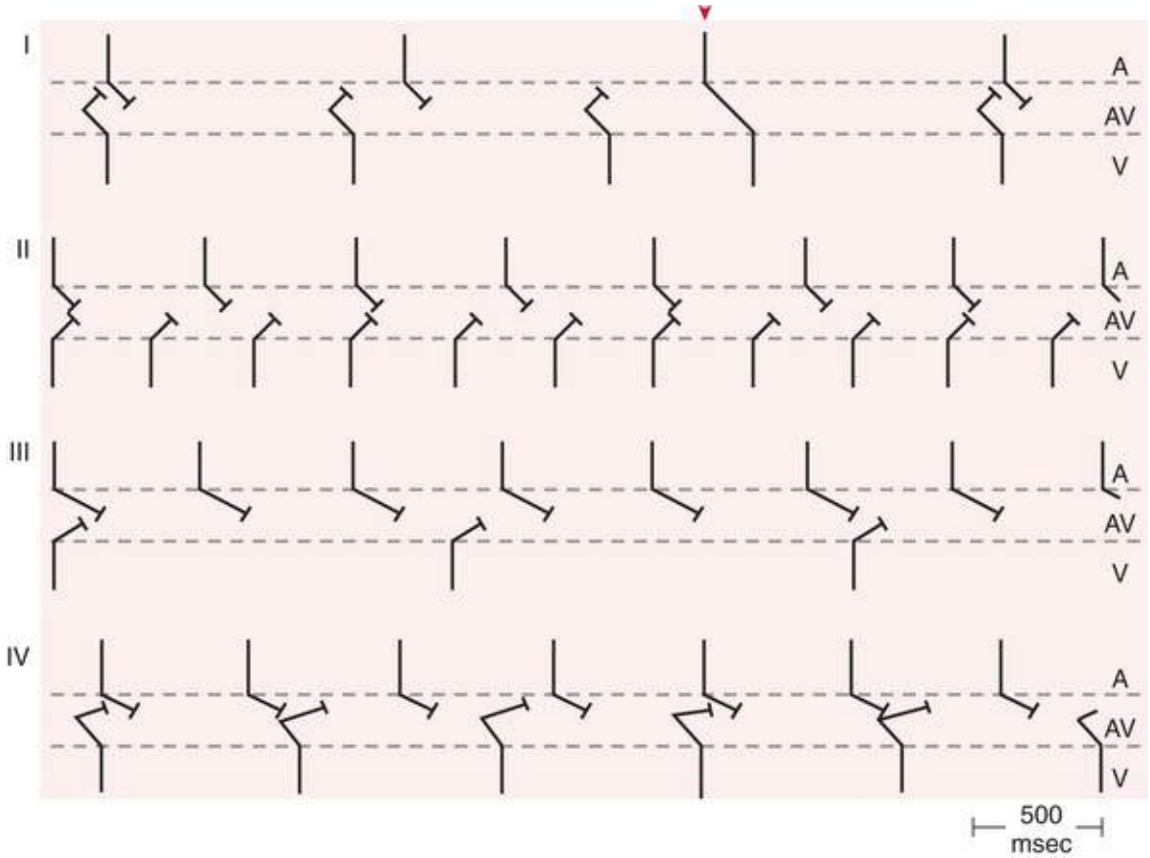
For patients with transient or paroxysmal AV block and presyncope or syncope, the diagnosis can be elusive. Ambulatory monitoring (Holter or external loop recorders) can be useful, but monitoring for longer periods may be necessary, with extended (>3 weeks) Holter or external loop recorders being

required. Longer periods of recording require an implantable loop recorder to establish the diagnosis. In patients with presyncope or syncope, one should suspect intermittent infrahisian block in those with BBB or an intraventricular conduction defect. An EPS to evaluate AV conduction thoroughly (including infusion of isoproterenol and/or procainamide) may be warranted to make the diagnosis, particularly in those with severe symptoms (**see Chapter 35**).

Drugs cannot be relied on to increase the heart rate for more than several hours to several days in patients with symptomatic heart block without producing significant side effects. Therefore, temporary or permanent pacemaker insertion is indicated for patients with symptomatic bradyarrhythmias. For short-term therapy, when the block is likely to be evanescent but still requires treatment or until adequate pacing therapy can be established, vagolytic agents such as atropine are useful for patients who have AV nodal disturbances, whereas catecholamines such as isoproterenol can be used transiently to treat patients who have heart block at any site (see earlier, Sinus Bradycardia). Isoproterenol should be used with extreme caution or not at all in patients with acute MI. The use of transcutaneous or temporary transvenous pacing is preferable. For symptomatic AV block or high-grade AV block (e.g., infrahisian, type II AV block, third-degree heart block not caused by congenital AV block), permanent pacemaker placement is the treatment of choice.[4,5] There is growing evidence that some patients with AV block, especially those with preexisting left ventricle dysfunction, may benefit from biventricular pacing rather than right ventricle–only pacing to prevent the development or progression of symptoms caused by heart failure.[6]

Atrioventricular Dissociation

As the term indicates, *dissociated* or *independent* beating of the atria and ventricles defines AV dissociation. AV dissociation is never a primary disturbance of rhythm but rather is a “symptom” of an underlying rhythm disturbance produced by one of three causes or a combination of causes that prevents the normal transmission of impulses from atrium to ventricle. See the online supplement for content on atrioventricular dissociation (**eFig. 40.9**).



EFIGURE 40.9 Diagrammatic illustration of the four causes of AV dissociation. A sinus bradycardia allowing escape of an AV junctional rhythm that does not capture the atria retrogradely illustrates cause I; intermittent sinus capture occur (arrow) and produce incomplete AV dissociation. For cause II, VT without retrograde atrial capture produces complete AV dissociation (**see Fig. 39.5 and eFig. 40.7**). As the third cause, complete AV block with a ventricular escape rhythm is diagrammed (**see Fig. 40.10 and eFig. 40.8**). In the **bottom panel,** the combination of causes II and III is shown, which represents a nonparoxysmal AV junctional tachycardia and some degree of AV block.

Atrioventricular Dissociation

Classification

1. Slowing of the dominant pacemaker of the heart (usually the sinus node), which allows escape of a subsidiary or latent pacemaker. Atrioventricular (AV) dissociation by default of the primary pacemaker to a subsidiary one in this manner is often a normal phenomenon. It may occur during sinus arrhythmia or sinus bradycardia and permit an independent AV junction rhythm to arise (**see Fig. 40.1A**).
2. Acceleration of a latent pacemaker, for example, a tachycardia in which the atria are not required and that usurps control of the ventricles. An abnormally enhanced discharge rate of a usually slower subsidiary pacemaker is pathologic and typically occurs during nonparoxysmal AV junctional tachycardia or VT without retrograde atrial capture (**eFig. 40.10**).
3. A block, generally at the AV junction, that prevents impulses formed at a normal rate in a dominant pacemaker from reaching the ventricles and allows the ventricles to beat under the control of a subsidiary pacemaker. Junctional or ventricular escape rhythm during AV block, without retrograde atrial capture, is a common example in which block gives rise to AV dissociation. Complete AV block is not synonymous with complete AV dissociation. Patients who have complete AV block have complete AV dissociation, but patients who have complete AV dissociation may or may not have complete AV block (**see Fig. 40.10 and eFig. 40.8**).
4. A combination of causes, as when excess digitalis results in the production of nonparoxysmal AV junctional tachycardia associated with sinoatrial (SA) or AV block.

EFIGURE 40.10 Nonparoxysmal AV junctional tachycardia in a healthy young adult. **Top,** This tachycardia occurs at a fairly regular interval (W-shaped complexes) and is interrupted intermittently with sinus captures that produce functional right and left bundle branch blocks. **Middle,** Two P waves are indicated by *arrowheads*. The junctional discharge rate is approximately 120 beats/min (cycle length = 500 msec), and the rhythm is irregular, sometimes shortened by sinus captures or delayed by concealed conduction that resets and displaces the junctional focus. **Bottom,** Carotid sinus massage slows both the junctional and the sinus discharge rates.

Mechanisms

With this classification in mind, it is important to emphasize that AV dissociation is not a diagnosis and is used in a manner similar to jaundice or fever. One must state that "AV dissociation is present and is caused by…" and then give the cause. An accelerated rate of a slower, normally subsidiary pacemaker and a slower rate of a faster, normally dominant pacemaker that prevents conduction because of physiologic collision and mutual extinction of opposing wavefronts (interference) or the manifestations of AV block are the basic disturbances producing AV dissociation. The atria in all these cases beat independently from the ventricles, under control of the sinus node or ectopic atrial or AV junctional pacemakers, and can exhibit any type of supraventricular rhythm. If a single pacemaker establishes control of both the atria and the ventricles for one beat (capture) or a series of beats (e.g., sinus rhythm, AV junctional rhythm with retrograde atrial capture [**see eFigs. 40.7 and 40.8**], ventricular tachycardia [VT] with retrograde atrial capture), AV dissociation is abolished for that period. Conversely, whenever the atria and ventricles fail to respond to a single impulse for one beat (premature ventricular complex without retrograde capture of the atrium) or a series of beats (VT without retrograde atrial capture), AV dissociation exists for that period. Interruption of AV dissociation by one or a series of beats under the control of one pacemaker, anterogradely or retrogradely, indicates that the AV dissociation is incomplete. Complete or incomplete dissociation can also occur in association with all forms of AV block. Usually, when AV dissociation results from AV block, the atrial rate exceeds the ventricular rate. For example, a subsidiary pacemaker with a rate of 40 beats/min can escape in the presence of a 2 : 1 AV block when the atrial rate is 78 beats/min. If the AV block is bidirectional, AV dissociation results.

Electrocardiographic and Clinical Features

The ECG demonstrates the independence of P waves and QRS complexes. P wave morphology depends on the rhythm controlling the atria—sinus, atrial tachycardia, junctional, flutter, or fibrillation. During complete AV dissociation, both the QRS complex and the P waves appear to be regularly spaced without a fixed temporal relationship to each other. When the dissociation is incomplete, a QRS complex with a supraventricular contour occurs early and is preceded by a P wave at a PR interval exceeding 0.12 second and within a conductible range. This combination indicates ventricular capture by the supraventricular focus. Similarly, a premature P wave with retrograde morphology and a conductible RP interval may indicate retrograde atrial capture by the subsidiary focus.

Physical findings include a variable intensity of the first heart sound as the PR interval changes, atrial sounds, and *a* waves in the jugular venous pulse lacking a consistent relationship to ventricular contraction. Intermittent large (cannon) *a* waves may be seen in the jugular venous pulse when atrial and ventricular contractions occur simultaneously. The second heart sound can split normally or paradoxically, depending on the manner of ventricular activation. A premature beat representing ventricular capture can interrupt a regular heart rhythm. When the ventricular rate exceeds the atrial rate, a cyclic increase in intensity of the first heart sound is produced as the PR interval shortens, climaxed by a very loud sound (bruit de canon). This intense sound is followed by a sudden reduction in intensity of the first heart sound and the appearance of giant *a* waves as the PR interval shortens and P waves “march through ” the cardiac cycle.

Management

Management is directed toward the underlying heart disease and precipitating cause. The individual components producing the AV dissociation, not the AV dissociation per se, determine the specific type of antiarrhythmic approach.

Pacemakers and Implantable Cardioverter-Defibrillators

Charles D. Swerdlow, Paul J. Wang, Douglas P. Zipes

Cardiac implantable electrical devices (CIEDs) deliver therapeutic electrical stimuli. An applied stimulus produces an electrical field that is proportional to the spatial derivative of the applied voltage (local change in voltage with respect to distance). This resultant field interacts with intrinsic cardiac

electrical activity. The response of the heart is mediated by the passive and active (ion channel) properties of cell membranes, by the properties of electrical connections between cardiac cells, and possibly by direct intracellular electrical effects (**see Chapter 34**).

Electrical therapy for cardiac arrhythmias includes low-voltage (1 to 5 V) pacing stimuli (pulses) and high-voltage (500 to 1400 V) stimuli (shocks). Pacemakers deliver pacing pulses to treat bradycardia. Implantable cardioverter defibrillators (ICDs) deliver shocks to defibrillate ventricular fibrillation (VF) or to cardiovert ventricular tachycardia (VT). They also deliver pacing pulses to treat bradycardia or sequences of rapid pacing pulses (antitachycardia pacing) to treat VT. Cardiac resynchronization therapy (CRT) pacemakers (CRT-P) or ICDs (CRT-D) also provide electrical therapy for heart failure in the form of pacing pulses that resynchronize the ventricular contraction sequence. This chapter covers antiarrhythmic electrical therapy delivered by CIEDs. See **Chapter 27** for CRT in the treatment of heart failure.

Pacemakers

Indications for Pacemakers

The Guidelines section at the end of this chapter provides guidelines for pacemakers and ICDs.[1] Pacemakers are indicated to relieve or prevent symptomatic bradycardia not resulting from a reversible cause. Although supported by strong expert consensus, these indications were developed before the era of randomized controlled trials (RCTs). The strongest indications relate to relief of symptoms confirmed to be caused by bradycardia. Pacing is also indicated in patients who have documented asymptomatic bradycardia and serious symptoms consistent with bradycardia, but no documentation of symptomatic bradycardia, provided that alternative causes for the symptoms have been excluded. Pacing is also indicated to prevent future symptomatic bradycardia in patients who are presently asymptomatic if the risk of rapid progression to serious symptoms is high. This indication is applied most frequently to patients with advanced disease of the His-Purkinje system who are at risk for abrupt, high-grade, atrioventricular (AV) block without an adequate escape rhythm (**see Chapter 40**).

Pacemaker Leads and Generators

Leads.
Transvenous pacemaker leads comprise a small, distal tip electrode for pacing and sensing with a fixation mechanism that anchors the lead to the heart, a proximal terminal that connects to the generator, and a lead body connecting the two (**Fig. 41.1A**). Unipolar leads have only a single-tip electrode. Bipolar leads have a second ring electrode located about 10 mm proximal to the tip. Pacemakers use a separate lead for each chamber paced.

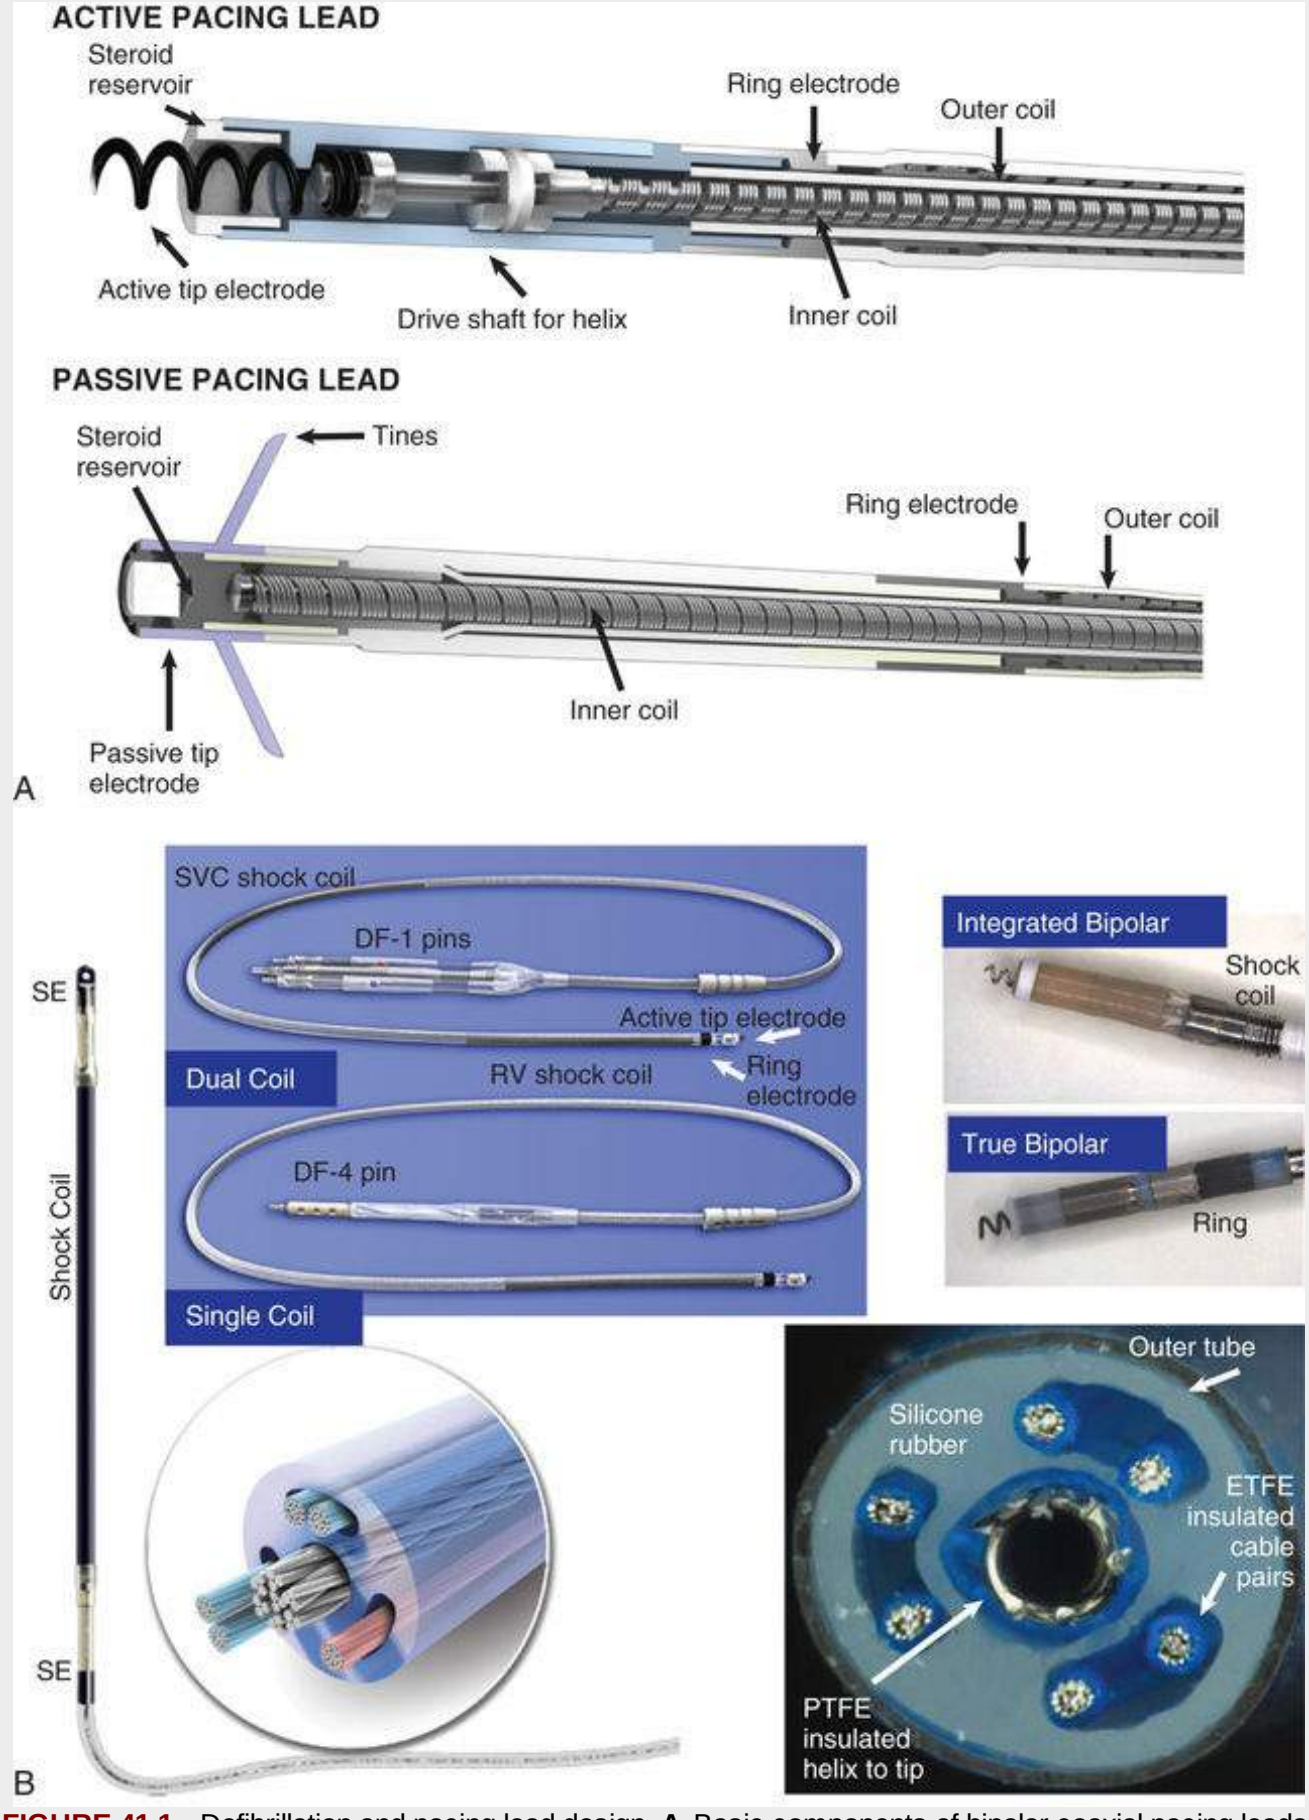

FIGURE 41.1 Defibrillation and pacing lead design. **A,** Basic components of bipolar coaxial pacing leads. **Top panel,** Active fixation design with helical screw serving as distal electrode. **Bottom panel,** Passive (tined design). **B,** Defibrillation leads. **Top left,** Dual-coil lead with DF-1 connector above single-coil lead with DF-4 connector. **Top right,** True bipolar *(top)* and integrated bipolar *(bottom)* defibrillation leads. The true bipolar lead senses between the distal tip and the proximal ring, which are dedicated for pacing and sensing. True bipolar leads have a single coil. In contrast, integrated bipolar leads pace and sense between the tip and the distal coil. The distal coil is used for sensing, pacing, and defibrillation. Integrated bipolar leads also contain a second, proximal coil, which increases the lead surface area for defibrillation.

Lower left, Subcutaneous ICD lead. **Lower right,** Cross section of transvenous ICD lead. *ETFE,* Ethyltetrafluoroethylene; *PTFE,* polytetrafluoroethylene; *RV,* right ventricular; *SE,* sensing electrode; *SVC,* superior vena cava.

Right atrial leads are frequently placed in or near the right atrial appendage. Most right ventricular (RV) leads are placed near the RV apex or septum; however, there is increasing interest in positioning RV leads to pace from or near the His bundle to improve the hemodynamics of RV pacing[2] (see later).

Generators.

Conventional pacemaker generators include a plastic header to which the leads are attached and a 10- to 15-cm^3 titanium casing or "can" that houses the battery, tiny capacitors that generate pacing pulses, and electronic circuitry for control and telemetry (**eFig. 41.1**). Battery performance must be predictable over time to provide an elective replacement indicator. Usually, generators are implanted subcutaneously over the pectoral muscle in the chest.

Recent advances in microelectronics permitted development of leadless capsule pacemakers[3,4] that comprise both the generator and the lead system. These pacemakers are placed in the RV endocardium through a catheter delivery system (**Fig. 41.2**) and thus are not susceptible to complications caused by transvenous leads. Leadless capsule pacemakers have two major limitations: first-generation devices permit only single-chamber ventricular pacing, and the feasibility of extracting chronically implanted devices is unknown.

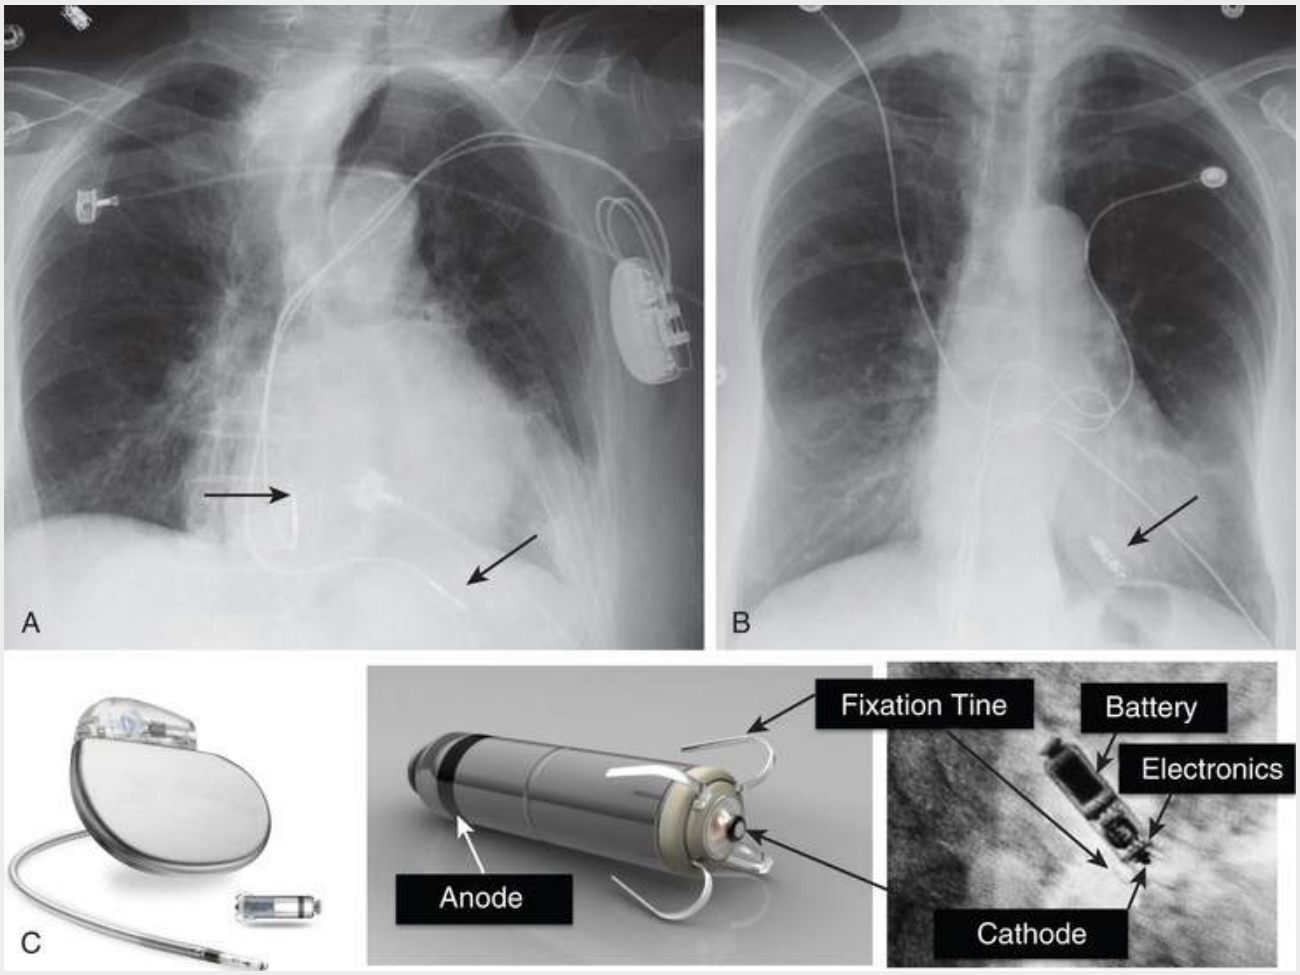

FIGURE 41.2 Transvenous versus leadless pacemakers. **A,** Radiograph of transvenous pacemaker with generator in left pectoral pocket. *Left arrow* denotes tip of atrial lead. *Right arrow* denotes tip of ventricular leads. Leads have active fixation screws. **B,** Radiograph of leadless capsule pacemaker implanted in right ventricular apical septum (*arrow*). **C, Left panel,** Transvenous pacemaker and lead to scale with one model of leadless capsule pacemaker. The lead's active fixation mechanism is shown in Fig. 41.1. **Middle panel,** Enlarged image of leadless capsule pacemaker. **Right panel,** Right anterior oblique cinefluoroscopy frame shows components of leadless capsule pacemaker.

Principles: Capture, Sensing, and Hemodynamics of Pacing

Pacemakers sense intracardiac electrical signals (electrograms) and deliver low-voltage electrical stimuli (pulses) when the intrinsic cardiac rate is too slow.

Cardiac Electrical Stimulation.

Cardiac pacing requires a local stimulus that creates a field sufficient to depolarize (reduce the membrane potential of) local myocardium during diastole to threshold voltage and thus initiate a self-propagating wavefront of depolarization. A stimulus that brings local myocardium to threshold is said to "capture" it. Pacemaker electrodes with small surface area (1 to 5 mm^2) provide sufficient current

density to achieve a sufficient field strength (approximately 1 V/cm) with minimum battery energy.

Waveform.

The waveform of an electrical pulse is the temporal pattern of its amplitude, measured by voltage (or current). Voltage is a critical parameter for pacing because it determines the electrical field that interacts with the heart. In general, current is linearly related to voltage by Ohm's law (V = IR, where V is voltage, I is current, and R is resistance). Waveform duration is critical for characterization of either a pacing or a defibrillation waveform because the stimulus interacts with the heart for the duration of the waveform. Furthermore, the time course of the heart's response to the stimulus depends on time-dependent passive and active ion channel processes, collectively referred to as the *membrane time constant* (τ_m) (**see Chapter 34**). Either pacing or defibrillation pulses are most efficient when their durations approximate τ_m. Thus the most easily measured electrical parameter relevant to pacing is voltage (or current) as a function of time (**eFig. 41.2**).

Strength-Duration Relationship.

The strength-duration curve plots stimulus strength required for pacing as a function of pulse duration (**Fig. 41.3**). It can be represented by an inverse exponential or hyperbolic function. Two parameters, the rheobase and the chronaxie, characterize this curve. The *rheobase* is the minimum current for a pulse of infinite duration that results in depolarization. The *chronaxie* is the pulse duration on the curve that corresponds to twice the rheobase current; it approximates τ_m. The chronaxie is important for design of efficient pacing pulses because a pulse with duration equal to the chronaxie paces with the lowest energy. This is important for generator size and longevity.

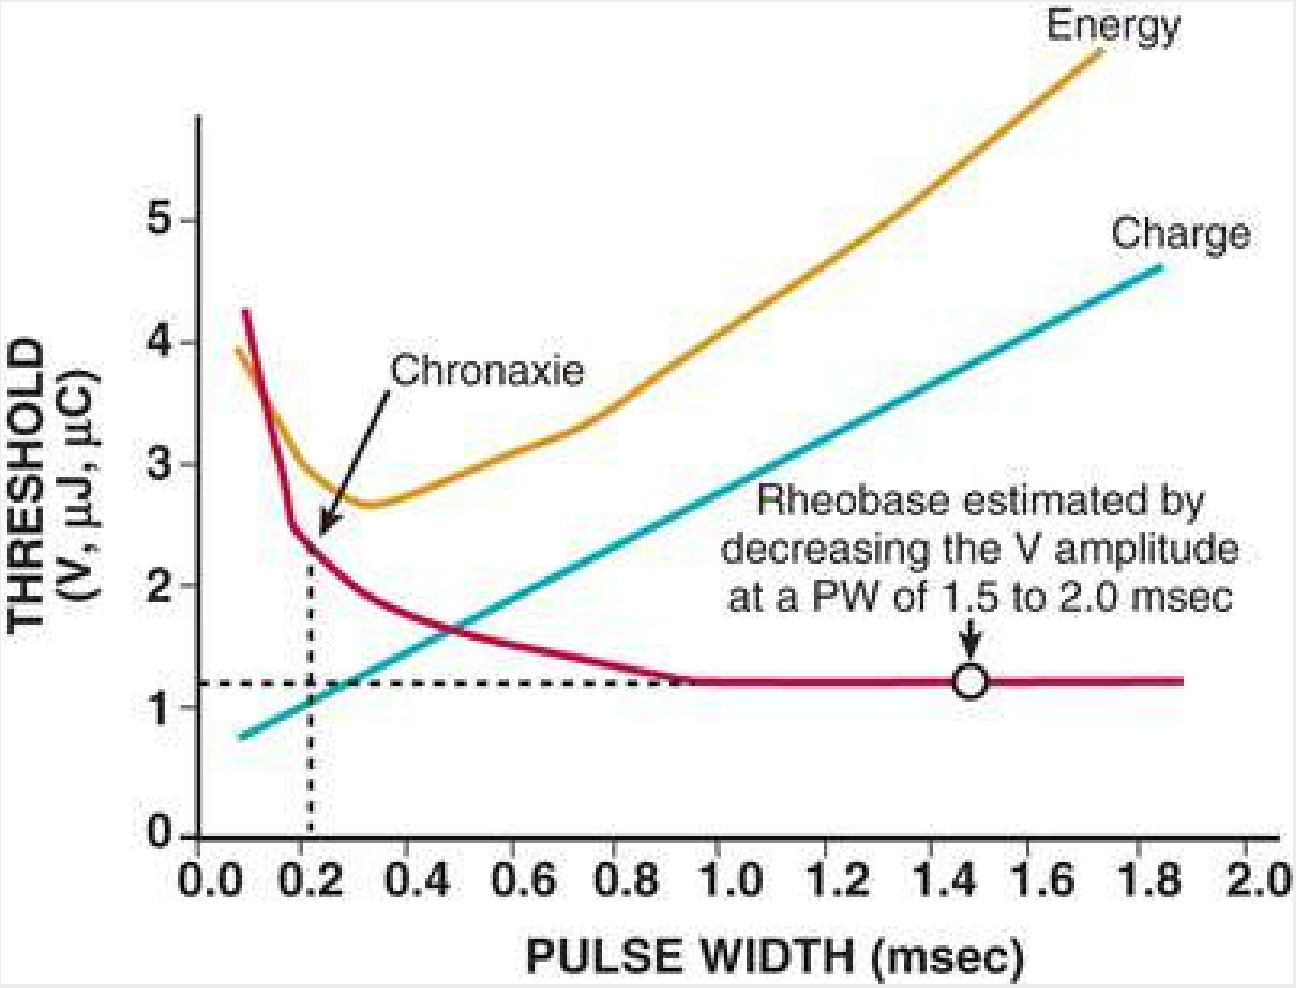

FIGURE 41.3 Relationships among chronic ventricular strength-duration curves from a canine, expressed as potential (V), charge (μC), and energy (μJ). Rheobase is the threshold at an infinitely long pulse width (PW) duration. Chronaxie is the pulse duration at twice the rheobase. (From Stokes K, Bornzin G. The electrode-biointerface stimulation. In Barold SS, editor. Modern Cardiac Pacing. Mount Kisco, NY: Futura; 1985, pp 33-77.)

Pacing Pulses: Polarity, Strength, and Duration.

Because pacing requires a voltage applied between two points, two electrodes are always required. However, in common use, the terms “unipolar” and “bipolar” refer to the number of intracardiac electrodes. Thus, *bipolar pacing* is performed between intracardiac cathodal tip and anodal ring electrodes. *Unipolar pacing* is performed between a cathodal tip electrode and the pacemaker generator housing that serves as the anode. Unipolar pacing at high outputs can result in pectoral muscle stimulation from voltage applied to the pacemaker can.

The durations of pacing pulses are optimized to capture with minimum energy consumption. Typically, voltage is set to a safety margin of 1.5 to 2 times the voltage threshold at durations near the chronaxie (0.4 to 0.5 msec for transvenous leads, 0.2 to 0.3 msec for leadless capsule pacemakers). Automatic assessment of pacing capture threshold is performed by closed-loop feedback algorithms that periodically measure the pacing threshold and adjust the output. When performed on a beat-to-beat basis, it can conserve battery by delivering safe pacing with an output minimally above the pacing threshold.

Metabolic and Drug Effects on Pacing Threshold.

The most clinically important metabolic abnormality is *hyperkalemia,* which raises pacing thresholds and alters sensing by causing conduction delays and local conduction block. Marked acidosis or alkalosis and profound hypothyroidism also raise the pacing threshold. **eTable 41.1** summarizes drug effects. Sodium channel–blocking drugs increase pacing thresholds. This is particularly true for class IC

drugs (e.g., flecainide) during pacing near the upper rate limit or antitachycardia pacing (ATP) because of use dependence, the enhancement of drug-induced sodium channel blockade at faster rates.

Electrograms and Pacemaker Sensing

Intracardiac Electrograms.

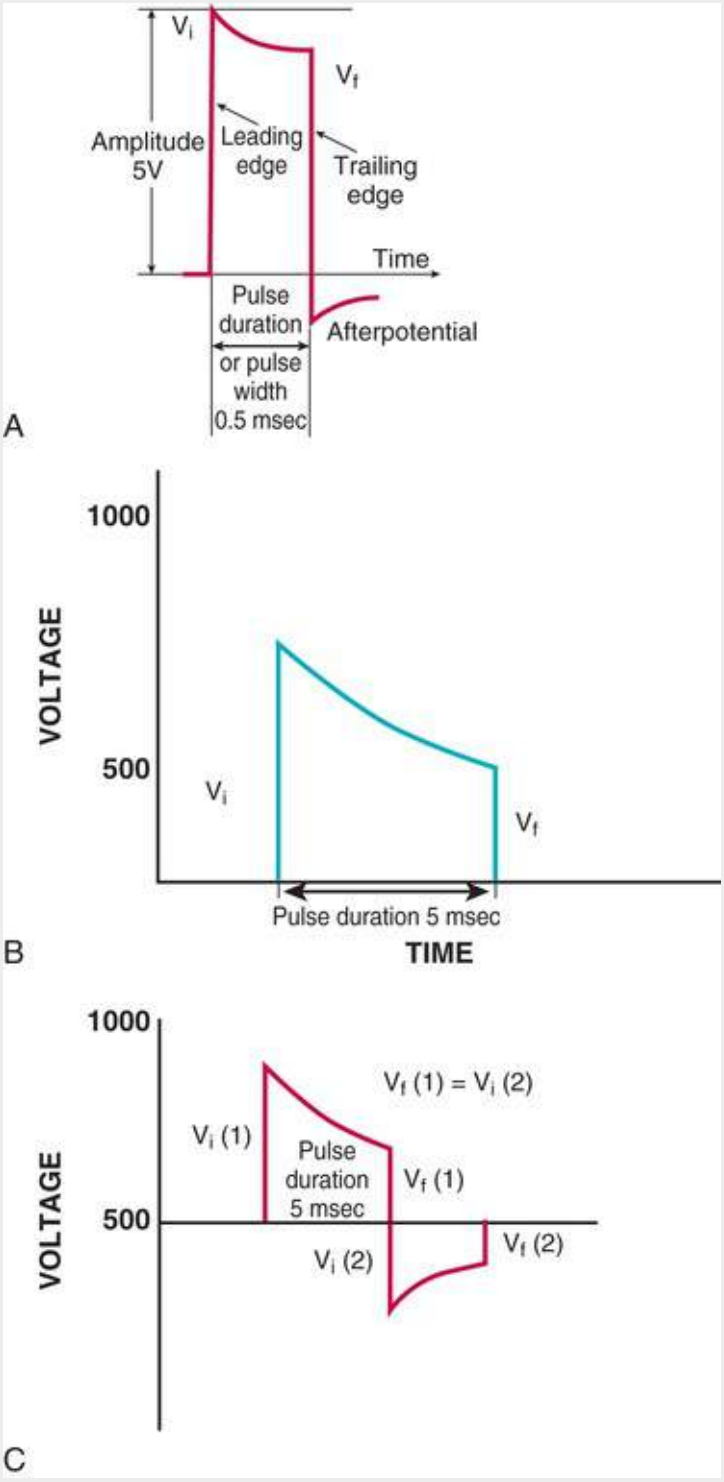
An electrogram (EGM) displays the electrical potential difference between two points in space as a function of time. The electrocardiogram (ECG), recorded from the body's surface, records electrical activity from much of the heart. In contrast, EGMs recorded from small intracardiac electrodes record only local activity. Because EGMs record a potential difference between two points, two electrodes are always required. However, as in pacing, the terms “unipolar” and “bipolar” refer to the number of intracardiac electrodes in the recording pair. *Unipolar* EGMs are recorded between a small electrode on the lead tip and a large remote (indifferent) electrode, the generator can. The location of the remote electrode has little effect on the EGM, but it may record noncardiac potentials, such as pectoral myopotentials. EGM signals that do not originate in local myocardium adjacent to the intracardiac electrode(s) are called *far-field signals*. These include both noncardiac signals and cardiac signals originating at a distance. In the context of CIEDs, far-field signals originate in a different cardiac chamber.

The typical amplitude of transvenous atrial and ventricular EGMs is in the range of 1.0 to 5 mV and 5 to 20 mV, respectively. The frequency content of ventricular and atrial EGMs is similar (5 to 50 Hz). T waves have lower frequency content (1 to 10 Hz), whereas most noncardiac myopotentials and electromagnetic interference (EMI) have higher frequencies (**eFig. 41.3**). This permits use of electronic bandpass filters to reduce sensing of signals that do not represent myocardial depolarization (oversensing).

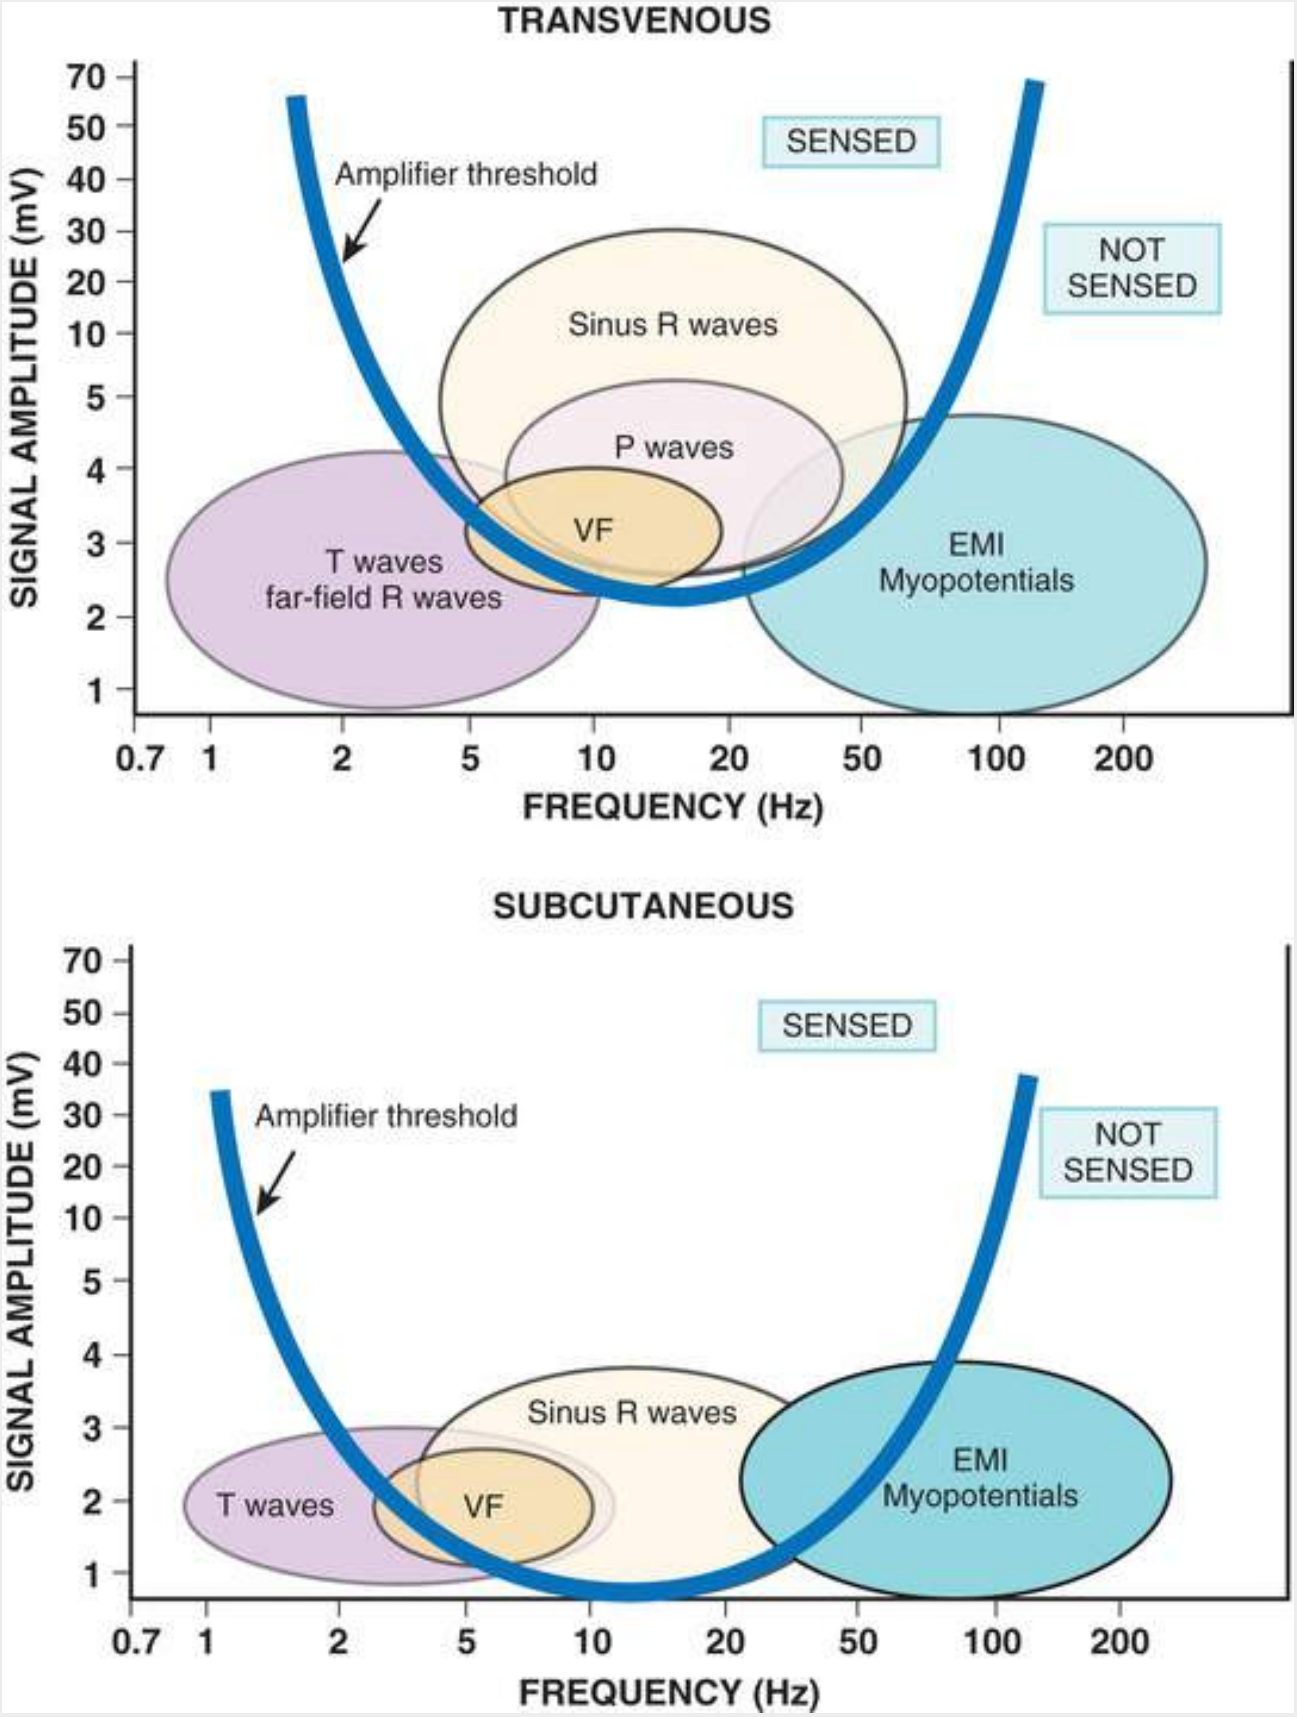
Sensing.

When a depolarization wavefront passes the tip electrode, a deflection in the EGM signal travels instantaneously through the electrode to the generator. There, the signal is amplified, filtered, processed by the sensing electronics, and compared to a threshold voltage (*sensing threshold*; **eFig. 41.4**). A sensed event occurs when the processed signal exceeds this sensing threshold, and the device determines that an atrial or ventricular depolarization has occurred.

Most pacemaker sensing thresholds are programmed to fixed values, typically about 2.0 mV for ventricular channels and 0.3 to 0.6 mV for atrial channels, with bipolar sensing to allow sensing of lower-amplitude P waves and atrial EGMs during atrial fibrillation (AF). Highly sensitive programmed values can result in *oversensing*, sensing of unintended signals not originating in the cardiac chamber of interest. EGMs sensed from a different cardiac chamber (usually ventricular signals sensed on the atrial channel) are referred to as *far-field* EGMs. Because the sensing dipole is smaller in bipolar sensing circuits than unipolar circuits, oversensing of noncardiac signals (e.g., pectoral myopotentials, EMI) is less likely to occur with bipolar sensing, especially with closely spaced electrodes.

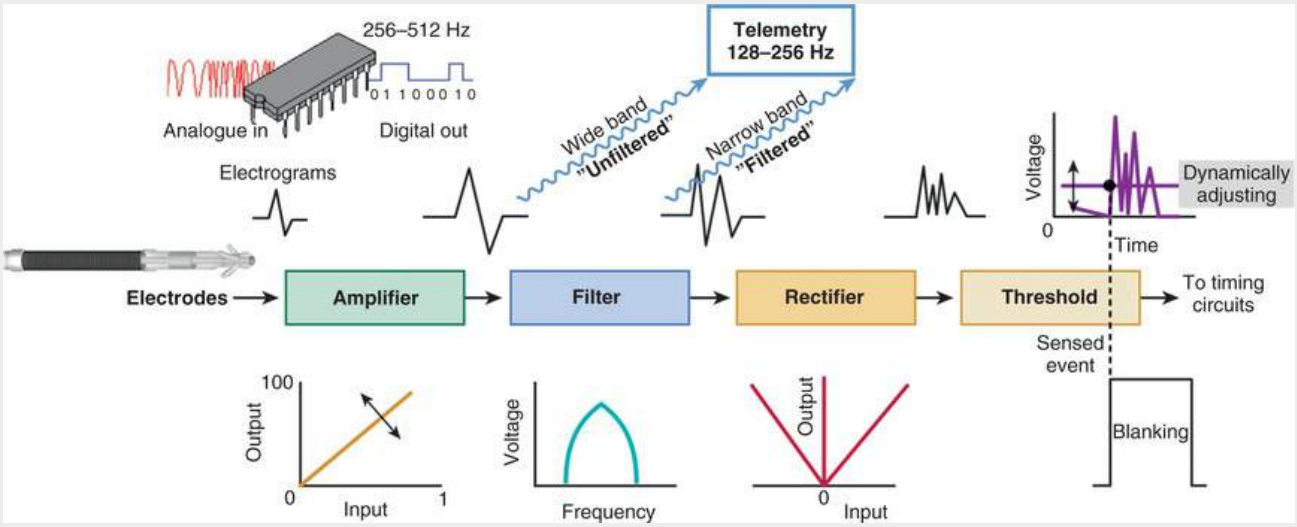


EFIGURE 41.2 Pacing and defibrillation waveforms. All pacing and defibrillation pulses in implantable devices have capacitive-discharge waveforms with a fixed leading-edge voltage and a trailing-edge voltage determined by the waveform duration and time constant. **A,** Pacing waveform. **B,** Monophasic truncated exponential waveform with initial voltage V_i and final voltage V_f. In comparison to the pacing waveform, the voltage is approximately 100 times greater, and the duration is approximately 10 times greater. **C,** Biphasic truncated exponential waveform with initial voltage of the second phase, V_i (2), equal to the final voltage of the first phase, V_f (1). This "single-capacitor" waveform is generated by reversing polarity during capacitor discharge and is the waveform used in all ICDs.



EFIGURE 41.3 Signal amplitude versus frequency. **Top,** Approximate characteristics of the premature ventricular beats (PVCs) and R waves that pacemakers and transvenous ICDs are intended to sense and characteristics of T waves that they are intended not to sense. The sense amplifier's filters are designed to sense signals that are above the U-shaped amplifier threshold curve and to reject signals that are below the curve. PVCs and R waves have higher dominant frequency than T waves. Myopotentials usually have higher-frequency components than intracardiac signals. T waves and far-field R waves have lower frequencies. As shown, there are overlaps in these amplitude-frequency characteristics that cause oversensing or undersensing in particular situations. The *ellipses* representing the amplitude-frequency characteristics in this figure are conceptual and are not based on quantitative measurements. **Bottom,** Corresponding diagram for electrograms (EGMs) recorded by subcutaneous ICDs. R wave amplitude and frequency content are lower. Thus there is more overlap with T waves, especially ventricular fibrillation

(*VF*). For subcutaneous ICDs, it is not possible to rely on filtering alone to reject T wave limits reliably while retaining accurate sensing in VF. *EMI,* Electromagnetic interference. (From: Swerdlow C, Brown M, Bordachar P. Sensing and detection with cardiac implantable electronic devices. In Ellenbogen KA, Kay GN, Lau CP, Wilkoff BL, editors. Clinical Cardiac Pacing, Defibrillation, and Resynchronization Therapy. 4th ed. Philadelphia: Saunders; 2016.)



EFIGURE 41.4 Functional block diagram of ICD sense amplifier. The analog differential EGM signal recorded between two implanted electrodes is first digitized at a sampling rate of 256 to 512 Hz and then amplified for subsequent processing. Bandpass filtering reduces the amplitude of lower-frequency signals such as T waves and far-field R waves and higher-frequency signals such as myopotentials and electromagnetic interference. Both the wide-band (unfiltered) and narrow-band (filtered) signals are down-sampled to 128 to 256 Hz for telemetry. After filtering, the signal usually is rectified to nullify effects of polarity. The threshold operation compares the amplitude of the amplified, filtered, and rectified signals with the sensing threshold voltage. The ICD's timing circuits record a sensed event at the instant the amplitude of the processed signal exceeds the threshold voltage. After sensing, the amplifier is blanked (turned off) for a short period, so that each depolarization is sensed only once. In older ICDs, the blanking period displayed on the programmer represented true hardware blanking. In modern ICDs, hardware blanking lasts only 20 to 30 milliseconds, followed by software blanking in which the ICD does not display or count signals that exceed the sensing threshold. Programmable values control the high and lower limits on the sensing threshold, which automatically adjusts on a beat-by-beat basis (see text discussion). Circuit designs may integrate some functions, such as amplification and filtering. (From Swerdlow CD, Asirvatham SJ, Ellenbogen KA, Friedman PA. Troubleshooting implanted cardioverter-defibrillator sensing problems. I. Circ Arrhythm Electrophysiol 2014;7(6):1237-61.)

ETABLE 41.1

Common Interactions Between Drugs and Pacemakers/Implantable Cardioverter-Defibrillators (ICDs)

Pacemakers
Effects on Pacing Threshold
Higher threshold
Class 1C drugs (e.g., flecainide)
Amiodarone (chronic effect, especially atrial thresholds)
Lower pacing threshold
Glucocorticoids
Isoproterenol and epinephrine
Effect on Pacing Burden
Increased atrial pacing burden: drugs that cause sinus bradycardia (e.g., beta blockers, amiodarone, lithium)
Increased ventricular pacing burden: drugs that slow AV conduction (e.g., beta blockers, amiodarone)
ICDs
Frequency of VT or VF
Increased
Antiarrhythmic drugs
Drugs with proarrhythmic side effects
Drugs that interact with proarrhythmic drugs
Decreased
Beta blockers
Antiarrhythmic drugs (e.g., sotalol, amiodarone)
Consideration for Detection of VT or VF
VT rate
Decrease (most oral antiarrhythmic drugs, especially class 1C, amiodarone)
SVT/AF ventricular rate
Decrease (beta blockers, amiodarone, sotalol)
Increase (class 1C drugs, 1 : 1 conduction of atrial flutter)
Device SVT-VT discrimination algorithms
VT interval stability (class IC drugs, amiodarone: more irregular)
Altered EGM morphology
Therapy for VT or VF
Defibrillation energy requirement
Increase (class IB, class IC, chronic amiodarone, verapamil)
Decrease (sotalol, dofetilide)

AF, Atrial fibrillation; *AV,* atrioventricular; *EGM,* electrogram; *SVT,* supraventricular tachycardia; *VF,* ventricular fibrillation; VT, ventricular tachycardia.

Hemodynamics Related to Pacing

Chronotropic Response and Rate-Adaptive Pacing

Heart rate and stroke volume determine cardiac output, which increases fivefold to sixfold from rest to meet metabolic demands of peak exercise. The ability to increase heart rate with exertion (chronotropic competence) provides most of this increase as exertion approaches its peak.

Rate-adaptive pacing adjusts the pacing rate to the metabolic demands of the body. A sensor located in the pacemaker generator or lead monitors a signal that indicates the need for a faster rate. Common sensors monitor body motion (accelerometer), respiration (minute ventilation), or cardiac motion (endocardial acceleration); each has specific advantages and limitations. Some pacemakers combine two sensors (blended sensor) in designs intended to maximize the benefits and minimize the limitations of each sensor. Algorithms translate the sensor values to pacing rate. Most algorithms have programmable parameters to achieve the optimal heart rate for the body's metabolic needs.

Atrioventricular Synchrony

Atrial filling of the left ventricle begins in early diastole and continues as long as the mitral valve remains open. Immediately before ventricular systole, the atria contract, resulting in a bolus of blood (atrial transport) that contributes appreciably to ventricular stroke volume. Maximizing this atrial contribution to

cardiac output requires optimal timing of atrial systole immediately before ventricular systole, atrioventricular synchrony. Loss of physiologic AV synchrony may reduce cardiac output by 20% to 25%. Patients with impaired diastolic function or impaired systolic function are most dependent on atrial transport. Patients with long PR intervals exhibit several causes of mechanical AV dyssynchrony (despite electrical synchrony), depending on the degree of PR prolongation.[5] Thus, in dual-chamber pacemakers, the AV delay is programmed to achieve efficient AV mechanical synchrony.

Any condition that alters the timing of atrial or ventricular electrical activation can impair mechanical AV synchrony. *Pacemaker syndrome* refers to the constellation of symptoms caused by loss of AV synchrony, including fatigue, shortness of breath, chest pain, headache, and neck pulsations. It may occur with AV dissociation or 1 : 1 AV association that results in an adverse sequence of ventricular and atrial contraction. The most hemodynamically disadvantageous AV timing relationship occurs during ventricular pacing with retrograde (V-A) conduction, resulting in reverse (VA) synchrony and atrial contraction while the mitral and tricuspid valves are closed.

Effect of Ventricular Pacing on Synchrony of Ventricular Contraction

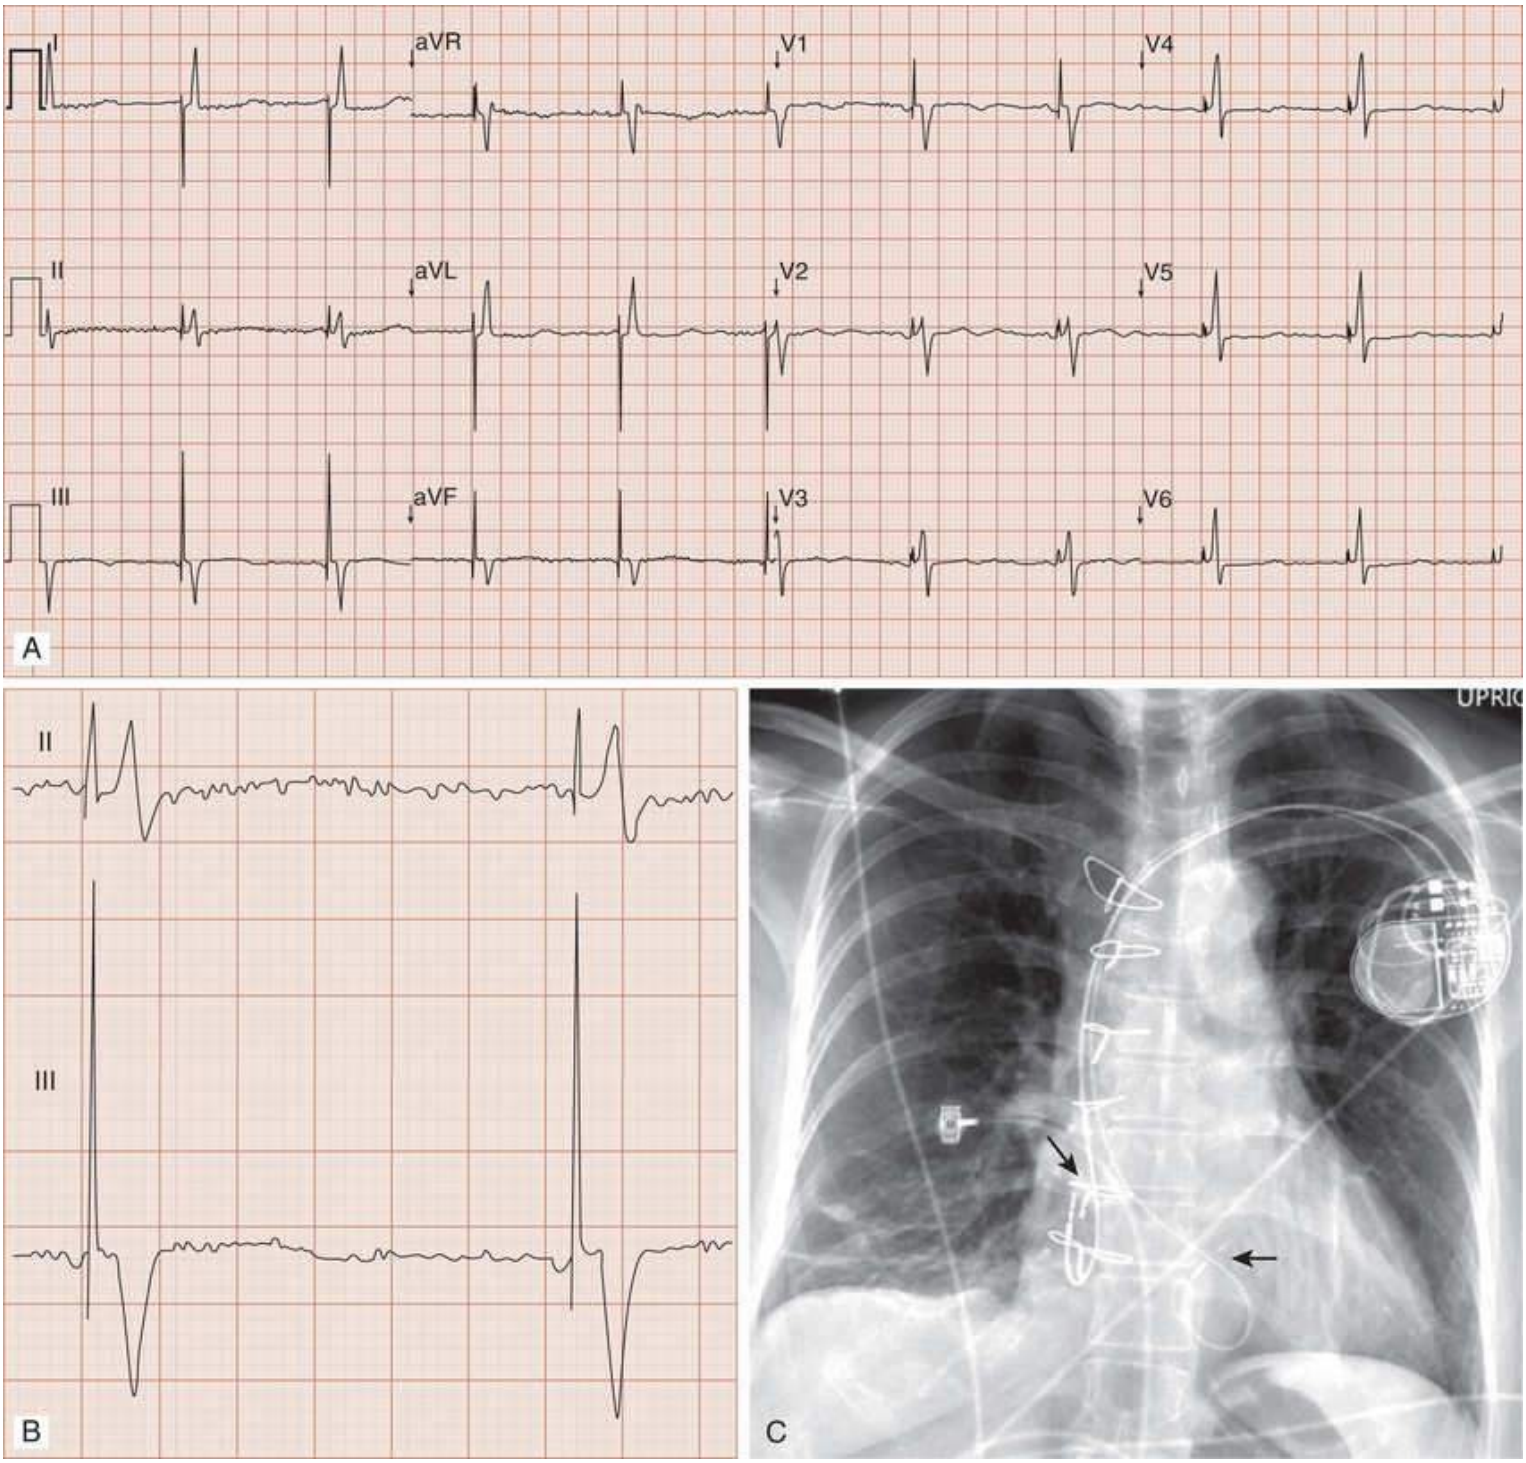
Adverse Consequences of Right Ventricular Pacing.

In patients with impaired AV conduction, DDD pacing ensures that the AV interval is in the physiologic range. However, right ventricular (RV) apical pacing produces both intraventricular and intraventricular dyssynchrony,[2] even if the pacing pulse is synchronized to the atrial impulse. Pacing alternative RV sites such as the septum and outflow tract have not reduced dyssynchrony consistently. Pacing-induced dyssynchrony is hemodynamically-significant in patients with left ventricular (LV) dysfunction, in whom it increases the incidence of heart failure (HF) and persistent AF[2] (**see Chapter 27**).

Dual-chamber programming strategies that promote intrinsic AV conduction can minimize RV pacing in patients with AV conduction (see later). In patients with normal PR intervals, these strategies retain hemodynamic AV synchrony; but in patients with long PR intervals, they sacrifice some or all of the hemodynamic benefits of AV synchrony to avoid RV pacing–induced dyssynchrony. Further, these strategies cannot be used in patients with persistent AV block.

Permanent His Bundle Pacing.

An alternative approach is to pace the His bundle using an active-fixation RV lead.[2,6] The paced QRS complex activates the ventricle over the physiologic His-Purkinje system, restoring ventricular electrical synchrony in patients with normal ventricular conduction and in some with bundle branch block (**eFig. 41.5**). Compared with RV apical pacing, small randomized studies indicate that His Bundle pacing improves exercise capacity, ventricular synchrony, and LV ejection fraction (LVEF); observational data indicate that it reduces HF hospitalizations. However, His bundle pacing using present technology has limitations. Experienced operators achieve procedural success in only about 80% of cases, and pacing thresholds are more than twice as high as RV thresholds, reducing generator longevity.



EFIGURE 41.5 Permanent His bundle pacing. **A,** 12-Lead ECG shows atrial synchronous ventricular pacing with narrow QRS complex. **B,** Enlarged image of leads II and III. There is a 35-millisecond isoelectric interval between pacing stimulus and QRS corresponding to the His-ventricular (HV) conduction interval between His bundle and ventricular myocardium. **C,** *Left arrow* in radiograph denotes atrial lead tip in lateral right atrium. *Right arrow* denotes ventricular lead in His Bundle.

Pacemaker Mode and Timing Cycles

Definitions

Pacing modes describe which chambers are sensed and paced and are characterized by a four-letter code (**Table 41.1**). The first letter indicates the chamber paced: A for atrium, V for ventricle, and D for dual—both atrium and ventricle. The second letter denotes the chamber sensed. The third letter describes pacemaker function: I for inhibition, T for triggered, and D for dual—tracking of atrial activity but

inhibited by ventricular activity. “O” indicates absence of any of these functions. The fourth letter is R, for rate-adaptive pacing.

BPEG, British Pacing and Electrophysiology Group; *NASPE,* North American Society of Pacing and Electrophysiology.

Modified from Bernstein AD, Daubert JC, Fletcher RD, et al. The revised NASPE/BPEG generic code for antibradycardia, adaptive-rate, and multisite pacing. Pacing Clin Electrophysiol 2002;25:260.

Timing cycles are the rules that define a pacemaker's beat-by-beat response to sensed and paced beats. Often it is easier to analyze timing cycles in terms of their associated time intervals measured in milliseconds (msec) rather than in rate measured in beats per minute (bpm). Since 1 minute is equivalent to 60,000 milliseconds, the interval in milliseconds corresponding to a rate in beats per minute can be determined by dividing the 60,000 by the rate (**eTable 41.2**).

ETABLE 41.2

Interval (milliseconds) vs. Rate (beats per minute)

Bradycardia						
Interval (msec)	1500	1200	1000	800	700	600
Rate (bpm)	40	50	60	75	86	100
Tachycardia						
Interval (msec)	450	400	360	350	320	300
Rate (bpm)	133	150	167	171	188	200

Specific Pacing Modes

The *VVI* mode is the basic single-chamber ventricular mode. Pacing occurs when the ventricular rate slows below the programmed *lower rate limit* (**Fig. 41.4**). The interval corresponding to the lower rate limit is the ventricular pacing interval. Usually, this is equal to the interval between a sensed ventricular event and the next paced ventricular event, referred to as the “ventricular escape interval.” There is no atrial sensing, so AV synchrony is not preserved. This mode is indicated in patients with permanent AF and in those in whom AV synchrony is less important than simplicity of the pacing system.

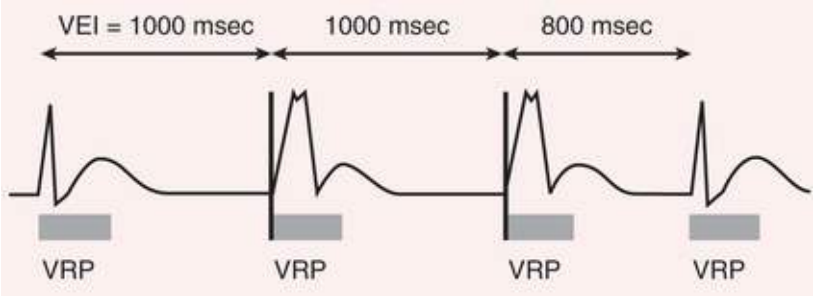

FIGURE 41.4 The VVI timing cycle consists of a defined lower rate limit and a ventricular refractory period (VRP, represented by *rectangles*). When the ventricular escape interval (VEI) from the ventricular sensed event of 1000 milliseconds is completed, a paced event occurs. Because no ventricular sensed event occurs within 1000 milliseconds after the paced event, a second ventricular paced event occurs. Because a ventricular sensed event occurs 800 milliseconds later, a ventricular paced event does not occur. A VRP begins with any sensed or paced ventricular activity.

The *AAI* mode is the corresponding single-chamber atrial pacing mode (**Fig. 41.5**). It is appropriate for patients with sinus node dysfunction and intact AV conduction. Because it does not provide ventricular pacing, AAI mode should not be used in patients who are at risk for AV block.

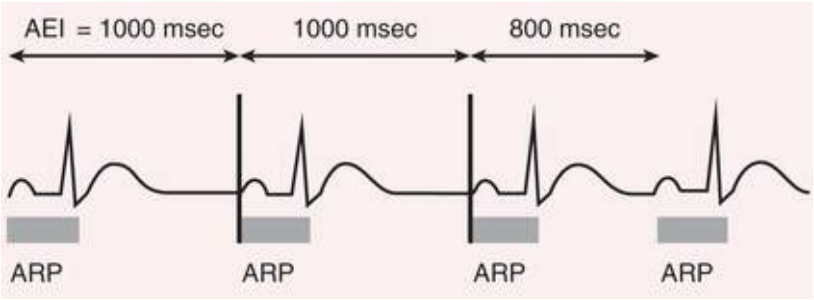

FIGURE 41.5 The AAI timing cycle consists of a defined lower rate limit and an atrial refractory period (ARP, represented by *rectangles*). When the atrial escape interval (AEI) from the atrial sensed event of 1000 milliseconds is completed, a paced event occurs. Because no atrial sensed event occurs within 1000 milliseconds after the paced event, a second atrial paced event occurs. Because an atrial sensed event occurs 800 milliseconds later, an atrial paced event does not occur. An ARP begins with any sensed or paced atrial activity.

The *DDD* pacing mode preserves AV synchrony whenever possible (**Fig. 41.6**). In DDD mode the atrial rate cannot go lower than the programmed lower rate. The AV delay is the maximum permitted time from an atrial event to a ventricular event. If a spontaneous ventricular event does not occur by the time the AV delay elapses, a ventricular paced event occurs. In the setting of AV block, all ventricular events are paced. The special characteristic of the DDD pacing mode is the ability to “track” intrinsic atrial activity so that a ventricular beat follows each P wave in order to maintain AV synchrony. The *upper rate limit* is the maximum rate at which intrinsic atrial activity will be tracked, and it is selected to exceed the patient's maximum sinus rate. The upper rate limit prevents rapid ventricular tracking of atrial activity in AF and other atrial tachyarrhythmias.

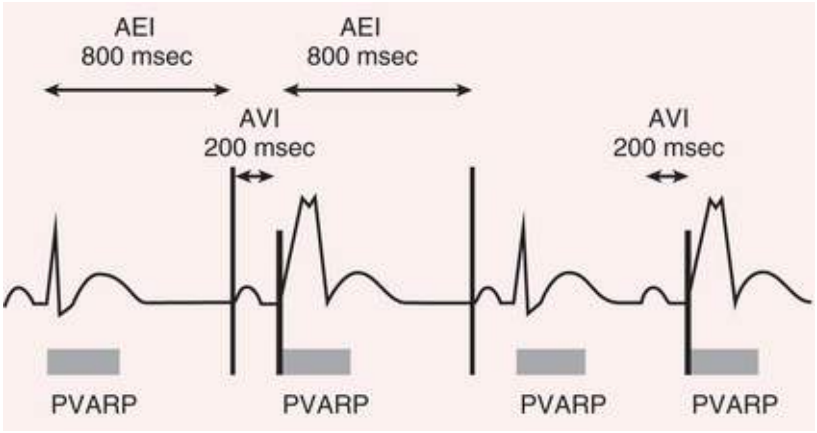

FIGURE 41.6 The timing cycle in DDD consists of a lower rate limit, an AV interval, a ventricular refractory period (not shown), a postventricular atrial refractory period (PVARP), and an upper rate limit. Because an intrinsic atrial event occurs and is followed by an intrinsic ventricular event within the AV interval, no ventricular pacing occurs in the first beat. In ventricular-based timing, the time from a ventricular paced or sensed event to the next atrial paced event is called the atrial escape interval (AEI), which is the lower rate limit interval minus the AV interval. Because no intrinsic atrial event occurs before the AEI times out, a paced atrial event occurs in the second beat. Since no intrinsic ventricular event occurs within the AV interval after this atrial paced event, a ventricular paced event occurs. Following this ventricular paced event an atrial paced event is delivered when the AEI times out 800 milliseconds later to initiate the third beat. Since AV conduction follows this atrial paced event, ventricular pacing is inhibited. The fourth beat begins with an intrinsic atrial event that is not followed by an intrinsic ventricular event within the AV interval. Hence the intrinsic atrial event is "tracked" and followed by a paced ventricular event.

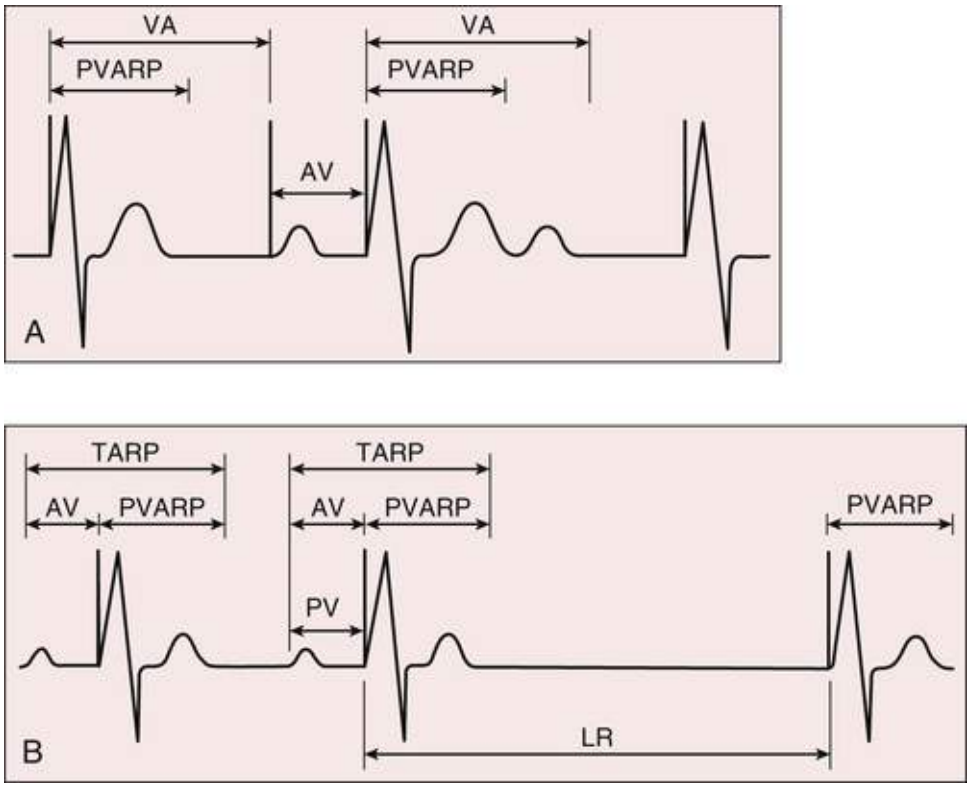
The DDI and VDD pacing modes comprise complementary subsets of DDD functionality (**eFig. 41.6**). The *DDI* mode lacks atrial tracking and is suitable for patients with sinus bradycardia, with or without intact AV conduction. Because AV synchrony is lost when the sinus rate exceeds the lower rate limit, the DDI mode is rarely programmed unless atrial sensing problems prevent reliable mode switching in DDD mode. The *VDD* mode lacks atrial pacing and is suitable for patients with normal sinus node function and AV block. It can be achieved using a single lead with additional atrial sensing electrodes, permitting ventricular tracking of atrial activity to achieve AV synchrony. The VDD mode should not be used in patients with sinus bradycardia, since ventricular pacing without AV synchrony will occur at the lower rate limit, equivalent to the VVI mode.



EFIGURE 41.6 **A,** DDI pacing mode. **B,** VDD pacing mode. See text for details and abbreviations.

Optimizing Dual-Chamber Pacing

Automatic Mode Switching

The DDD and VDD pacing modes need a method to prevent rapid ventricular pacing as a result of ventricular tracking of atrial EGMs during paroxysmal AF, other atrial tachyarrhythmias, or EMI. Automatic mode switching initiates a temporary mode change to a nontracking mode (usually DDI or DDIR) in response to an atrial sensed rate above a specified value. When the atrial rhythm slows sufficiently, the mode switches back to an atrial tracking mode (**Fig. 41.7**).

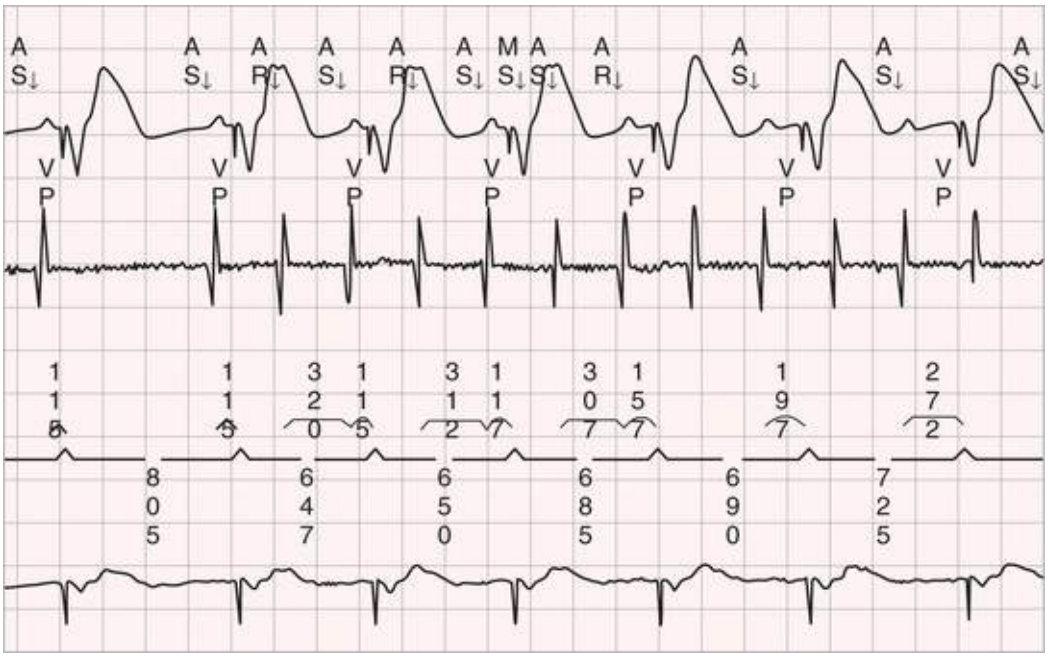


FIGURE 41.7 Mode switch from the DDDR to the DDIR mode during transient atrial tachycardia (AT). The top channel is the surface electrocardiogram (ECG) with markers. The second channel is the atrial electrogram (EGM). The third channel displays atrial intervals above the line and ventricular intervals below the line. The bottom channel is the ventricular EGM. The first two atrial events (AS) are sinus beats tracked with the programmed interval for atrial synchronous pacing. The AT begins with the third atrial event. Mode switch (MS) occurs after the fourth rapid atrial event interval. In the DDI mode, P waves are not tracked, so the AV interval varies. AS, Atrial sense; AR, event in atrial refractory period; VP, ventricular pace.

"Noise" reversion algorithms are intended to prevent pacemaker inhibition during continuous ventricular oversensing, such as that occurring during EMI. They initiate a fixed-rate, asynchronous pacing modes (DOO, VOO) for the duration of oversensing.

Programming to Avoid Unnecessary Right Ventricular Pacing

Facilitating AV conduction is important to minimize RV pacing in patients without permanent AV block. The first approach was to prolong the AV interval or extend it periodically ("positive search AV hysteresis"). The primary limitation is that it may result in extremely long AV delays that cause pacemaker syndrome.[5] There is no consensus about the maximal acceptable PR interval, but 350 to 400 milliseconds is typically used.

A second strategy is a variation on AAIR pacing with backup ventricular pacing. Some algorithms use the AAIR pacing mode when AV block is not present but switch automatically to a DDDR mode when AV block is detected. This strategy can be tolerant of occasional single beats of AV block without resorting to consistent RV pacing, and thus delivers less RV pacing than strategies that prolong the AV interval. However, it may mimic intermittent failure of ventricular pacing for a single beat (**Fig. 41.8**). Another variation is AAIR pacing with backup VVIR pacing.

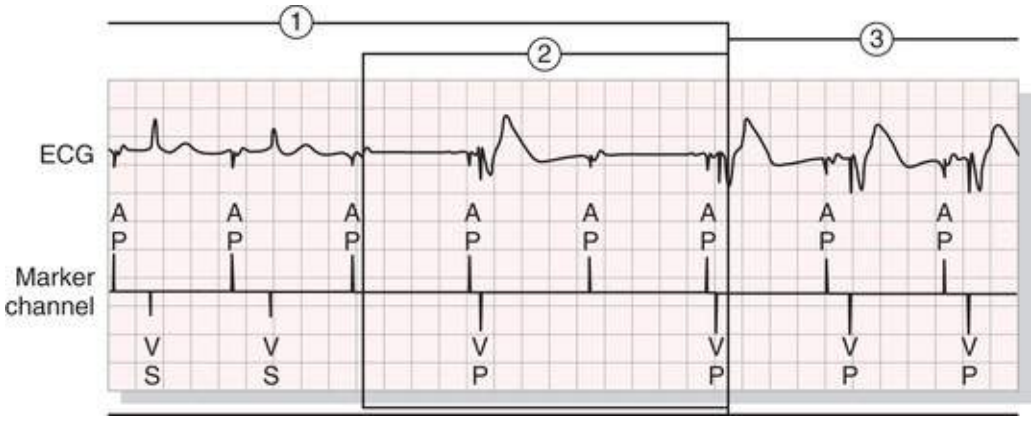

FIGURE 41.8 One algorithm to minimize right ventricular pacing. Initially, AAIR pacing is seen *(1)*; if an atrial pace event occurs without a ventricular sensed event, a ventricular backup output occurs *(2)*, and the pacemaker then switches to the DDDR mode *(3)*. The paced AV interval after a nonconducted beat has a short AV delay (80 msec).

Single- versus Dual-Chamber Pacing Mode and Pacemaker Selection

An expert consensus document provides recommendations for selection of single- versus dual-chamber pacemakers.[7] **Fig. 41.9** provides a simplified overview.

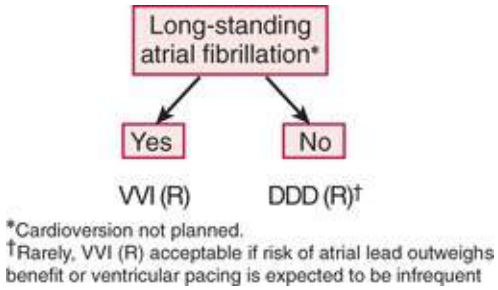

FIGURE 41.9 Selection of pacemaker modes and generators. See text for details.

Sinus Node Disease.

In patients with sinus node disease, RCTs demonstrate that DDD pacing reduces AF and pacemaker syndrome in comparison with VVI pacing.[8] These studies report inconsistent results regarding mortality, reduction in HF, stroke, and quality of life.[7] Rate-adaptive pacing is recommended for patients with significant, symptomatic *chronotropic incompetence*, the inability to increase heart rate for metabolic needs of exertion. When programming AAIR, it is important that the sensor-driven atrial rate is not fast enough to cause AV block.

AV Block and Bifascicular/Trifascicular Block.

Expert consensus recommends dual-chamber pacing over single-chamber ventricular pacing provided sinus rhythm is present.

Blanking and Refractory Periods

Definitions.

After each paced or sensed event, the sense amplifier is turned off for a short hardware *blanking period* (20 to 250 msec) to prevent multiple sensed events during a single cardiac depolarization. The blanking period's role is particularly important following a paced event because of the large amplitude signal and polarization effect. Following each blanking period, there is usually a software *refractory period* during which sensed events are not used to reset the timing cycle but may be used to calculate rate for features such as mode switching (**Fig. 41.10**). Some newer pacemakers include additional software blanking. Events "sensed" during software blanking periods are not used to control timing cycles, but may be used for specialized functions, such as detecting oversensing or atrial arrhythmias.

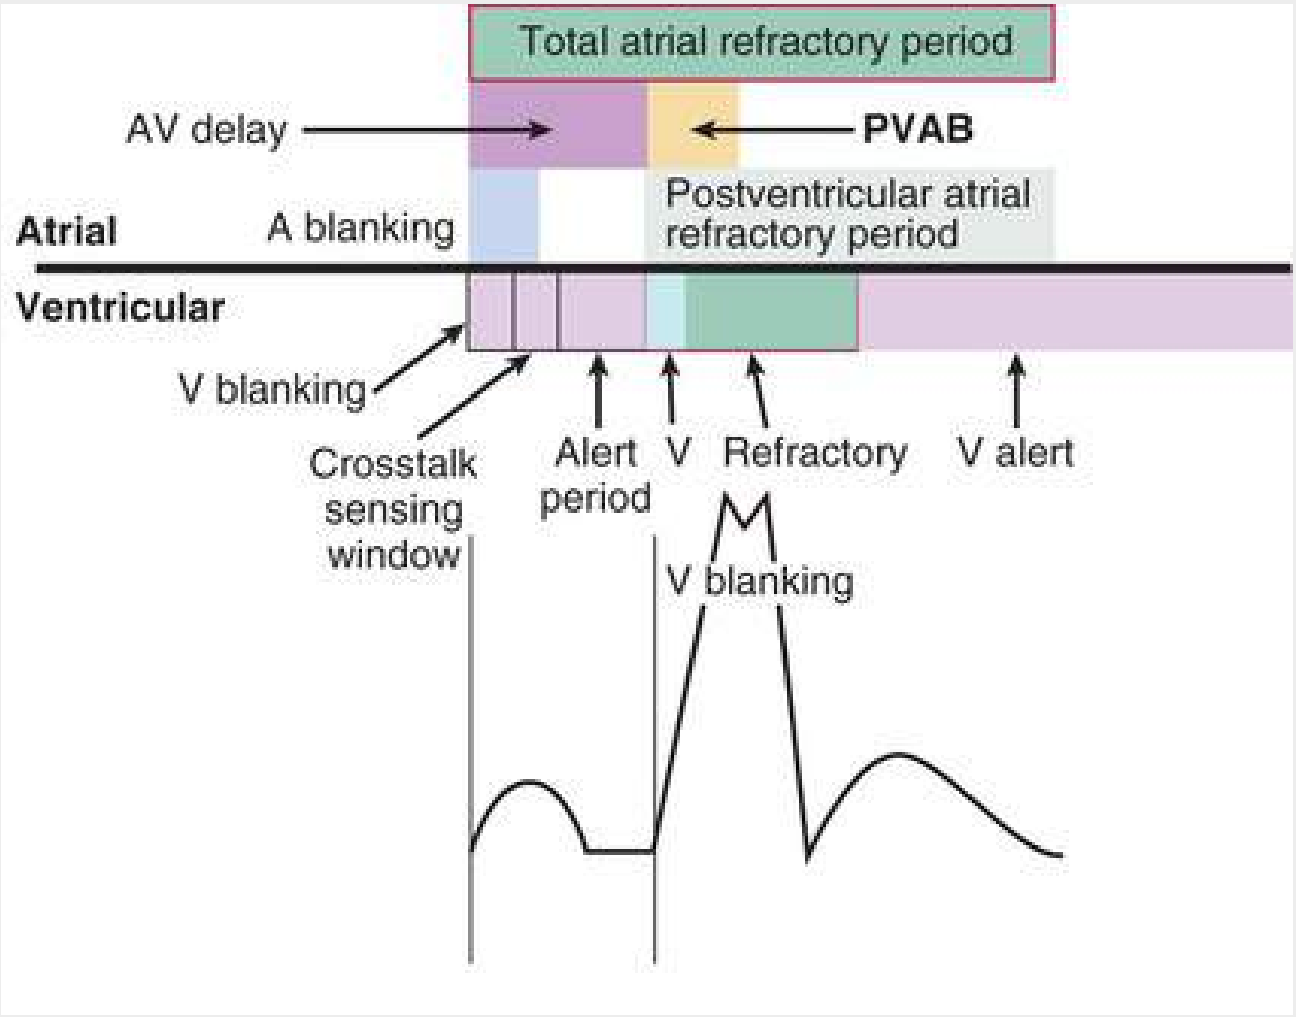

FIGURE 41.10 Schematic representation of the timing cycle interactions of most refractory and blanking periods in contemporary dual-chamber pacemakers. **Top,** Atrial channel; **bottom,** ventricular channel. Total atrial refractory period (TARP) is the sum of the AV delay and the postventricular atrial refractory period (PVARP). Postventricular atrial blanking (PVAB) is the time that the atrial channel is blanked after a ventricular event. "A blanking" is the atrial blanking period, representing the blanking period after an atrial event. There are two ventricular blanking periods, one after the atrial paced event, which prevents atrial paced events from being sensed on the ventricular channel, and one after the ventricular event. A ventricular sensed event in the crosstalk sensing window will result in safety pacing. There are two ventricular alert periods, one at the end of the AV delay and one after the ventricular refractory period.

Postventricular Atrial Refractory Period and Upper Rate Limit Behavior.

In the DDD mode, the *postventricular atrial refractory period* (PVARP) starts with a sensed or paced ventricular event and defines a period on the atrial channel during which a spontaneous atrial event is not tracked (**Fig. 41.10**). It serves multiple important roles critical to DDD pacing, including avoiding pacemaker-mediated tachycardia (PMT) and setting a boundary on upper rate behavior. Since the paced

ventricular rate cannot exceed the programmed upper rate limit (URL), an algorithm is needed to determine how the ventricular pacing rate should be adjusted in patients with AV block when the sinus rate exceeds URL. All pacemakers extend the AV delay when the sinus rate exceeds URL so that the ventricular pacing rate remains at the programmed upper rate. Since the sinus rate is faster than the ventricular pacing rate, the P waves will occur progressively earlier after each successive ventricular paced beat until the P wave times within PVARP and is not tracked. This progressive prolongation of the AV delay until a sinus beat is not tracked is often called “pseudo–AV Wenckebach” (**Fig. 41.11**). If the sinus rate increases further, every other P wave falls in the PVARP, resulting in 2 : 1 atrial tracking (2 : 1 block) and an abrupt decrease of ventricular rate that usually results in exertional intolerance. Because of this, it is important to keep the programmed upper rate and the 2 : 1 AV block rate higher than the maximum sinus rate during exercise. The 2 : 1 AV block rate corresponds to the interval represented by the sum of the programmed AV delay and the PVARP, called the *total atrial refractory period* (TARP).

Pacemaker Troubleshooting

Noninvasive troubleshooting tools include history, chest radiography, surface ECG, stored device data (programming, lead impedance values and trends, stored EGMs, marker channels), and real-time device data (pacing-sensing thresholds, real-time EGMs during pocket manipulation or arm motion). The most common pacing problems can be classified as failure to capture, failure to pace, pacing at a rate inconsistent with the programmed rate, and unanticipated rapid pacing (**Table 41.2**).

TABLE 41.2

Common Causes of Pacemaker Problems

Failure to Capture
Pacing output below threshold
Changes at electrode-myocardial interface
Output programmed below threshold
Lead dislodgement
Lead insulation failure or conductor fracture
Connection problem between header and lead
Functional failure to capture (undersensing or asynchronous pacing)
Failure to Pace
Corrected by magnet or programming to asynchronous mode
Oversensing of physiological or nonphysiological signals
Not corrected by magnet or programming to asynchronous mode
Failure in the pulse generator
Lead conductor fracture
Connection problem between header and lead
Pacing at a Rate Not Consistent with Programmed Rate
Shorter-than-expected escape interval: undersensing
Longer-than-expected escape interval: oversensing
Battery depletion
Unanticipated Rapid Pacing
Pacemaker-mediated tachycardia
Inappropriate ventricular tracking of rapid sensed atrial rates, electromagnetic interference, or myopotentials
Sensor-driven pacing unrelated to patient activity

Failure to Capture

Failure to capture is defined as a pacing stimulus without subsequent cardiac depolarization (**Fig. 41.12**). It can be related to the pacing system, the patient, or patient-system interactions. The most common cause is an elevated pacing threshold caused by changes at the electrode-myocardial interface. System-related causes are common in the perioperative period, especially lead dislodgment. An otherwise sufficient stimulus will fail to capture if it occurs in the physiologic refractory period of a spontaneous depolarization. This “functional failure to capture” can result from undersensing.

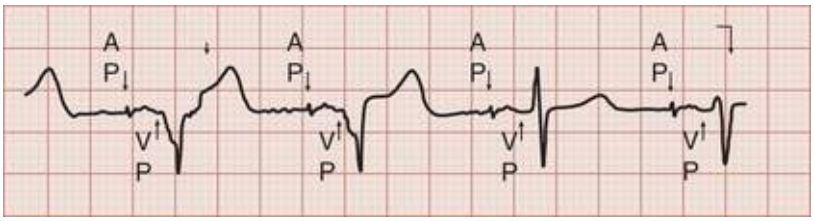

FIGURE 41.12 Failure to capture. Surface ECG lead with atrial and ventricular markers. AP, Atrial paced; VP, ventricular paced. The third and fourth beats show failure of ventricular capture with conducted QRS complexes. The conducted QRS complexes are timed in the postpacing ventricular blanking period and are thus not sensed.

Failure to Pace

Failure to output an indicated pacing stimulus is most frequently caused by oversensing of physiologic or nonphysiologic signals, resulting in inhibition of the pacing output (**Fig. 41.13**), causing failure to pace. Lead or header-connector problems can cause both oversensing of noncardiac signals and impedance abnormalities (see later, ICD Troubleshooting and ICD Lead Failure). Rarely, failure to pace can be caused by failure of the output circuit in the pulse generator or an open circuit (e.g., lead fracture, loose set screw). The combination of failure to capture and failure to pace usually indicates a pacing-system problem rather than a physiologic problem.

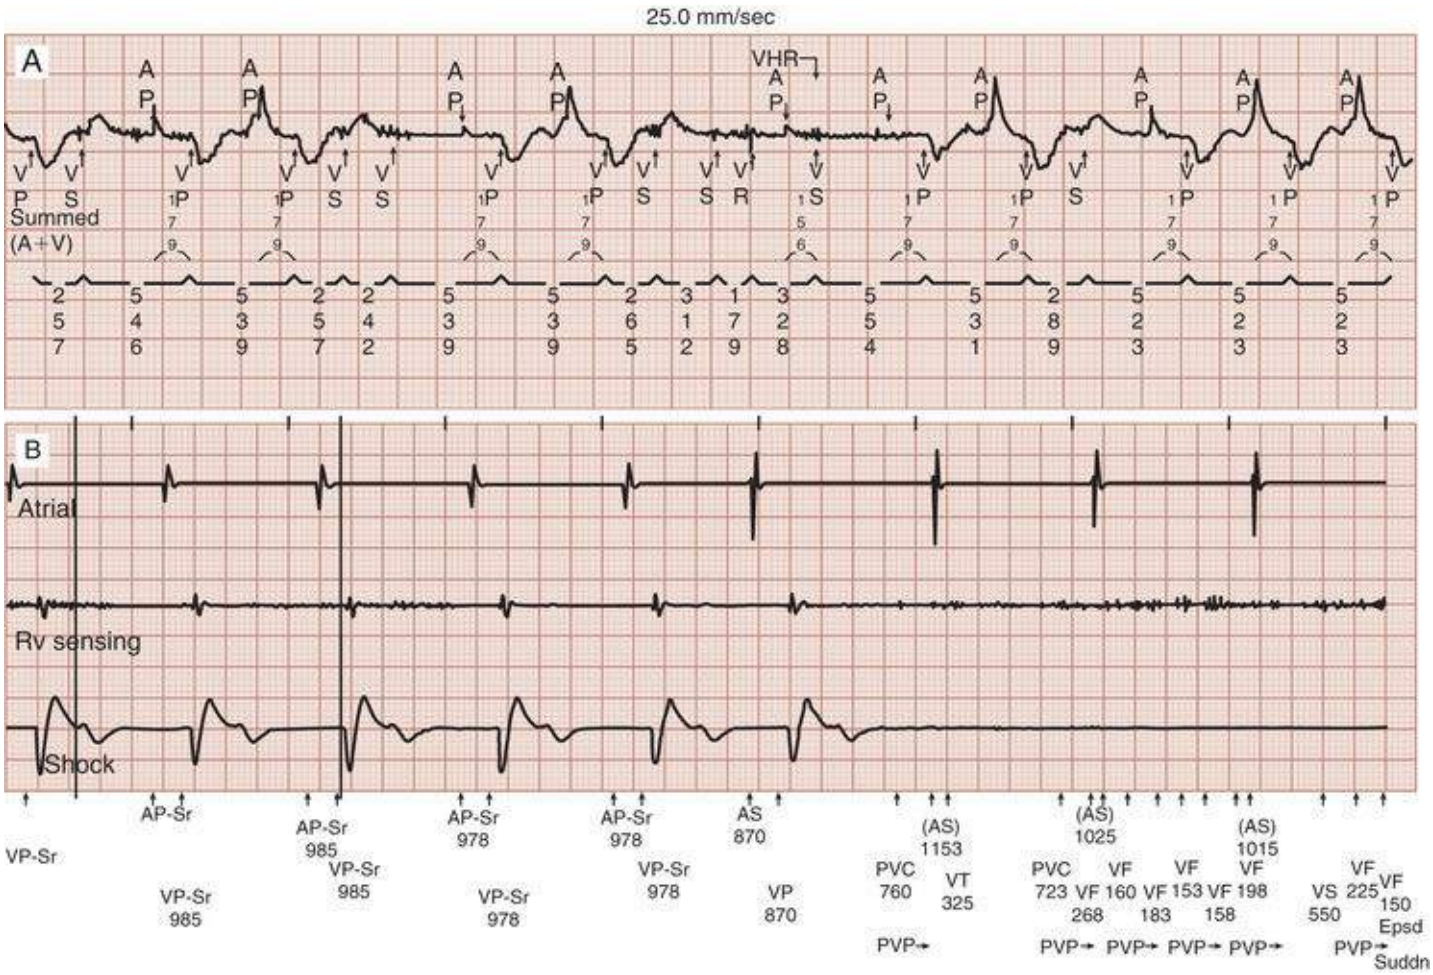

FIGURE 41.13 Ventricular oversensing. **A,** Dual-chamber electrogram (EGM) showing ventricular oversensing caused by lead fracture. The summed EGM (a composite of atrial and ventricular EGMs) with markers and interval channel are shown. VS events denote oversensing caused by lead fracture and correspond to the artifact seen on the summed EGM. The VS events reset the timing cycle and delay the onset of the atrial paced events, which are followed by ventricular paced events. "VHR" indicates that the ventricular oversensed events have resulted in detection of a ventricular high rate (VHR). The number values on the *top* of the interval channel indicate the AV interval, whereas the number values on the *bottom* of the interval channel indicate the VV interval. AP, Atrial pacing; VP, ventricular pacing; VS, ventricular sensing. **B,** Oversensing of diaphragmatic myopotentials in a patient with complete heart block and a dual-chamber ICD with integrated bipolar, right ventricular (RV) sensing. Atrial bipolar, RV integrated bipolar, and RV coil-can shock EGMs and dual-chamber marker channels are shown. Myopotentials are relatively uniform, low-amplitude signals with a dominant frequency in the range 80 to 200 Hz. Oversensing inhibits pacing, resulting in ventricular asystole best identified on the shock channel. Simultaneously, the ICD classifies most rapidly sensed intervals in the VF zone ("VF" markers). VF is detected at right of tracing when enough intervals are classified in the VF zone, initiating a VF episode ("Epsd"). Diaphragmatic myopotentials have greater amplitude on the RV sensing channel than atrial channel because of its larger sensing dipole and proximity of the RV lead tip to the diaphragm.

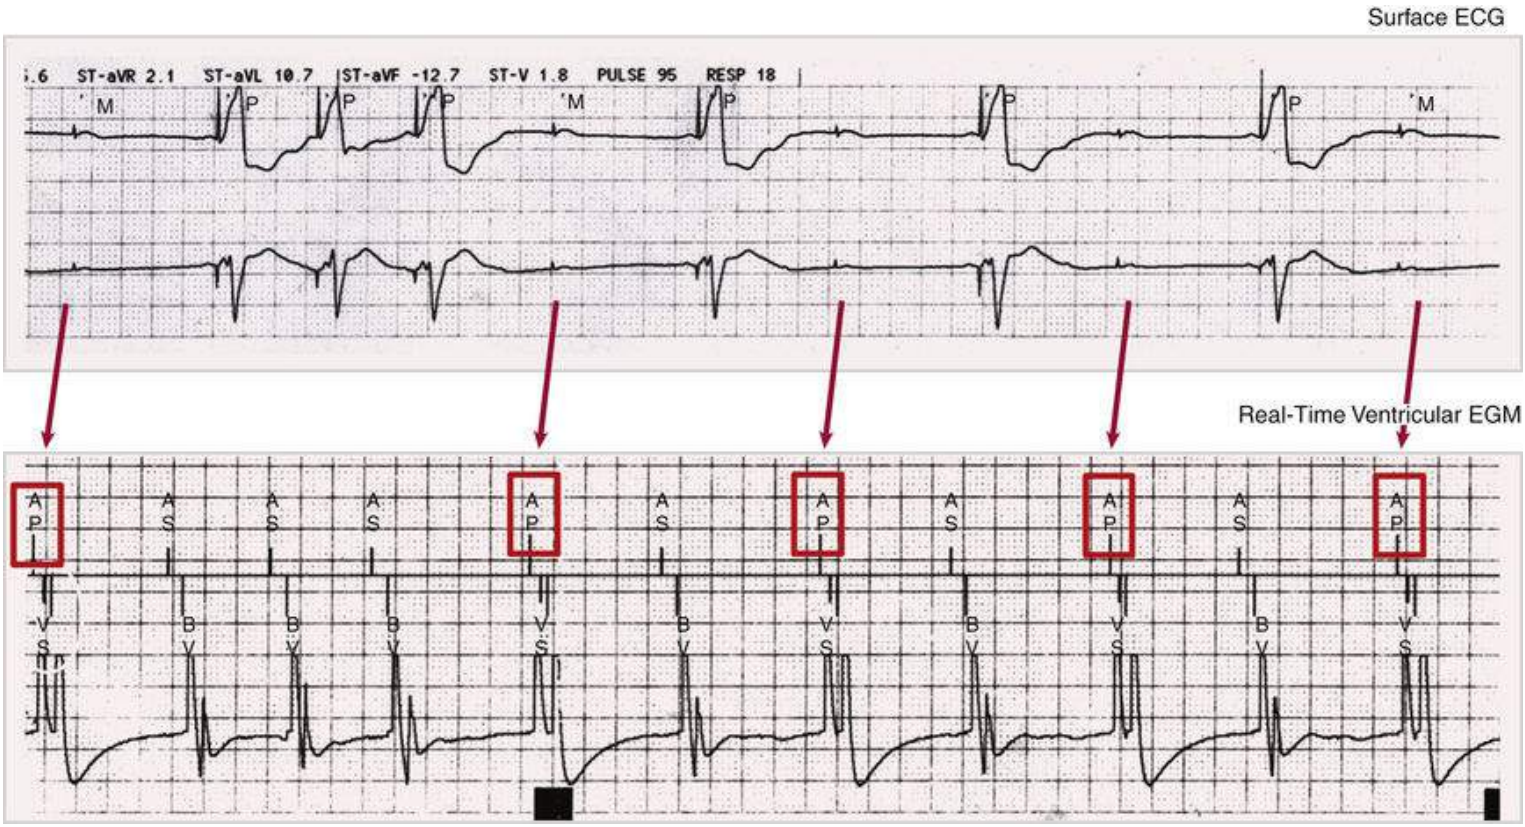
Crosstalk is a specific form of oversensing in which the pacing stimulus is sensed in the opposite chamber. Clinically, the most important crosstalk is oversensing of the atrial pacing stimulus on the ventricular channel, resulting in inhibition of ventricular pacing in a patient with AV block (**eFig. 41.7**). It is minimized by ventricular blanking after atrial pacing. Settings that promote crosstalk include high atrial output, ventricular sensing parameter programmed to a very sensitive value, and short duration of ventricular blanking after atrial pacing. Pacemakers have features to prevent crosstalk, including ventricular blanking after atrial pacing and ventricular safety pacing in response to a sensed event in the AV interval. Safety pacing may be identified electrocardiographically by a shorter-than-programmed AV delay, usually 80 to 130 milliseconds.

EFIGURE 41.7 Ventricular undersensing: telemetry with a surface ECG **(top),** atrial (A) EGM **(middle),** and ventricular (V) EGM **(bottom).** Markers correspond to the ventricular channel. There are six ventricular events but only three with marker annotation. The first ventricular event is neither sensed nor annotated. The second ventricular event is paced (V). The third is intrinsic (R). The fourth is not sensed and is followed approximately 360 milliseconds later by a paced event (V) that corresponds to an escape interval timed from the event marked "R." Undersensing results in escape intervals shorter than the programmed escape interval. The final intrinsic event is not sensed.

Pacing at a Rate Inconsistent With Programming

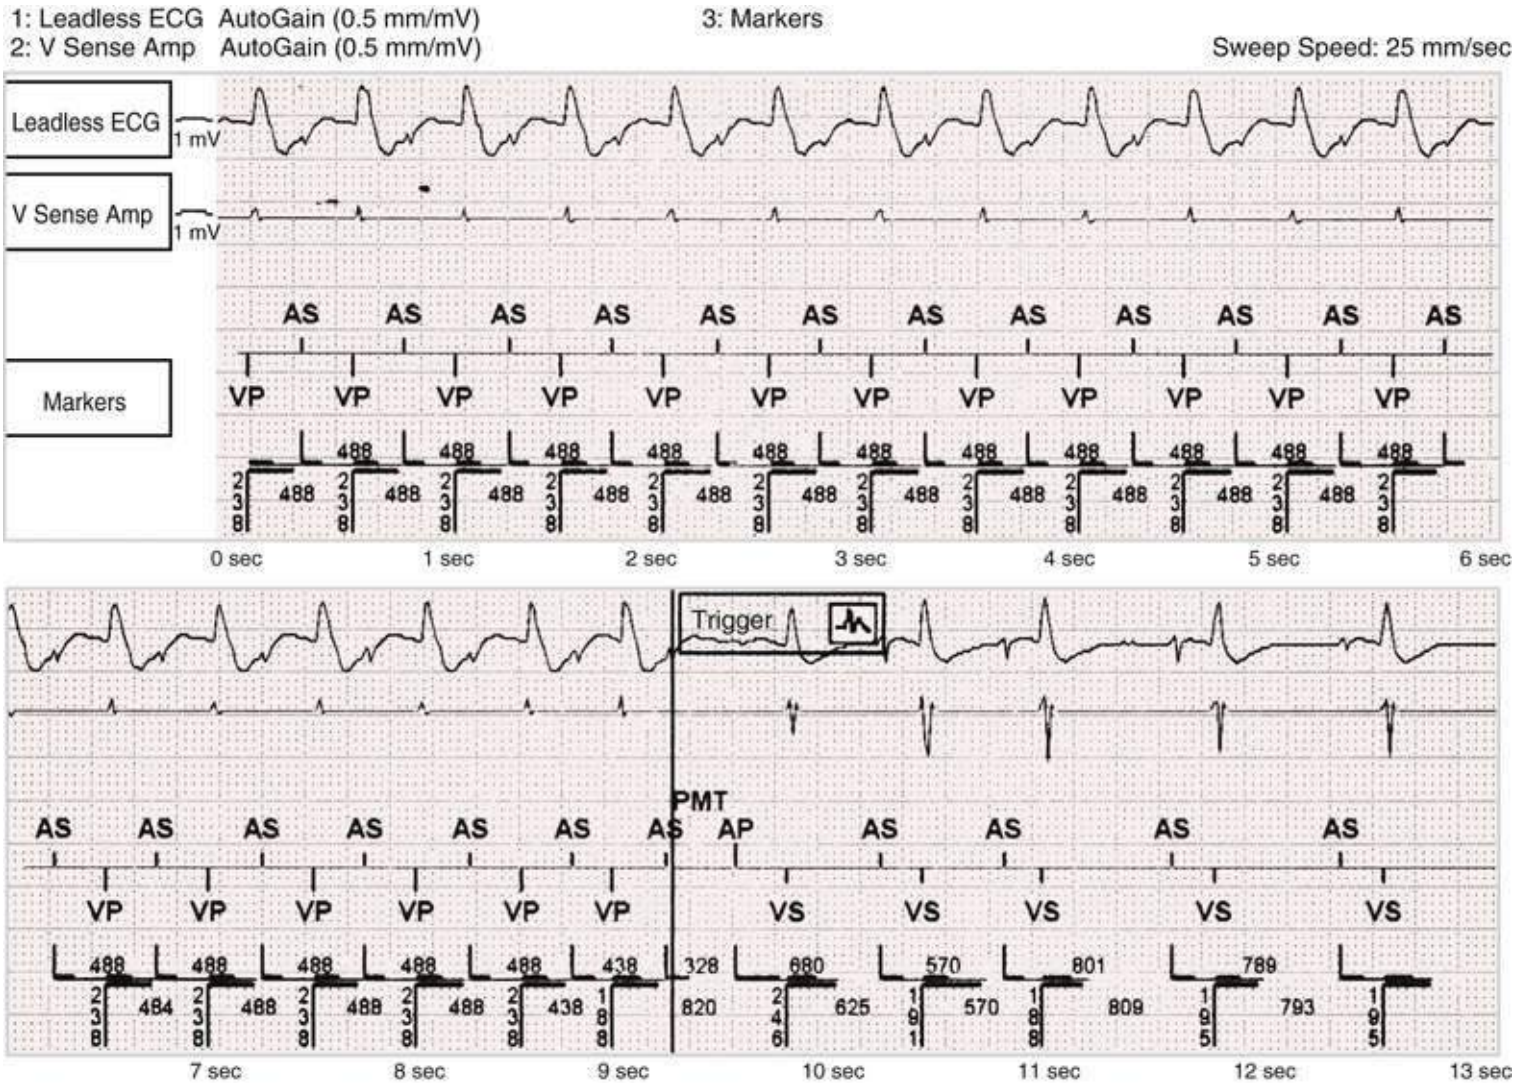
Pacing with a shorter-than-expected escape interval usually indicates undersensing (**eFig. 41.8**). Pacing with a longer-than-expected escape interval usually indicates oversensing (**Fig. 41.13**). As with oversensing, undersensing can be related to the pacing system, the patient, or patient-system interactions. EGMs of premature beats may not be sensed even if sensing of normal beats is reliable. Consistent pacing at a rate slower than the programmed lower rate limit usually indicates oversensing of a constant signal during each cardiac cycle (usually T wave oversensing). It may also indicate battery depletion.



EFIGURE 41.8 Crosstalk inhibition. *Upper panel,* Surface ECG showing intermittent failure of ventricular output when the surface ECG is assessed. *Lower panel,* Dual-chamber marker channel and real-time ventricular EGM showing oversensing during the AV interval of a high-amplitude potential that saturates the sensing amplifier. A, Atrial; B, biventricular pacing; S, sensed event; V, ventricular.

Unanticipated Rapid Pacing

In dual-chamber pacemakers, rapid pacing, usually at or near URL, is most often caused by a PMT or ventricular tracking of rapid signals on the atrial channel (**eTable 41.3**). In patients with retrograde conduction, if the PVARP is too short, a premature ventricular beat that is conducted retrogradely and sensed on the atrial channel may be tracked, initiating a repetitive sequence of ventricular pacing, retrograde conduction, and atrial tracking of the retrogradely conducted EGM. In this “endless loop” type of PMT, the pacemaker functions as the anterograde limb of AV reentrant tachycardia (AVRT), and the conduction system functions as the retrograde limb (**eFig. 41.9**). In contrast, ventricular tracking of rapid, sensed atrial signals can be caused by failure to mode switch during atrial tachyarrhythmias or sensing of extracardiac signals (e.g., pectoral myopotentials, EMI). Both can be terminated by programming to a nontracking mode. Less frequently, rapid sensor-driven rates may occur if the sensor responds to signals that are unrelated to patient activity, such as an accelerometer responding to vibrations in a helicopter or a minute ventilation sensor responding to respiratory rate in an asthma attack.



EFIGURE 41.9 Pacemaker-mediated tachycardia (PMT). The **top panel** shows a far-field EGM similar to a surface ECG. The second channel gives the ventricular EGM. Below are the atrial and ventricular markers. Each ventricular paced event is followed by an intrinsic atrial event. In the **bottom panel** this pattern is identified as PMT. The final atrial sensed event following the last ventricular paced beat is not tracked and is followed by an atrial paced beat that is conducted to the ventricle. This stops the PMT.

ETABLE 41.3

Common Causes of Rapid Ventricular Pacing

Ventricular Pacing at Upper Rate Limit in DDD Mode
Pacemaker-mediated tachycardia
Ventricular tracking of rapid atrial signals
Atrial tachyarrhythmias
Rapid oversensed signals (e.g., electromagnetic interference, lead- or connection-related oversensing)
Other Causes
Sensor-driven pacing
Magnet application
Algorithms for rate regularization in atrial fibrillation
Rate-smoothing algorithms that prevent abrupt change in ventricular rate

Proarrhythmia

Rarely, pacing can be proarrhythmic in either the atrium or the ventricle. Pacing-induced short-long-short sequences may initiate initiating pause-dependent VT/VF (**eFig. 41.10**). These typically result from algorithms that promote AV conduction or loss of ventricular capture, which occurs routinely during threshold testing. Thus, an external defibrillator should be available during pacemaker programming.

EFIGURE 41.10 Pacing-induced proarrhythmia seen on electrocardiographic tracing from patient with pacemaker programmed to VVI at approximately 70 pulses/min. There is a longer V-V interval representing oversensing (*); a subsequent pacing spike occurs with failure to capture (**); and in the terminal portion of the tracing, VT develops and the pacemaker does not sense the tachyarrhythmia. Pacing artifacts can be seen during VT, labeled "V-U" (ventricular undersensing).

Misinterpretation of Normal Pacemaker Function

Historically, fusion and pseudofusion beats on the ECG have been a source of confusion (**eFig. 41.11**). At times, the surface ECG may not permit determination of the chamber paced. For example, atrial undersensing during AF results in functional failure of atrial capture but can be misinterpreted as failure of ventricular capture. Algorithms that minimize RV pacing to promote intrinsic AV conduction may also cause confusion (**see Fig. 41.8**).

EFIGURE 41.11 Fusion and pseudofusion on a three-channel ECG tracing from an ambulatory monitor. *Fusion* indicates that depolarization occurs in part because of intrinsic activation and in part because of capture from the pacemaker stimulus. *Pseudofusion* indicates that the pacemaker stimulus does not alter intrinsic QRS morphology on the surface ECG. This occurs when the stimulus is delivered after intrinsic activation depolarizes the ventricles. The first QRS is intrinsic. The second and fourth beats represent fusion. The third beat is pseudofusion; that is, the underlying morphology is almost identical to the intrinsic QRS. The final QRS represents paced depolarization.

Implantable Cardioverter Defibrillators

Indications for ICDs

ICDs are indicated for prevention of sudden death from VT/VF, either as *secondary prevention* in patients who have been resuscitated from VT/VF or *primary prevention* in patients who have not had VT/VF but are at sufficiently-high risk (see later, Guidelines).

Secondary Prevention

ICDs are the treatment of choice for secondary prevention of VT/VF, providing patients remain at risk for recurrence of VT/VF and have sufficient life expectancy and quality of life to justify implantation. The strong consensus for secondary prevention ICDs is based on the AVID trial and other RCTs that compared antiarrhythmic drugs to ICDs.[9]

Primary Prevention

Presently, more than 80% of ICDs are implanted for primary prevention based primarily on two RCTs.[9] The MADIT II trial of patients with ischemic cardiomyopathy and LVEF of 30% or less demonstrated significant survival benefit continuing through 8 years of follow-up. The SCD-HeFT trial of patients with LVEF of 35% or less found that ICDs reduced total mortality in patients with both ischemic and nonischemic cardiomyopathy. However, retrospective analyses indicate that ICDs do not prolong life in identifiable subgroups with extensive comorbidities, including advanced HF and renal failure. Further, these trials were performed before present pharmacologic therapy and CRT of HF. A subsequent RCT of patients with nonischemic cardiomyopathy and LVEF of 35% or less found that ICDs did not reduce total mortality in patients who received guideline-directed medical therapy (GDMT) and indicated CRT pacemakers.[10]

Clinical trials do not support ICD implantation in low-LVEF patients within 40 days of myocardial infarction (MI) or 90 days of surgical revascularization; low-LVEF patients with recent percutaneous revascularization are not well represented in clinical trials.[11] With few exceptions,[12] ICD implantation in these patients is not indicated (see Guidelines).

Expert consensus statements provide recommendations for ICD implantation in patients under specific circumstances not covered in clinical trials[12] and clinical scenarios not addressed by guidelines.[13] These include high-risk patients with less common diseases, including specific cardiomyopathies (e.g., hypertrophic cardiomyopathy; **Chapter 78**), ion channelopathies[14] (**Chapters 33 and 35**), and certain forms of congenital heart disease[15] (**Chapter 75**).

ICD Leads and Generators

An ICD system comprises the generator and at least one defibrillation lead. Usually, the generator is implanted pectorally, and a single, transvenous defibrillation lead is implanted in the right ventricle (analogous to a ventricular pacemaker lead) (**Fig. 41.14A**). Dual-chamber ICDs incorporate a bipolar atrial pace-sense lead to provide dual-chamber bradycardia pacing and dual-chamber algorithms that discriminate supraventricular tachycardia (SVT) from VT. CRT-Ds incorporate an LV pacing lead (**see Chapter 27**). The totally subcutaneous[16] ICD system consists of a defibrillation lead implanted parallel to the sternum and tunneled to the ICD generator located near the left anterior axillary line (**Fig. 41.14B**).

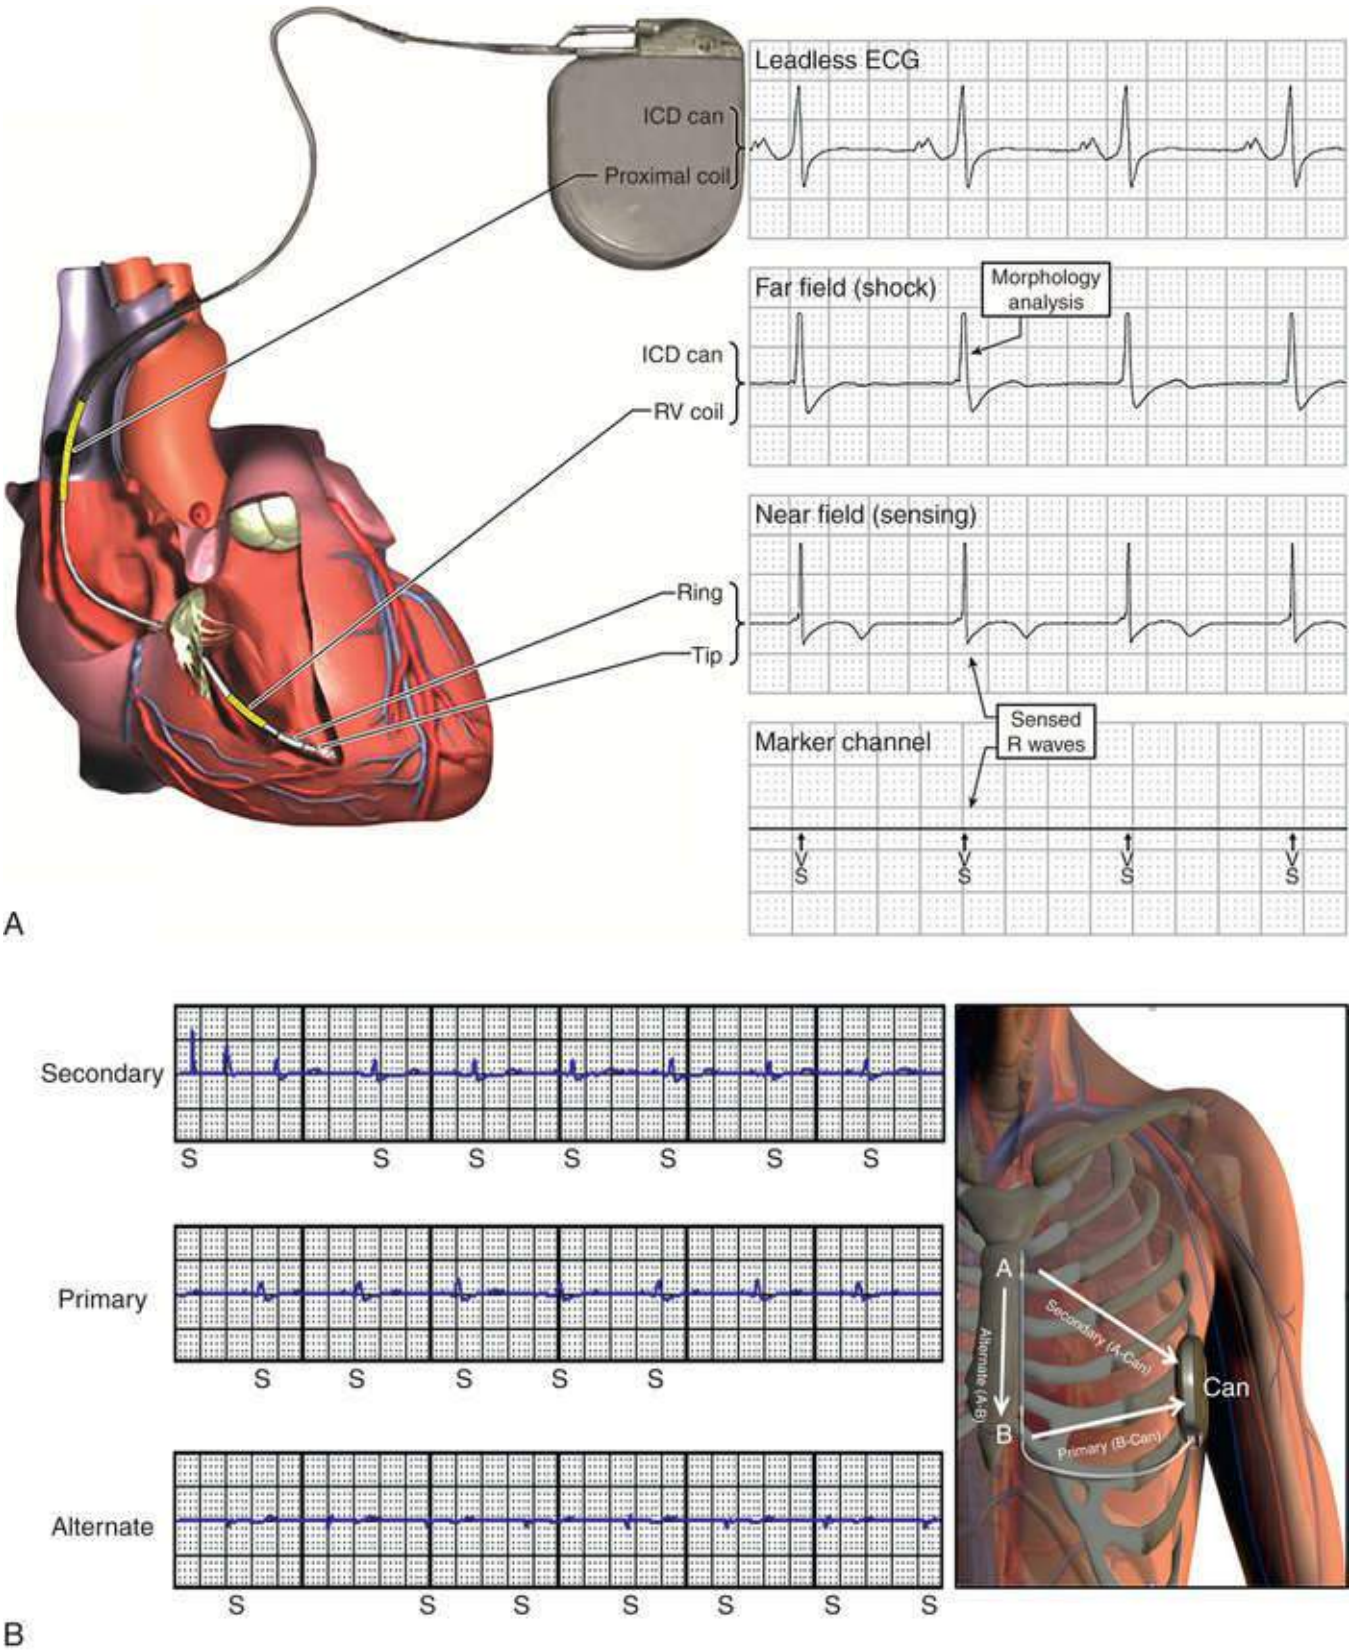


FIGURE 41.14 Implantable cardioverter-defibrillators and electrograms (EGMs). **A, Left**, Single-chamber ICD system, including left pectoral active can and right ventricle (RV) lead; **right,** telemetered EGM recorded between proximal coil and can ("leadless ECG"), high-voltage (shock) far-field EGM, and sensing near-field EGM, with annotated markers. The dual-coil lead uses true bipolar sensing between tip and ring electrodes. Marker channel denotes timing of sensed R waves from the near-field EGM (*arrows*) and ICD's classification of each ventricular event by letter symbols. Numbers indicate R-R intervals in milliseconds. "VS" denotes sensed ventricular events in the sinus rate zone. Sensing is accurate because there is a 1 : 1 correspondence between ventricular EGMs and markers. Morphology of shock EGMs stored during detected tachycardias is useful for distinguishing ventricular tachycardia from supraventricular tachycardia. Leadless electrocardiograms (ECGs) provide a signal with identifiable atrial EGM with a single-chamber ICD if a dual-coil lead is used. **B,** Subcutaneous ICD records subcutaneous EGMs from one of three vectors. The amplitude of the alternate vector is smallest (as in this tracing) because it often overlies atrial tissue and the sternum. The secondary vector is prone to myopotential artifact because it

usually overlies the pectoralis muscles. “S” denotes sensed ventricular events in the sinus rate zone.
(From Swerdlow CD, Friedman P. Implantable cardioverter-defibrillator: clinical aspects. In Zipes D, Jalife J, editors. Cardiac Electrophysiology: From Cell to Bedside. 7th ed. Philadelphia: Saunders Elsevier; 2018.)

Defibrillation Leads.

Right-ventricular defibrillation leads comprise a small, distal tip electrode for pacing and sensing with a fixation mechanism that anchors the lead to the heart, proximal terminals that connect to the generator, and a lead body connecting the two. The lead body consists of a flexible, plastic, insulating cylinder with longitudinal lumens through which conductors run from the proximal terminals to small pace-sense electrodes and larger shock coil electrodes. This “multilumen” design permits more conductors in a smaller diameter than coaxial designs typically used in pacemaker leads.

All defibrillation leads have a distal (RV) defibrillation coil and a tip pace-sense electrode. Optionally, they may have a second ring sensing electrode, which is dedicated to the pace-sense circuit, to permit *dedicated bipolar* sensing and pacing between the tip and ring. If the lead has only a tip electrode, *integrated bipolar* sensing and pacing occur between the tip electrode and the distal defibrillator coil, which is integrated into the defibrillation circuit. *Dual-coil* leads have a second proximal defibrillation coil in the superior vena cava. For single-coil leads, shocks are delivered between the RV defibrillation coil and the housing (“can”) of the generator. In dual-coil leads, the proximal pole has the same polarity as the can. Left pectoral implants are preferred over right pectoral implants because the defibrillation vector to the can includes more of the left ventricle. The new standard DF-4 connector permits conductors to all the lead's electrodes to connect to the generator with a single pin, minimizing connection problems compared with the older DF-1 connector.[17]

The subcutaneous ICD lead utilizes a multilumen design with the shock coil straddled by two small sensing electrodes (**Fig. 41.14B**).

ICD Generators.

ICD generators include a clear-plastic header that connects to the lead(s) and a titanium can that houses high-voltage electronics, in addition to the battery and other low-voltage components found in pacemakers (**eFig. 41.1B**).

Unlike pacemakers, ICDs must deliver high-voltage shocks in addition to low-voltage pacing pulses. However, low-voltage batteries have approximately 1000 times the energy density of high-voltage capacitors. Thus, ICDs require a high-voltage transformer and charging circuit to convert electrochemical energy stored in an electrochemical cell (about 3 V) to the high voltage needed for defibrillation shocks (750 to 900 V for transvenous ICDs; 1400 V for subcutaneous ICDs). Unlike pacemaker batteries, ICD batteries must be able to deliver high current (up to 3 A) and high power (up to 10 W) to provide high-voltage electricity for shocks. The charging circuit requires 6 to 15 seconds for transvenous ICDs and 15 to 25 seconds for subcutaneous ICDs. During charging, high-voltage electricity is stored in a high-voltage capacitor. To deliver the shock, the high-voltage capacitor is disconnected from the charging circuit and connected to the shock electrodes.

ICD System Selection

Transvenous versus Subcutaneous ICD Systems

The subcutaneous ICD[16] eliminates morbidity associated with transvenous lead insertion, lead-related complications during MRI scans, and the hazards of transvenous extraction when lead removal is required. Candidates for a subcutaneous ICD undergo screening using surface ECG electrodes to assess the risk of T wave oversensing or R wave double-counting; 7% to 10% of candidates fail screening. Despite this, inappropriate shocks caused by oversensing are more common in subcutaneous ICDs than in modern transvenous ICDs (5% to 10% versus <2% in the first year).[16,18] Subcutaneous ICDs cannot perform ATP, resynchronization, or long-term bradycardia pacing. However, future models are expected to communicate with leadless capsule pacemakers. **eTable 41.4** compares transvenous and subcutaneous ICDs.

ETABLE 41.4

ICD System Selection: Subcutaneous (S) vs. Transvenous ICD

SUBCUTANEOUS-ICD	TRANSVENOUS ICD
	Advantages	
Eliminates need for vascular, intravascular lead, and related complications (e.g., pneumothorax) No intravascular system infection Implant possible without fluoroscopy Lead failure may be less likely Relative simplicity and safety of lead extraction	Bradycardia, antitachycardia, and cardiac resynchronization pacing No preimplant ECG screening necessary Fewer inappropriate and avoidable shocks Greater battery longevity Shorter charge time; faster shock delivery Smaller pulse generator Long-term follow-up data
Patient Selection	
Limited vascular access (e.g., dialysis) History or high risk of intravascular infection (e.g., prosthetic valve) Intracardiac shunt Young patient (ease of lead extraction and possible greater lead longevity)	Need bradycardia, antitachycardia, or cardiac resynchronization pac Fail subcutaneous ICD ECG screening

Images from Lewis GF, Gold MR. Safety and efficacy of the subcutaneous implantable defibrillator. J Am Coll Cardiol 2016;67(4):445-54.

Dual- versus Single-Chamber Transvenous ICDs

In addition to providing dual-chamber bradycardia pacing, dual-chamber ICDs provide atrial EGMs that enhance physician interpretation of stored EGMs and permit both diagnostics for AF and dual-chamber algorithms to discriminate SVT from VT. The present consensus recommends reserving dual-chamber ICDs for patients who need dual-chamber pacing or have SVT and monomorphic VT at overlapping ventricular rates.[12]

Transvenous Defibrillation Leads

Dual versus Single Coil.

Dual-coil leads improved defibrillation efficacy of early ICDs but do not provide a clinically significant advantage for left pectoral implants of present ICDs.[19] They provide better defibrillation for some right-sided implants as well as reliable atrial cardioversion and alternate EGMs for diagnostic interpretation. However, the proximal coil often adheres to the superior vena cava. If lead extraction is required, this increases procedural difficulty and may increase risk. Thus, single-coil leads usually are preferred for left pectoral implants.

Integrated versus Dedicated Sensing Bipoles.

Compared with dedicated bipolar leads, the integrated bipolar design simplifies the lead by reducing the number of conductors. However, reliable leads have been developed with both designs. Integrated bipolar EGMs have a wider field of view than dedicated bipolar EGMs and are thus more likely to oversense nonphysiologic signals or physiologic signals that do not reflect local myocardial depolarization[20] (**see Fig. 41.13**).

ICD Therapy

Transvenous ICDs deliver two types of therapy for tachyarrhythmias: low-voltage trains of ATP stimuli (pulses), and high-voltage cardioversion or defibrillation stimuli (shocks). ICDs deliver shocks to treat VF and *tiered therapy* to treat VT–first ATP and then shocks if ATP is unsuccessful. Because ICDs synchronize almost all defibrillation shocks to the intracardiac EGM, cardioversion and defibrillation are essentially equivalent when delivered by ICDs.

Antitachycardia Pacing

ATP refers to the use of pacing stimuli to terminate reentrant tachycardias. In patients with structural heart disease, most monomorphic VT is reentrant (**see Chapter 39**) and thus can be terminated by ATP. Current subcutaneous ICDs cannot deliver ATP.

Principles

Bradycardia pacing requires only that the stimulus capture fully excitable, local myocardium during diastole. In contrast, ATP stimuli must interact with the specific reentrant circuit driving the VT, which usually is remote from the site of pacing, and it must do so while most of the myocardium is refractory or relatively refractory. Thus the required stimulus strength is higher than that for bradycardia pacing in fully excitable myocardium. The ATP stimulus must then propagate to the reentry circuit through relatively refractory myocardium and capture myocardium in the VT circuit during an excitable gap in refractoriness. To facilitate propagation in relatively refractory myocardium and ensure that at least one stimulus enters the excitable gap, ATP is delivered as a sequence or “train” of 3 to 10 stimuli at a rate faster than the VT (**Fig. 41.15**). ATP terminates VT by causing bidirectional block, which occurs when the stimulus propagates antidromically to collide with the head of the circulating wavefront and blocks orthodromically in tissue rendered inexcitable by the preceding wavefront (**see Chapters 34 and 36**). Clinically, the cycle length of ATP is programmed as a percentage of the VT cycle length (adaptive ATP). More than one ATP sequence may be required because of the uncertainties introduced by the multiple variables involved. However, the number of programmed ATP trains must be limited to prevent hemodynamic collapse during prolonged VT and repeated sequences of even faster ATP.

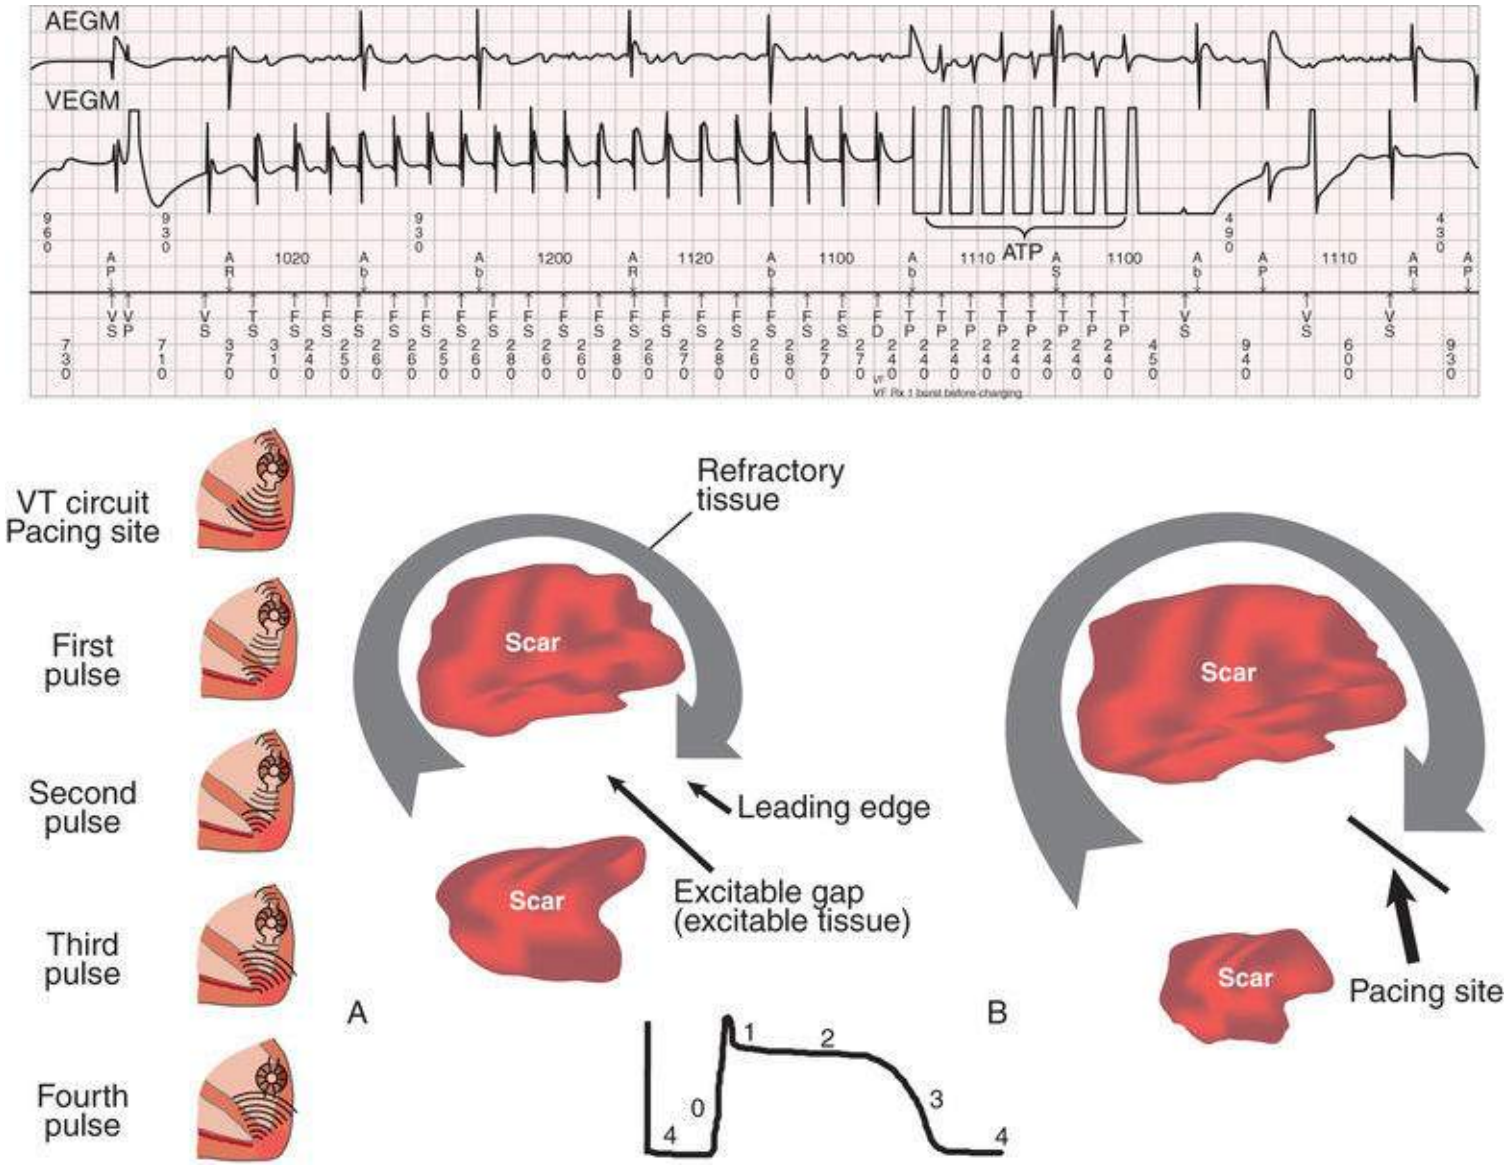

FIGURE 41.15 Antitachycardia pacing (ATP) for monomorphic ventricular tachycardia (VT): stored atrial (AEGM) and ventricular (VEGM) electrograms and atrial and ventricular marker channels from an episode of rapid monomorphic VT (cycle length, 240 to 270 milliseconds; rate, 220 to 250 beats/min). VT with AV dissociation begins with the second VEGM. After 18 intervals shorter than the programmed ventricular fibrillation (VF) detection interval of 320 milliseconds, an adaptive train of eight ATP pulses is delivered at a cycle length of 240 milliseconds, 88% of the VT cycle length, to terminate the VT. On the marker channel, VS, TS, and FS indicate intervals classified in the sinus, VT, and VF rate zones, respectively. FD, Detection of VF; TP, ATP. Note that a burst of ATP is delivered even though the intervals are in the VF zone. AP, Atrial paced events. "Ab" and "AR" indicate atrial intervals in the postventricular atrial blanking and refractory periods, respectively. At the **lower left,** vertical panels show a conceptual model of why multiple ATP pulses are required in a train. The **top panel** shows that during VT the region between the pacing lead in the right ventricular apex and the VT reentry circuit in the left ventricle is activated by the circuit. Subsequent panels represent conditions after the first, second, third, and fourth ATP pulses. After each successive pulse, ATP propagates to more of the region before colliding with the VT wavefront. The **lower panel** shows a conceptual model of the interaction between ATP pulses and the VT circuit. In **A,** the circuit around a fixed scar is depicted by the *large curved arrow.* The head of the arrow depicts the leading edge of the wavefront, and the body of the arrow back to the tail (*gray*) represents depolarized tissue that is refractory because the wavefront has just propagated through it. The repolarized tissue between the tip and the tail of the arrow is excitable ("excitable gap"). For the head of the arrow to continue around the scar, an excitable gap must be present; if the wavefront encounters refractory tissue, it cannot proceed. In **B,** a wavefront generated by an ATP pulse enters the excitable gap and terminates the VT. Tachycardias with a small excitable gap (i.e., the head of the arrow follows the tail very closely so that only a small "moving rim" of excitable tissue is in the circuit) are less likely to be terminated with ATP. (**Lower panel,** From Hayes DL, Friedman PA, editors. Cardiac Pacing and Defibrillation: A Clinical Approach. 2nd ed. West Sussex, UK: Wiley-Blackwell; 2008.)

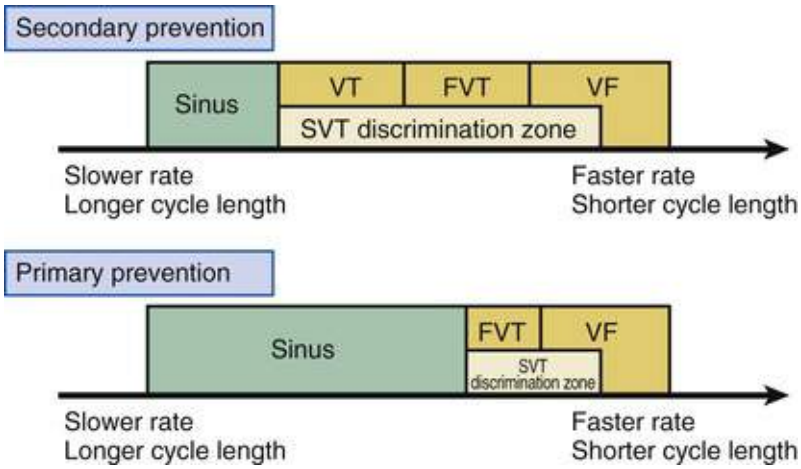
Clinical Application

Despite these uncertainties, ATP has become the primary transvenous-ICD therapy for monomorphic VT because ATP is painless, whereas shocks are painful. In comparison with shocks, ATP improves quality of life, reduces hospitalizations for VT, requires much less power, and does not depress myocardial contractility acutely.[21] However, ATP can fail for reasons that do not affect shocks, such as conduction block between the pacing site and the reentry circuit. Rarely, ATP may be proarrhythmic or may accelerate hemodynamically stable VT to unstable VT/VF.

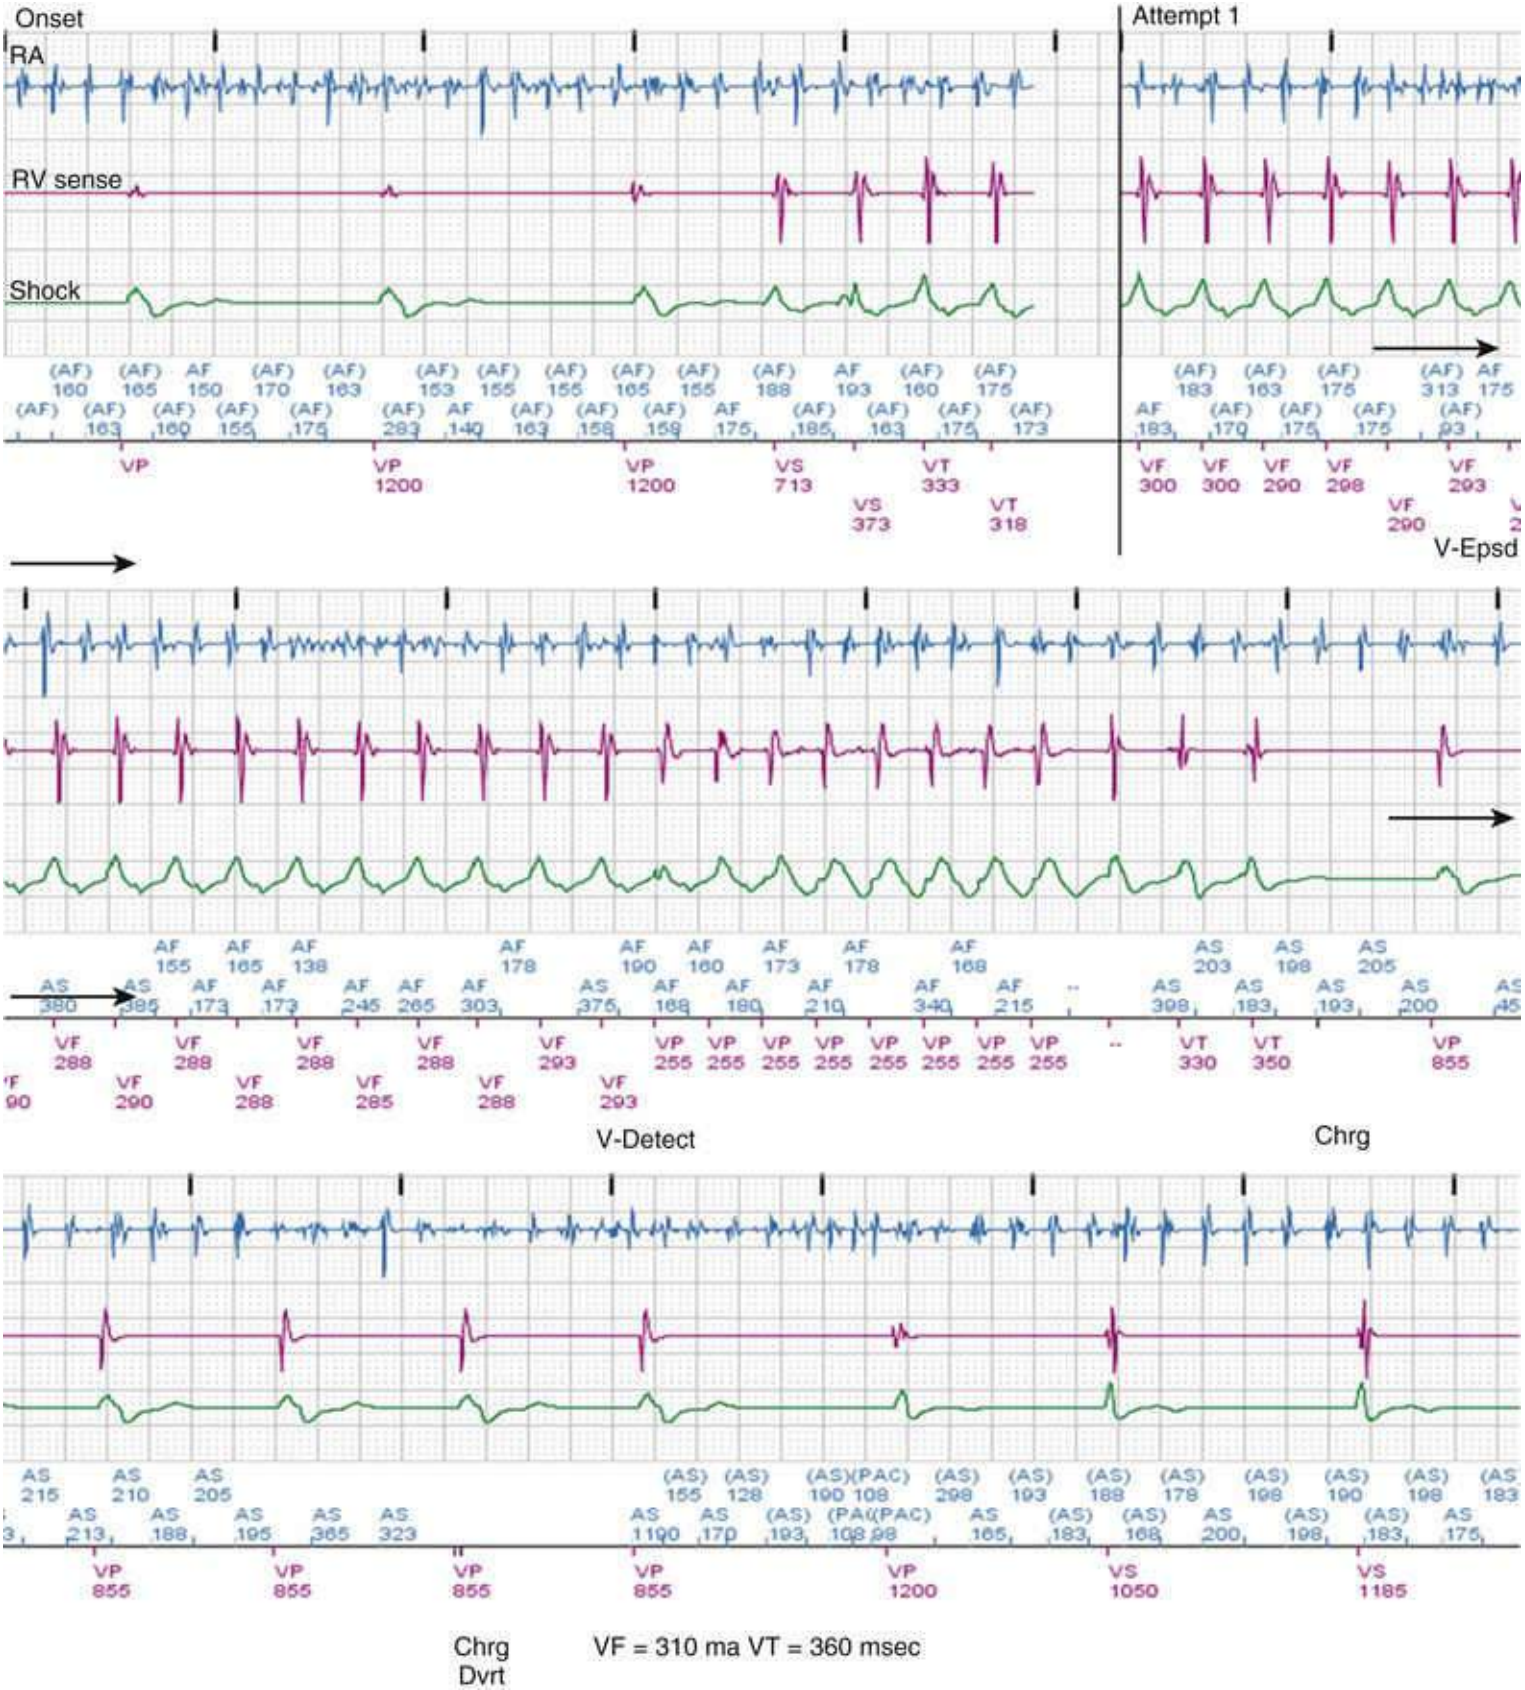
Early studies reported that ATP terminated 80% to 95% of slow VT (<180 beats/min) and 70% or more of fast VT (>180 beats/min). However, these studies were performed with short detection durations, and many of these VTs probably would have terminated spontaneously with presently recommended longer detection durations. This is an example of the concept of "avoidable therapy" discussed later. With longer detection durations, ATP terminates about 80% of slower VTs and 40% to 50% of faster VTs, with a low risk of acceleration (1% to 5%).[21]

Tiered Therapy and Therapy Zones

ICDs have up to three rate-based therapy zones to permit zone-specific therapy for VT/VF (**eFig. 41.12**). Many ICDs permit programming of an additional monitor-only zone between the sinus tachycardia and slowest VT zones. Usually, two to four sequences of ATP are programmed for slower VTs, one or two sequences faster VTs, and at most one sequence for rhythms detected in the fastest "VF" zone. ATP may be effective in an ICD-defined "VF" zone because most arrhythmias detected in this rate-defined zone (usually >185 to 220 beats/min) are fast, monomorphic VT (**eFig. 41.13**). Two sequences terminate approximately 90% of VTs that can be terminated by ATP. If ATP is unsuccessful, the ICD delivers shocks.



EFIGURE 41.12 ICD rate detection zones. Some ICDs permit programming of an additional monitor-only zone. **Upper panel** shows programming for secondary prevention patients; **lower panel** shows programming for primary prevention patients. Generally, the sinus-ventricular tachycardia (VT) rate boundary should be slow enough to ensure detection of all hemodynamically compromising VTs. The optional boundary between the two VT zones should be based on the cycle length at which different durations for detection or different antitachycardia pacing (ATP) is preferred. The VT-ventricular fibrillation (VF) rate boundary is based on the cycle length below which shocks should not be delayed for more than one trial of ATP. Additionally, programming a nontherapy, monitor-only detection zone permits storing EGMs for tachycardias slower than the slowest zone in which VT therapy is programmed. FVT, Fast ventricular tachycardia.



EFIGURE 41.13 ICD EGM illustrates tiered therapy. The continuous stored EGM shows atrial (RA), near-field integrated bipolar (RV Sense), and far-field (Shock) EGMs. The dual-chamber marker channel displays atrial intervals above and ventricular intervals below the line. The atrial rhythm throughout is AF (marker channel). The first three ventricular intervals are paced at 1200 milliseconds (50 beats/min). The fourth beat shows the onset of regular tachycardia, which accelerates to a cycle length of 300 to 290 milliseconds. The *vertical line* denotes interruption of recording after the onset of tachycardia until just before VF is detected initially (V-Epsd at end of **top panel**). Persistence of device-detected "VF" is confirmed in the middle of the **middle panel** (V-Detect), followed by ATP in the VF zone, which terminates the tachycardia. ATP is followed by post-therapy pacing for 5 beats at 855 milliseconds (70 beats/min). Because ATP was delivered in the VF zone, the ICD begins to charge as soon as ATP is completed. In the **lower panel,** "Chrg Dvrt" indicates that the ICD classifies the tachycardia episode as completed, so the charge on the high-voltage capacitors is dissipated. Thus the patient is spared a shock, but the battery

loses the corresponding energy. The last two ventricular EGMs in the **lower panel** represent slowly conducted AF and differ markedly in morphology from tachycardia EGMs. The ICD's classification of this rhythm based on rate alone is “VF.” The ICD does not apply SVT-VT discriminators in the VF zone. The physician's classification is monomorphic VT during AF based on an abrupt onset of rapid, regular tachycardia with morphology different from conducted beats during AF. The ICD should be reprogrammed so that this tachycardia is classified in a VT zone and ATP can be delivered without charging.

Defibrillation

Principles

Bioelectrical Stimulation for Defibrillation.

Pacing pulses are required only to generate a local electric field sufficient to bring excitable myocardial cells to threshold voltage, but defibrillation pulses (shocks) must generate a global electric field throughout all or almost all of the ventricles that is strong enough to alter refractoriness and conduction in partially refractory myocardium. Defibrillation electrodes are much larger than pacing electrodes because of the requirement for global stimulation. Although the required field strength is only a few multiples of that required for pacing (1 V/cm versus 3 to 5 V/cm), shocks need approximately 1 million times more energy than pacing pulses because of the spatial difference in field requirements and the differences in required pulse duration (0.3 to 0.6 msec versus 6 to 12 msec).

Waveforms.

As discussed in relation to pacing, stimulating waveforms are best specified by voltage and duration. However, by custom ICD shocks are specified as delivered energy, even though energy is not a direct determinant of defibrillation. Biphasic waveforms defibrillate more efficiently (lower voltage) than monophasic waveforms (**eFig. 41.2B**). For transvenous ICDs, defibrillation is more efficient if the RV electrode is the anode (versus cathode) for phase 1 of a biphasic waveform.

Shock Strength for Defibrillation.

The relationship between shock strength and defibrillation success is described by a probability of success curve (**Fig. 41.16**). Thus the same clinically relevant strength may either succeed or fail on successive attempts. Nevertheless, the term *defibrillation threshold* (DFT) is often used as a shorthand to describe the results of testing defibrillation shocks with different strengths. The DFT is lower if the shock electrodes are positioned to provide a uniform electric field throughout the ventricles. It is increased by metabolic effects such as hyperkalemia, acidemia, and ischemia. **eTable 41.1** summarizes common drug effects on the DFT. Chronic amiodarone therapy increases DFT, whereas potassium channel–blocking drugs such as sotalol or dofetilide decrease DFT.

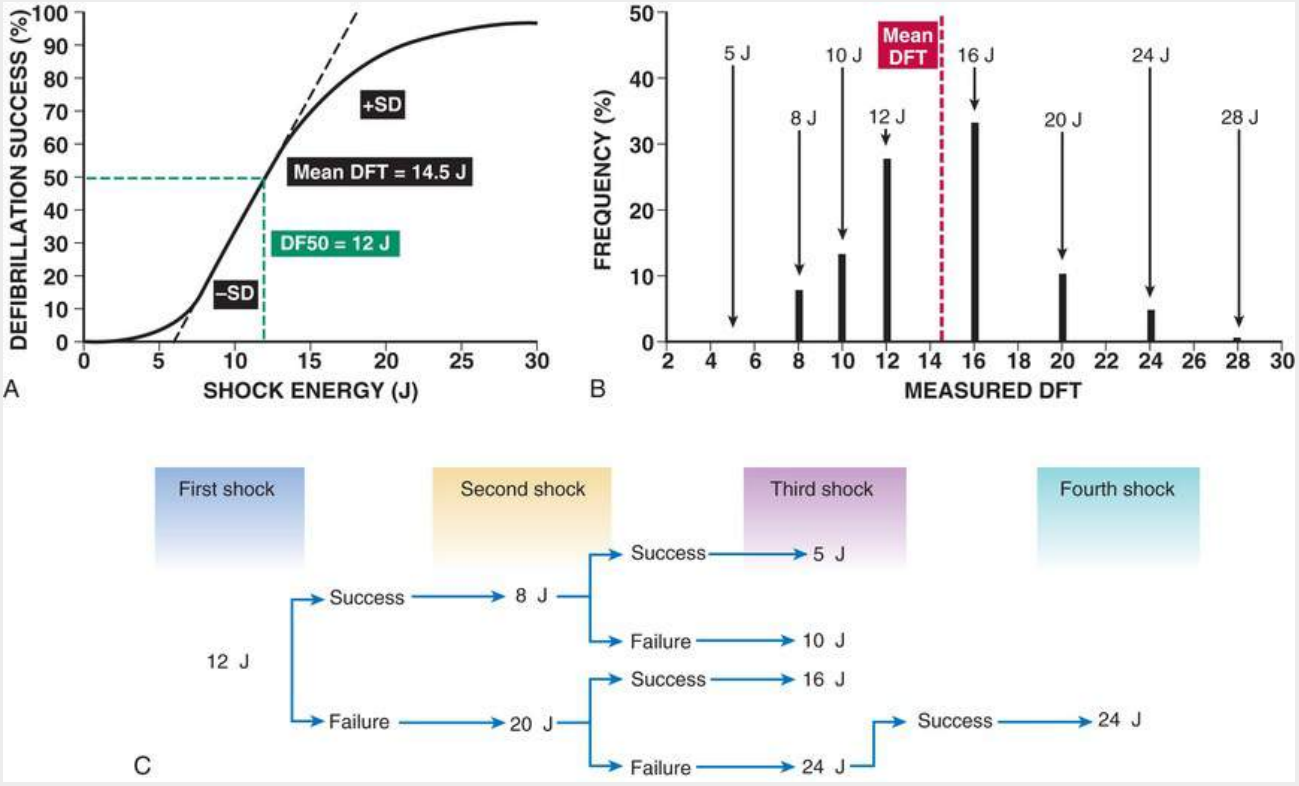


FIGURE 41.16 Relationship in an individual, simulated patient between the defibrillation probability-of-success curve and the measured defibrillation threshold (DFT) using a binary search protocol. **A,** Patient's defibrillation probability-of-success curve. **B,** Plot showing frequency of individual measured DFT values during repeated testing. **C,** Binary search sequence of three or four test shocks used to measure each DFT, starting at 12 J, the shock strength with a 50% probability of success (DF50). The process defined by the binary search protocol results in a single value, which the clinician records as the patient's "DFT." **B** shows the statistical distribution of 50,000 simulated repetitions of this binary search DFT process applied to the defibrillation probability-of-success curve. Even for the most frequently measured DFT value (16 J), there is only about a one-third chance that repeating the process will yield the same result. The mean measured DFT (14.5 J) corresponds to DF68 on the probability of success curve. However, 1 standard deviation of measured DFTs extends from DF30 to DF87. (Modified from Smits K, Virag N. Impact of defibrillation test protocol and test repetition on the probability of meeting implant criteria. Pacing Clin Electrophysiol 2011;34:1515.)

Clinical Application

Implant Testing.

For early ICDs, induction of VF at implant was required to ensure adequate sensing of VF and reliable defibrillation. Subsequently, improved ICD performance and risks of defibrillation testing led to evidence-based omission of defibrillation testing in many patients. Defibrillation safety margin usually is assessed by defibrillation testing, electrically inducing VF and defibrillating at one or more shock strengths (**Fig. 41.16**). With experienced personnel and proper equipment, serious complications are rare.[22] Defibrillation safety margin can also be assessed by vulnerability testing based on the upper limit of vulnerability (ULV; **Fig. 41.17**), which does not require induction of VF with its rare but serious risks.[23] Identifying modern ICD systems with insufficient defibrillation safety margins is challenging because defibrillation is probabilistic, and these devices constitute only about 5% of left pectoral implants.[24]

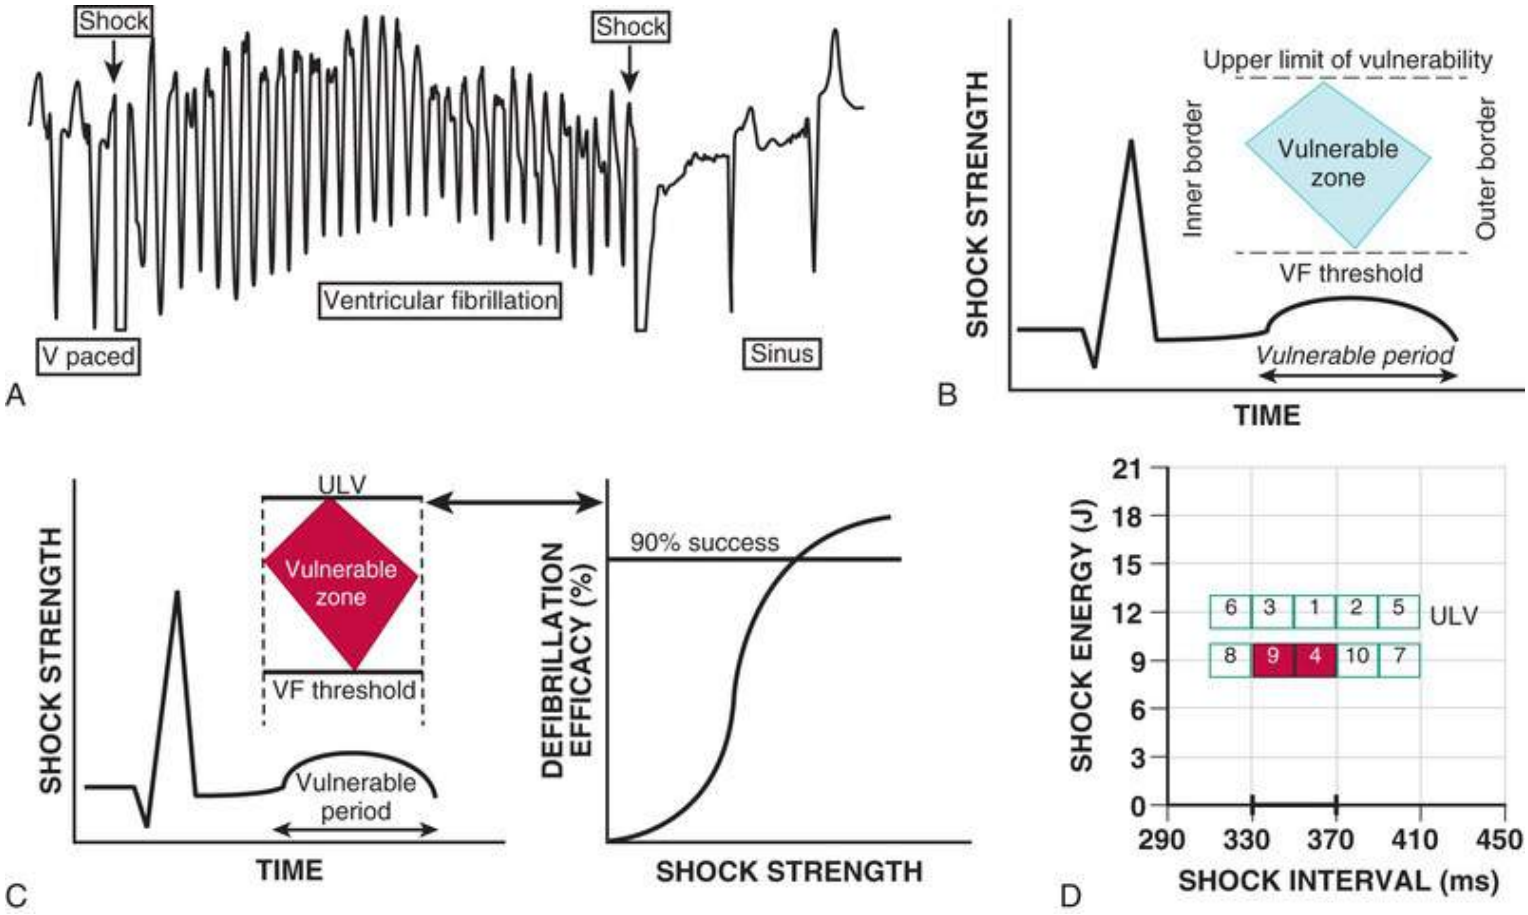

FIGURE 41.17 The vulnerable zone, upper limit of vulnerability (ULV), and the relationship between the ULV and efficacy of defibrillation shocks with the same strength. **A,** Effects of shocks in paced rhythm and VF. Recording during ICD implantation shows surface ECG lead II. At *left arrow,* 2-J monophasic shock delivered on T wave (T shock) of ventricular paced rhythm induces VF. At *right arrow,* 10-J biphasic shock terminates VF. **B,** The vulnerable zone to induction of VF is displayed as a bounded, homogeneous region in a two-dimensional space defined by time (coupling interval) on the abscissa and shock strength on the ordinate. *The ULV is the weakest shock strength at or above which VF is not induced at any time during the vulnerable period*. The upper border (ULV) and the lower borders (VF threshold) are defined by shock strength. The inner (*left*) and outer (*right*) borders are defined by time (coupling interval). **C,** Relationship between ULV and defibrillation probability of success curve. **Left panel** is a smaller version of **B. Right panel** shows defibrillation probability of success curve. The ULV corresponds to the shock strength with a 90% probability of success (DF90), and the ULV + 3 J approximates the DF100. **D,** Methodology. The peak of the vulnerable zone times near the peak of the latest peaking T wave on the surface ECG during ventricular pacing, but the precise relationship may vary from patient to patient. This panel shows procedure for using T shocks to determine a sufficient safety margin for ICD shocks (vulnerability safety margin) without inducing VF in 80% to 90% of patients, as well as the procedure for determining the shock strength at the ULV and the timing of the peak of the vulnerable zone, corresponding to the most vulnerable intervals. For each T shock, the coupling interval after the last pacing stimulus in the S1 train is plotted on the *abscissa,* and the shock strength is plotted on the *ordinate* in units of energy. Each *box* represents a shock in this two-dimensional space. Boxes are 20 milliseconds wide and centered on the measured shock coupling interval. *Open* (*green*) *boxes* represent shocks that did not induce VF. The lowest row of shocks that does not include a *red box* corresponds to the ULV. The height of each box denotes the resolution of tested shock strength, 3 J in this example. The *black bar* on the abscissa denotes the range of most vulnerable intervals. The left end of the bar denotes the inner border, and the right end denotes the outer border. The number in each box indicates its order in the shock sequence. *Filled* (*red*) *boxes* represent shocks that induced VF. *For clinical testing, only noninducing shocks 1, 2, 3, and 5 are sufficient to determine a safety margin for programming ICD shocks*. The remaining shocks are needed to determine the ULV for research purposes. (**D,** From Shehata M et al. Automatic determination of timing intervals for upper limit of vulnerability using ICD electrograms. Pacing Clin Electrophysiol 2008;31[6]:691-700.)

Clinical trials have established that clinical defibrillation testing does not improve outcomes for patients with new, left-sided ICDs and well-positioned defibrillation leads that have satisfactory sensing and pacing thresholds.[22,25] There are at least two plausible reasons: (1) clinical defibrillation failures can

be caused by factors that cannot be measured at implant, such as ischemia; and (2) the low incidence of VT/VF requiring shocks in primary prevention patients limits the impact of differences in defibrillation efficacy on total mortality. Accordingly, current recommendations do not require routine testing in all new, left-sided pectoral implants. However, assessment of defibrillation efficacy or shock testing is recommended for other implants, including subcutaneous ICDs.[25]

Shocks in Clinical Practice.

Shocks are the most reliable therapy for patients with life-threatening VT/VF (**Fig. 41.18**). Most shocks are programmed near maximum output because shock pain is independent of shock strength over the clinically useful range. Clinically, the first-shock success rate for spontaneous VF or rapid, hemodynamically unstable VT is 80% to 95%. ICDs can deliver four to eight shocks per VT/VF episode. Approximately 98% of all spontaneous VT/VF is terminated by the first two shocks, and the overall success rate approximates 99.9% for a VT/VF event.

FIGURE 41.18 Dual-chamber EGM showing polymorphic VT with AV dissociation treated with shock. The atrial EGM, high-voltage ("shock") EGM, and dual-chamber marker channel are shown. The *arrowhead* denotes shock, designated by *CD* (charge delivered) on the marker channel. After the shock, the atrial rhythm is sinus with premature atrial complexes; the ventricular rhythm is biventricular paced (BV) with premature ventricular complexes (PVCs) in the sinus rate zone (VS). The second BV beat (BV/VS) has a slightly shorter paced AV delay (110 versus 130 milliseconds) than first BV beat because a PVC occurs during the AV delay and triggers "safety pacing," a feature that reduces crosstalk inhibition.

Although ICD shocks for VT/VF can be lifesaving, minimizing shocks is important because they have adverse psychosocial consequences and increase utilization of medical care (**see Chapter 96**). Additionally, there is a strong correlation between patient mortality and ICD shocks for either VT/VF or AF.[26] This correlation primarily results from more advanced heart disease in patients who experience these shocks. Shocks may also play an incremental, independent causal role in increasing mortality.[25]

ICD Sensing and Detection

Delivery of appropriate ICD therapy depends on both accurate *sensing* of the EGMs that correspond to individual cardiac depolarizations and *detection* of arrhythmias by analyzing a sequence of sensed signals to determine the cardiac rhythm.

ICD Sensing

Dynamic Sensing Threshold.

ICDs need reliable sensing of low-amplitude EGMs during VF, whereas pacemakers do not. Because continuous high sensitivity results in undesirable oversensing, ICDs use feedback mechanisms based on R wave amplitude that adjust sensing threshold dynamically (**Fig. 41.19**) in relation to the amplitude of each sensed intrinsic depolarization or pacing pulse. Compared with a fixed sensing threshold, a dynamic threshold increases the likelihood of sensing low-amplitude and varying EGMs during VF, while reducing the likelihood of T wave oversensing. ICDs do not use unipolar sensing because of the high risk of oversensing when operating at a high sensitivity.

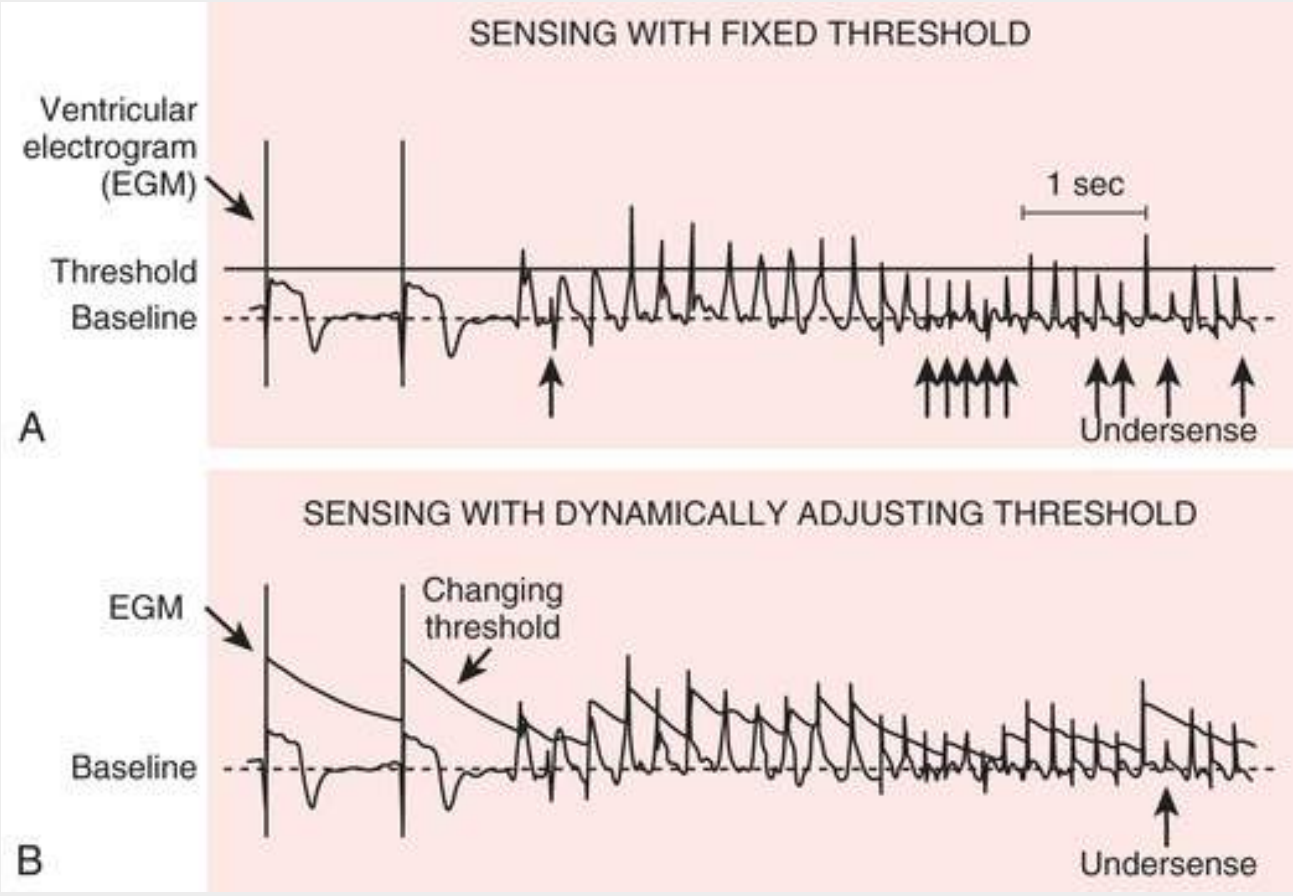

FIGURE 41.19 Dynamic versus fixed sensing threshold in VF. **A,** Fixed sensitivity requires that the sensed potential exceed a fixed threshold. Because of the highly variable amplitude during VF, undersensing occurs (*arrows*). If the threshold is lowered, T wave oversensing may occur. Note that the threshold is just above the T wave amplitude during sinus rhythm, first two complexes. **B,** Dynamic adjustment of sensitivity. At the end of the blanking period after each sensed (or paced) event, the sensing threshold is set to a high value. It then decreases with time until a minimum value is reached. Undersensing is diminished while still retaining a safety margin to prevent T wave oversensing. (Modified from Olson WH. Tachyarrhythmia sensing and detection. In Singer I, editor. Implantable Cardioverter-Defibrillator. Armonk, NY: Futura; 1994, pp 71-107.)

Enhanced Features to Prevent or Mitigate Oversensing.

Dynamic sensing alone cannot both ensure reliable sensing of VF and prevent all oversensing. Thus, ICDs include enhanced features to recognize and prevent oversensing, including “noise” rejection algorithms that reject high-frequency, noncyclic signals; algorithms that reject T waves based on frequency content or morphology (**Fig. 41.20**); and algorithms designed to withhold therapy from

oversensing caused by failure of pace-sense components in ICD leads.[20]

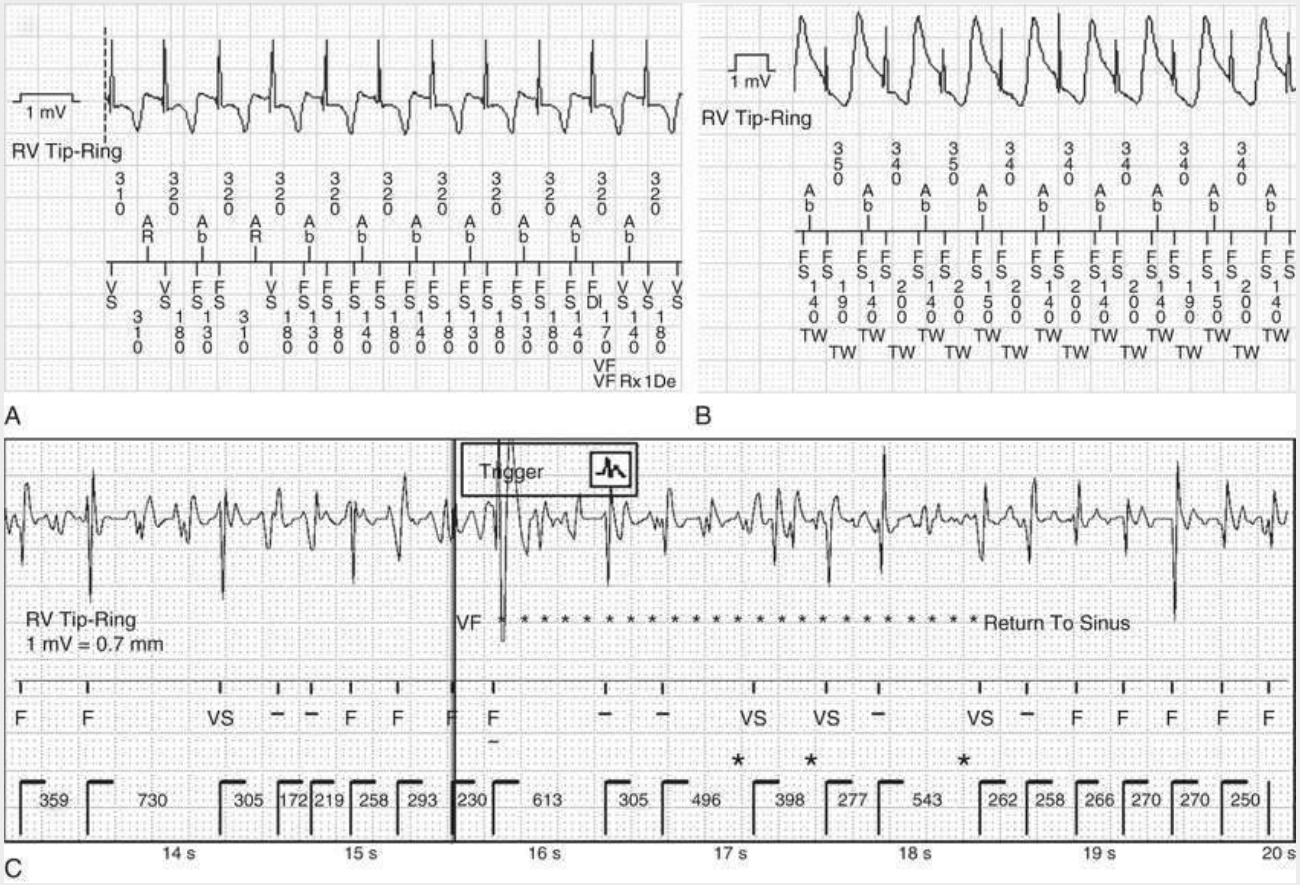

FIGURE 41.20 **A, B,** Oversensing of T waves. Wide-band dedicated bipolar RV EGMs during sinus tachycardia with dual-chamber markers. Each EGM shows the characteristic pattern of alternating high-frequency and low-frequency sensed events, with two ventricular events for each atrial event. One millivolt (mV) calibration markers are shown at *left.* **A,** Oversensing causes inappropriate detection of ventricular fibrillation (VF). High-amplitude T waves cause intermittent oversensing despite adequate (10 mV base to peak) R waves. "VF Rx [Therapy] 1 De" at *lower right* denotes inappropriate detection of VF. **B,** Enhanced sensing algorithm identifies the pattern of T wave oversensing therapy (TW markers) and prevents inappropriate detection of VF despite consistent T wave oversensing. Low-amplitude (1.5 to 4.0 mV) R waves are the root cause of this T wave oversensing. **C,** Undersensing. Dedicated bipolar, filtered EGM is shown during ongoing VF. Between 15 and 18 seconds (s), there are fewer markers than true EGMs indicating undersensing. The single-zone VF detection interval is 360 msec and programmed minimum sensitivity 0.3 mV. Undersensing occurs primarily from amplitude of EGMs changing faster than dynamic sensitivity can adjust despite EGM amplitudes that exceed the minimum sensitivity. Shortly after detection of VF at vertical line (Trigger, VF), three consecutive classified intervals (separated by one unclassified interval) are classified in the sinus zone (VS, *asterisks*). This results in clinically incorrect termination of the device-defined VF episode (Return to Sinus) despite ongoing VF. The ICD subsequently performed a second initial detection of VF and delivered a successful shock. (From Swerdlow CD, Friedman P. Implantable cardioverter-defibrillator: clinical aspects. In Zipes D, Jalife J, editors. Cardiac Electrophysiology: From Cell to Bedside. 7th ed. Philadelphia: Saunders Elsevier; 2018.)

Detection of Ventricular Tachycardia and Fibrillation

Rate and Duration for Detection

Fig. 41.21 provides an overview of the process ICDs use to detect VT/VF. A device-defined episode begins when *ventricular rate* and preliminary *duration* criteria are fulfilled. Essentially, the ICD determines whether the ventricular rate is fast enough for a long enough period to warrant further analysis.

Initial detection requires that enhanced sensing features confirm that sensed events are valid ventricular EGMs, that rate and duration requirements are fulfilled, and if applicable, that the ICD explicitly classifies the rhythm as VT rather than supraventricular tachycardia (SVT).

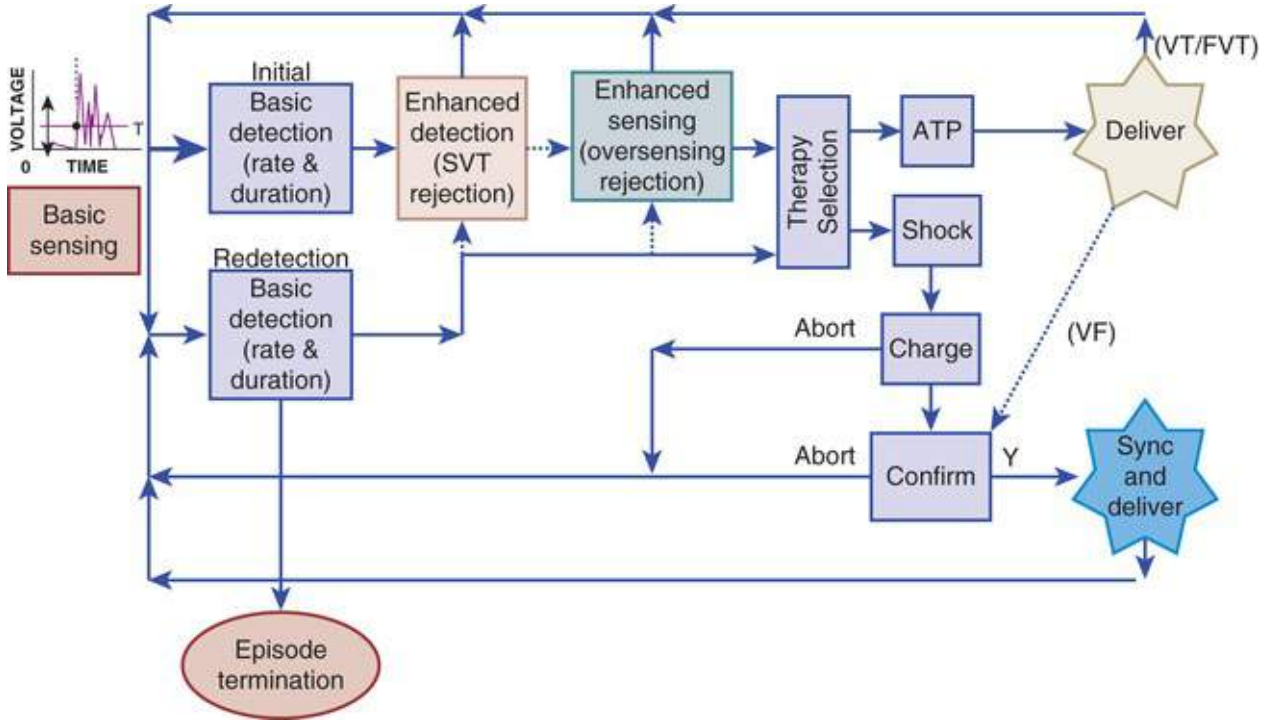

FIGURE 41.21 Overview of ICD detection algorithm. After initial basic (rate and duration) criteria are fulfilled, algorithms apply enhanced detection comprising supraventricular tachycardia–ventricular tachycardia (SVT-VT) discrimination, enhanced sensing features, to detect and redetect VT, fast ventricular tachycardia (FVT), and ventricular fibrillation (VF). Enhanced sensing features may be applied either before intervals are counted or (as shown) after rate and duration are fulfilled. In the first case, oversensed signals are rejected, and only validated intervals contribute to the count. In the second case, episodes are classified specifically as oversensing events. Next, SVT-VT discriminators may classify the tachycardia as SVT; otherwise it is classified as VT/VF. When VT/VF is detected, antitachycardia pacing (ATP) is delivered immediately, but shocks require capacitor charging, which takes 6 to 15 seconds for maximum-energy. After charging is completed, ICDs perform a brief *confirmation* or *reconfirmation* process to determine if VT/VF is still present. The shock is delivered if VT/VF is reconfirmed; otherwise it is aborted. After therapy, ICDs monitor the rhythm for persistence of VT/VF or return to baseline. *Redetection* is the process by which ICDs determine whether VT/VF persists; typically it is less strict than initial detection. If VT/VF is redetected, the next programmed therapy is delivered. Simultaneously, ICDs monitor for a sufficient duration of slow intervals to fulfill the *episode termination* criterion, returning to the initial detection criteria. The VT/VF episode continues until either the ICD redetects VT or declares *episode termination*. Y, Yes. (Modified from Swerdlow C, Brown M, Bordachar P. Sensing and Detection With Cardiac Implantable Electronic Devices. In Ellenbogen KA, Kay GN, Lau CP, et al, editors. Clinical Cardiac Pacing, Defibrillation and Resynchronization Therapy. 5th ed. Philadelphia: Saunders; 2017.)

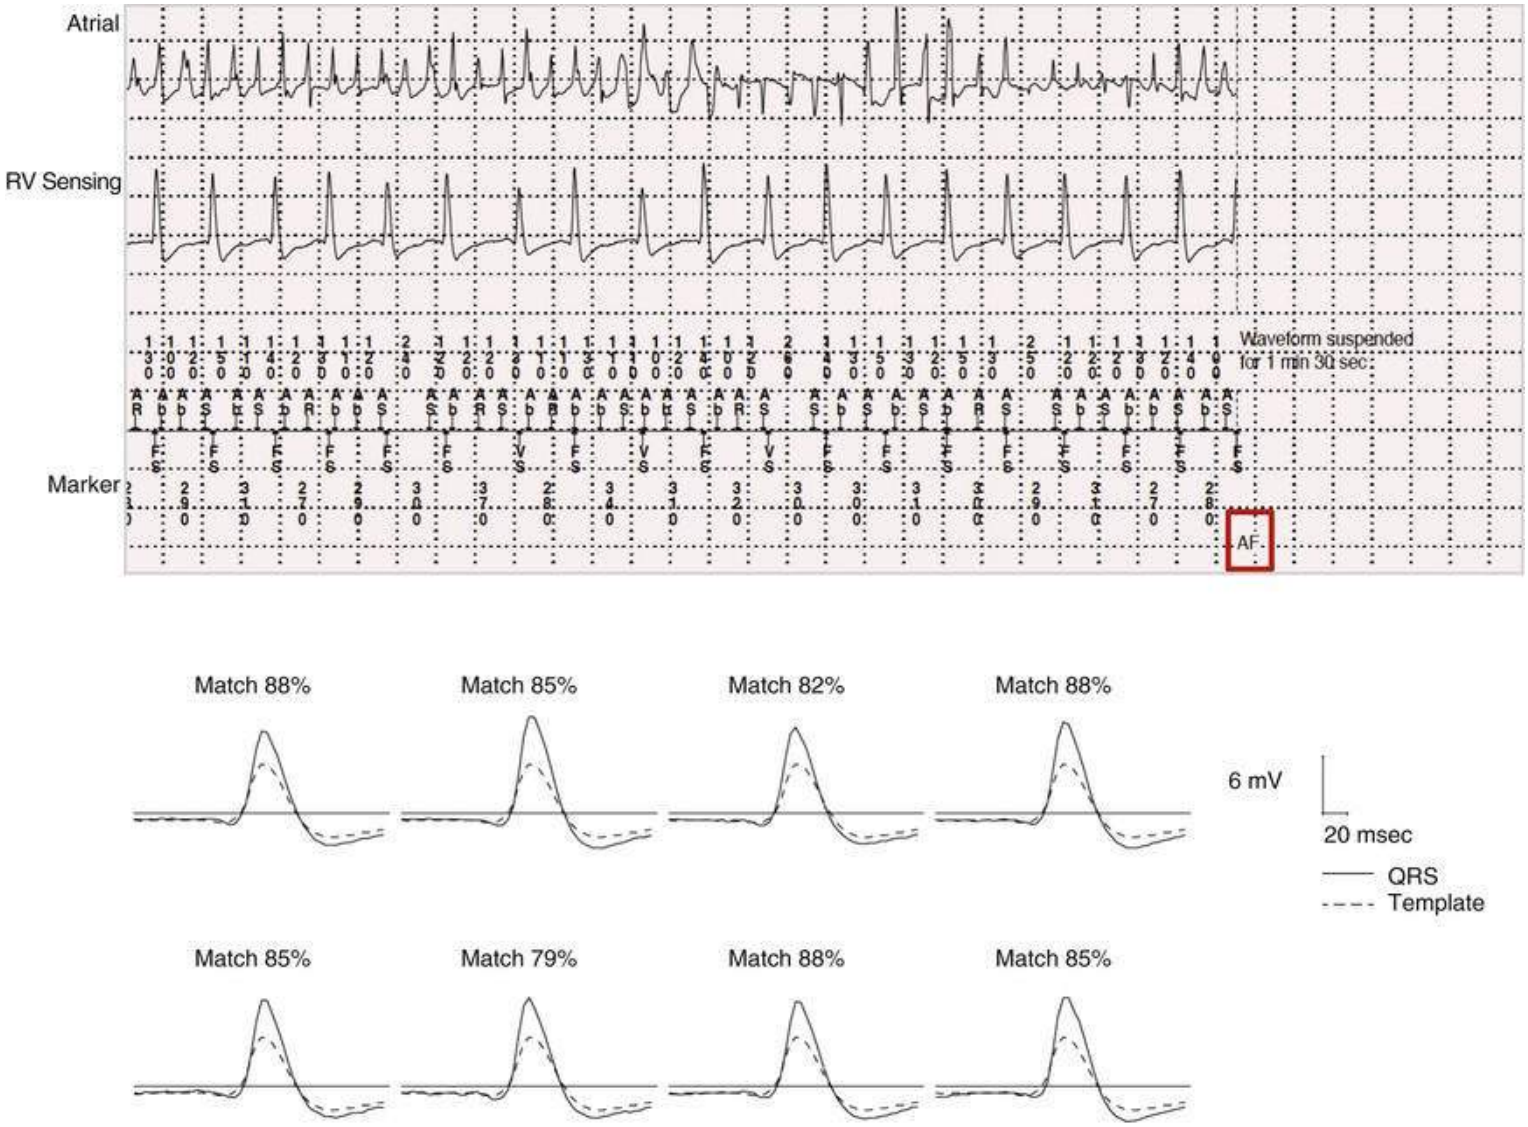
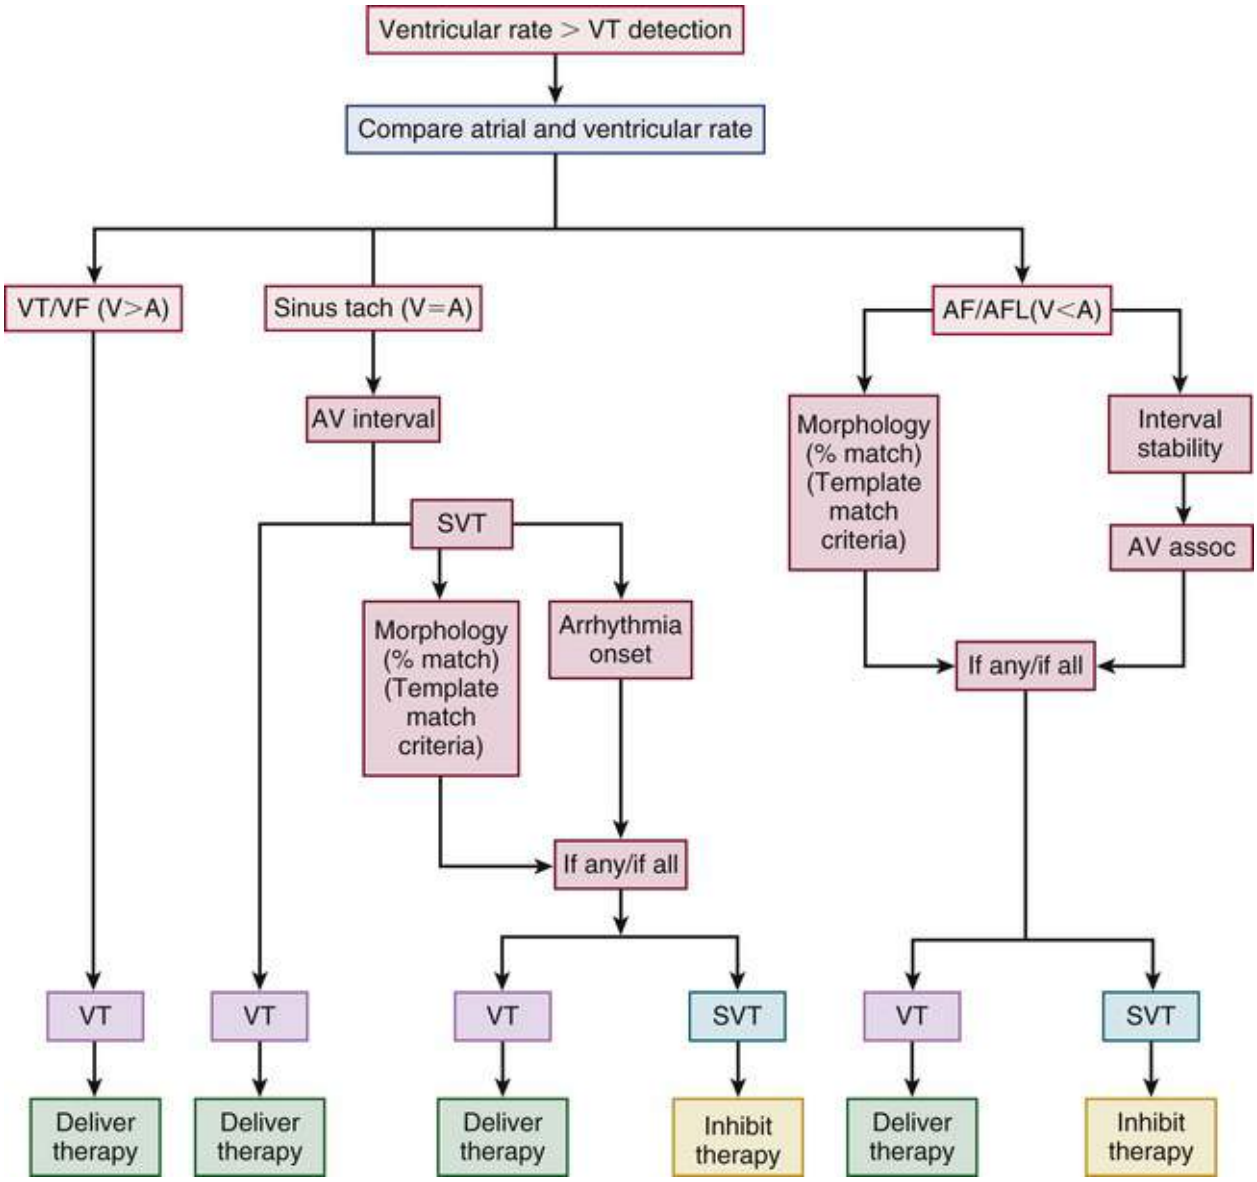
SVT-VT Discrimination

The combination of ventricular rate and duration serves as an implicit SVT-VT discriminator and suffices in many patients,[25,27] but patients in whom SVTs and VTs overlap in rate require an explicit discrimination process in which a sequence of sensed EGMs that satisfies rate and duration criteria for VT/VF are classified as either SVT or VT/VF. *Discriminators* are individual algorithm components or “building blocks” that provide a partial or complete rhythm classification for a subset of rhythms. Individual discriminators may be considered in relation to the EGMs analyzed (ventricular only or both atrial and ventricular), the rhythm that they identify (e.g., AF, sinus tachycardia, VT), or the type of EGM

information analyzed (intervals versus morphology).[25,27] **eTable 41.5** summarizes the most commonly used individual discriminators. *Discrimination algorithms* integrate complementary component discriminators to classify tachycardias as VT/VF or SVT (**eFigs. 41.13 to 41.15**).



EFIGURE 41.14 Correct classification of rapidly conducted atrial fibrillation (AF) by ventricular EGM morphology. The atrial EGM, right ventricular sensing EGM, and dual-chamber marker channel are shown. Most intervals are classified in the ventricular fibrillation (VF) zone (FS), which is programmed to less than 320 milliseconds. The "AF" designation at right of the marker channel (*red box*) indicates that the rhythm is classified as AF. The basis for this classification is shown in the **lower panel,** which compares the morphology of shock (high-voltage) EGMs during tachycardia (*solid lines*) with those of a template stored during baseline sinus rhythm (*dotted line*). Match percentages of 70% or greater between the two EGMs are considered sufficiently close that the rhythm is classified as "supraventricular." It is designated as AF based on the atrial rhythm.



EFIGURE 41.15 Supraventricular tachycardia (SVT)–ventricular tachycardia (VT) discrimination algorithm. This figure shows the hierarchic sequence of individual discriminators in one manufacturer's dual-chamber algorithm (St. Jude Medical). Most manufacturers use conceptually similar algorithms. The first step is comparison of atrial (A) versus ventricular (V) rate. Rhythms are classified into three Rate Branches: ventricular rate greater than atrial rate (V > A), ventricular rate equal to atrial rate (V = A), and ventricular rate less than atrial rate (V < A). All rhythms in the V > A rate branch are treated as VT. The V < A rate branch discriminates rapidly conducted atrial fibrillation (AF)/atrial flutter (AFL) from VT during AF/AFL. The V = A rate branch discriminates sinus tachycardia and other 1 : 1 SVTs from VT with 1 : 1 VA conduction. The primary single-chamber discriminator in both these rate zones is ventricular EGM morphology. If V < A, the algorithm may also apply regularity of the ventricular rhythm (interval stability to reject AF) and N:1 AV association (to reject atrial flutter). If V = A, the algorithm may also incorporate analysis of arrhythmia onset, which may be either chamber of onset or ventricular sudden onset to differentiate pathologic tachycardias form sinus tachycardia. When multiple single-chamber discriminators are used, they may be combined to detect VT only if all discriminators classify the rhythm as VT ("If All") or if any one of the discriminators ("If Any") classifies the rhythm as VT. "Morphology" indicates morphology of the ventricular EGM; Sinus Tach, sinus tachycardia; VF, ventricular fibrillation.

ETABLE 41.5

SVT-VT Discriminators Used in ICDs

DISCRIMINATOR	PURPOSE/INFORMATION	POTENTIAL WEAKNESSES
Single-Chamber Ventricular Discriminators		
R-R regularity	Discrimination of monomorphic VT (regular cycle lengths) from rapid AF (irregular cycle lengths)	May lose effectiveness as ventricular rates during AF increase; 2 : 1 atrial flutter has regular R-R intervals; may cause underdetection of VT with irregular R-R intervals
R-R onset	Identifies sudden ventricular rate changes	Not specific for atrial or ventricular tachyarrhythmias; may miss VT arising during sinus tachycardia
VEGM morphology	Abnormal VEGM morphology may indicate VT/VF	Confounded by conduction aberrancy or changes in "normal" VEGM morphology
Commonly Used Dual-Chamber Discriminators		
Comparison of atrial vs. ventricular rate	VT diagnosed if atrial rate is less than ventricular rate	Confounded by atrial undersensing or far-field R wave oversensing
P-R dissociation	P-R dissociation usually indicates VT	AV reentrant tachycardia; VT with 1 : 1 retrograde conduction; AF that conducts rapidly with apparent P-R dissociation
P-R patterns/relationships	Consistent P-R patterns/relationships usually indicate SVT	AV reentrant tachycardia and VT with 1 : 1 retrograde conduction
Chamber of onset (acceleration)	Identifies whether tachycardia initiates in atrium or ventricle	A single oversensed/undersensed event may result in misclassification.

AEGM, atrial electrogram; *AF,* atrial fibrillation; *AV,* atrioventricular; *SVT,* supraventricular tachycardia; *VEGM,* ventricular electrogram; *VF,* ventricular fibrillation; *VT,* ventricular tachycardia.

Strategic Programming to Reduce Shocks and ATP

Appropriate ICD shocks save lives but are painful to the conscious patient and have other adverse effects. Further, both shocks and ATP can be proarrhythmic. An expert consensus statement addresses strategies to program sensing, detection, and therapy to reduce adverse effects of ATP and shocks.[25] This statement classifies therapies as *appropriate* if delivered for sustained VT/VF and *inappropriate* if delivered for a rhythm other that VT/VF. In addition, it classifies appropriate therapy as *avoidable* if it could have been withheld without adverse clinical consequences. Examples of avoidable therapy include shocks for self-terminating VT or VT that could be terminated by ATP. Avoidable therapies are also referred to as *unnecessary*.

Strategic programming of sensing, detection, and therapy reduces inappropriate and avoidable therapies and may reduce overall mortality.[25] Such programming has reduced the rate of inappropriate or avoidable shocks to 2% to 5% for the first year after transvenous ICD implant[18,25] (**Table 41.3** and **eTable 41.6**).

TABLE 41.3

Strategic Programming Principles for Shock Reduction*

PRINCIPLE	RATIONALE
Sufficiently long detection time	Do not treat self-terminating VT. AF with rapid ventricular rate is less likely to exceed the rate threshold for a longer detection time.
Fast VT detection rate in primary prevention patients and secondary-prevention survivors of VF	Do not treat slower tachycardias, which are more likely to be SVT.
SVT-VT discrimination	Do not treat SVT.
ATP in all VT/VF detection zones	ATP is painless. Even in the "VF" zone, most rhythms are monomorphic VT; many can be terminated by ATP.
Maximum shock strength†	Minimize unsuccessful shocks for VT, VF, or AF with rapid ventricular rate.
Enhanced sensing features	Minimize shocks for oversensing.

*Providing AV conduction is normal and discriminator is reliable.

†Adult patients.

AF, Atrial fibrillation; *ATP,* antitachycardia pacing; *SVT,* supraventricular tachycardia; *VT,* ventricular tachycardia.

ETABLE 41.6

Selected Consensus Recommendations for Strategic ICD Programming*

TACHYCARDIA DETECTION PROGRAMMING RECOMMENDATIONS	CLASS	LEVEL OF EVIDENCE	COMMENT
Detection duration should be programmed to at least 6 to 12 seconds or 30 intervals.	I	A/B-R*	Reduce total therapies
For primary prevention adult patients, the slowest detection rate should be programmed to 185 to 200 beats/min.	I	A	Reduce total therapies
For secondary prevention patients, it is reasonable to program the slowest detection rate at least 10 beats/min less than documented VT rate but not greater than 200 beats/min.	IIa	C-EO	Reduce total therapies
Supraventricular tachycardia (SVT)–ventricular tachycardia (VT) discrimination algorithms should be programmed "on" up to 200 to 230 beats/min.	I	B-R	Reduce inappropriate therapies
Antitachycardia pacing (ATP) should be programmed for all VT/ventricular fibrillation (VF) zones up to 230 beats/min in all patients with structural heart disease.	I	A	Reduce shocks

**A,* Primary prevention; *B-R,* secondary prevention.

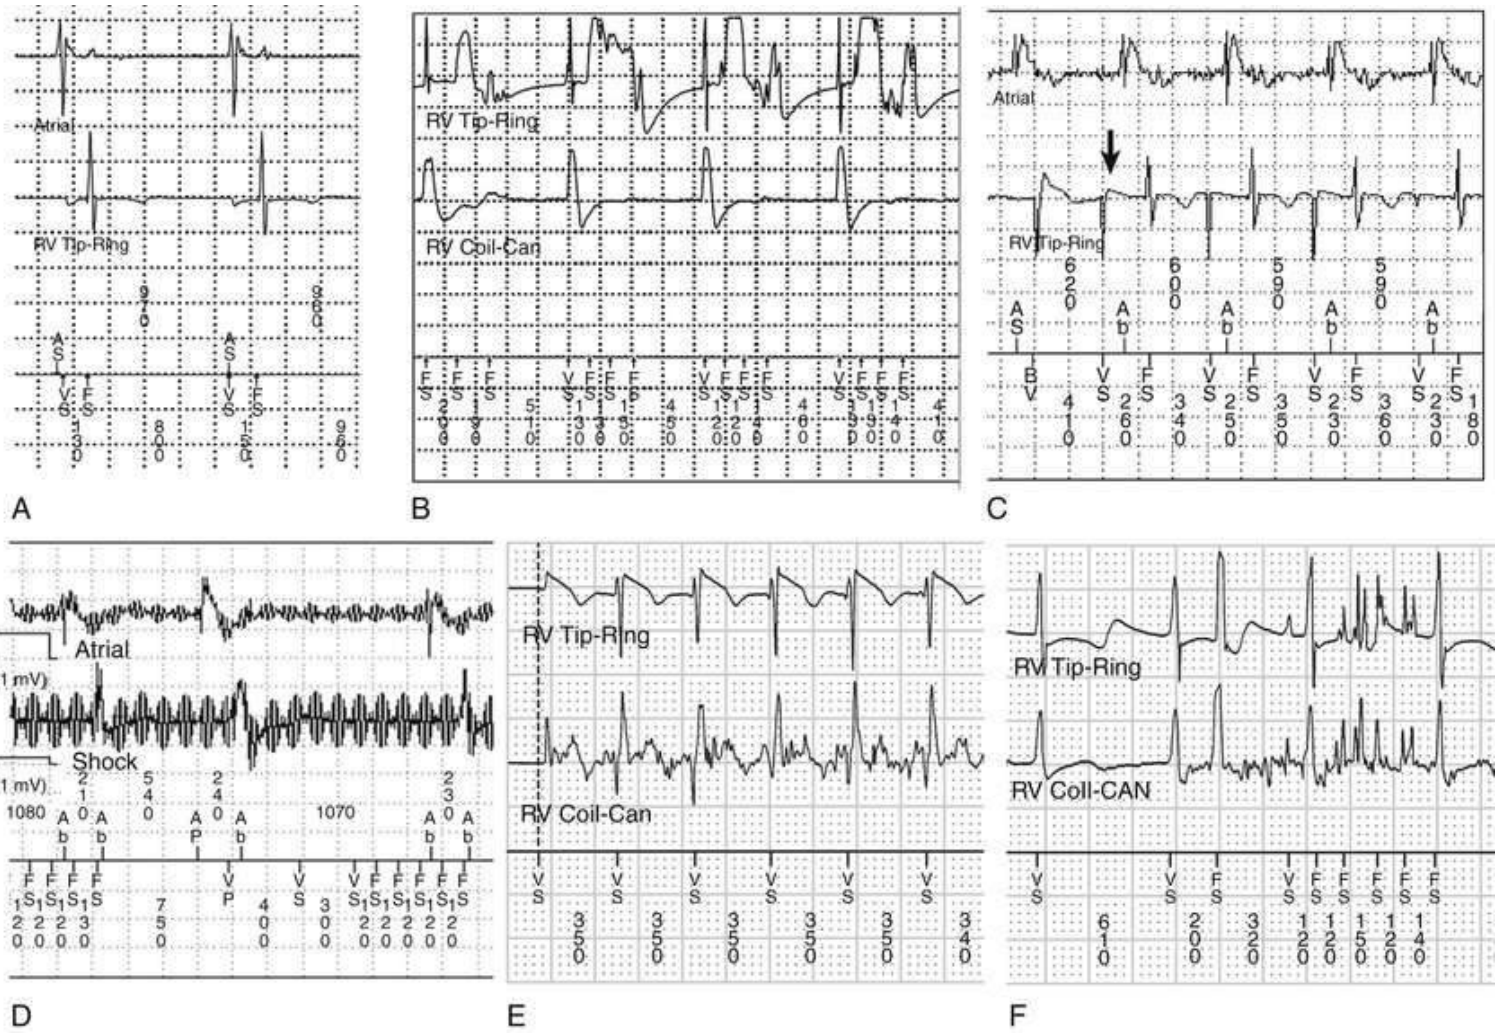
From Wilkoff BL, Fauchier L, Stiles MK, et al. 2015 HRS/EHRA/APHRS/SOLAECE expert consensus statement on optimal implantable cardioverter-defibrillator programming and testing. Heart Rhythm 2016;13(2):e50-86.

ICD Troubleshooting

Ventricular Oversensing

In early ICDs, ventricular oversensing of rapid signals usually presented as inappropriate detection of VT/VF with delivered therapy or aborted shocks. In modern ICDs with enhanced sensing features, oversensing typically presents as oversensing alerts.

Oversensing can be classified by EGM morphology, temporal pattern (cyclic versus noncyclic), source type (physiologic versus nonphysiologic), and source location (intracardiac versus extracardiac) (**eFig. 41.16**). Signals that vary with the cardiac cycle (cyclic signals) indicate an intracardiac sources. Nonphysiologic sources usually are extracardiac (e.g., EMI), except for those generated by intracardiac lead failures. Physiologic signals can be intracardiac (P, R, or T waves that cause one oversensed signal per cardiac cycle) or extracardiac (myopotentials). Specific sources can generate oversensed signals with characteristic features that differ from true cardiac EGMs in frequency content and amplitude.[20]



EFIGURE 41.16 EGM patterns of ventricular oversensing. Each panel shows labeled EGMs and marker channel. **Upper panels,** Cyclic oversensing patterns of intracardiac signals. **A,** Atrial and ventricular sensing EGMs in P wave oversensing. Cyclic oversensing of physiologic T waves and P waves or R-wave double-counting results in a pattern of 1 oversensed signal per true cardiac cycle that corresponds consistently to P waves, T waves, or a second component of R waves. In contrast, oversensing of cyclic, nonphysiologic signals from intracardiac lead failure is diagnosed by the superimposition of nonphysiologic signals on true ventricular EGMs at a fixed time in the ventricular cycle. **B,** Multiphasic signal superimposed on ST segment and T wave in Fidelis lead (Medtronic) ring-cable fracture results in multiple oversensed events per cardiac cycle. **C,** Cyclic spikes caused by inside-out insulation breach of Riata lead (St. Jude Medical). **Lower panels,** Noncyclic oversensing patterns of extracardiac signals. **D,** External electromagnetic interference (EMI) typically appears on multiple channels. The 60-Hz signal from line current appears with an 8-Hz modulation due to telemetry sampling at 128 Hz, just above the Nyquist limit. **E,** High-frequency pectoral myopotentials are a *normal* finding on EGMs that include the Can as one electrode. No oversensing occurs on marker channel. **F,** In-pocket lead, insulation breach results in oversensing of pectoral myopotentials on dedicated bipole in RV apex (upper EGM). Myopotential on lower (shock) EGM are a normal finding (see **E**) and do not indicate a breach of the conductor to the RV coil.

Shocks: Diagnosis and Management

Minimizing shocks requires strategic programming, use of patient alerts, and remote monitoring. Once shocks occur, diagnosis and management tools include clinical data (history, chest radiograph), ICD diagnostics (e.g., lead impedance trends), and stored EGMs.

Approach to the Patient with Shocks

Fig. 41.22 summarizes a three-step approach to the patient who presents with a shock. First, analyze

stored EGMs to determine if it was delivered in response to a tachycardia or oversensing. Second, if the shock responded to a tachycardia, determine if the rhythm is VT or SVT using established principles of ECG and EGM analysis. Third, determine if an appropriate shock for VT/VF could have been be avoided by either strategic programming (**see Table 41.3 and eTable 41.6**) or nondevice interventions (**eTable 41.7**)

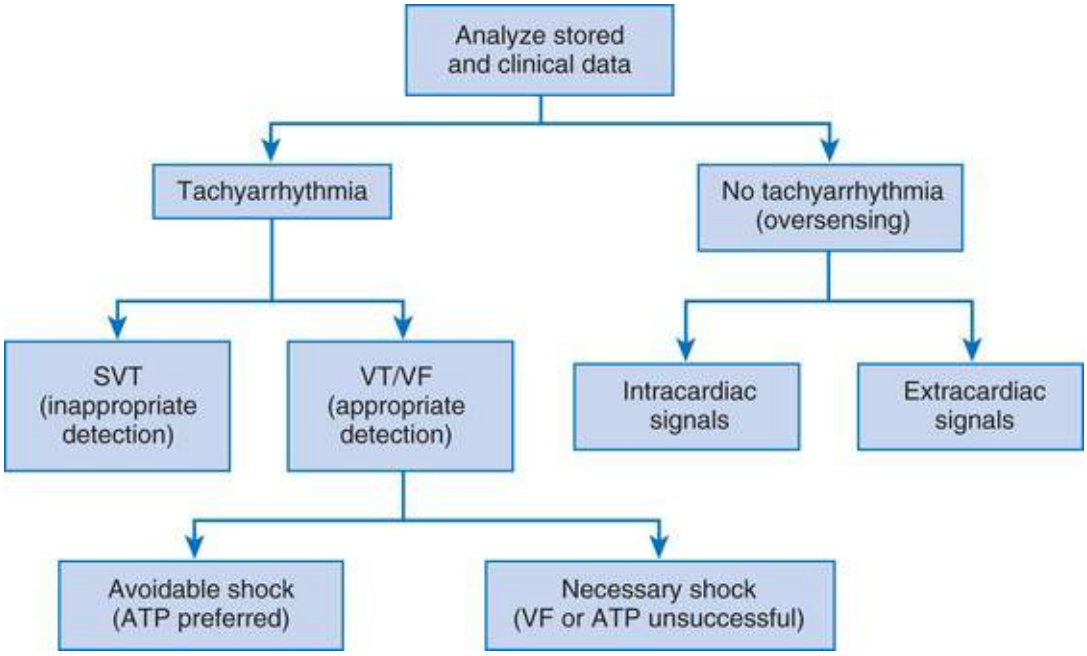

FIGURE 41.22 Differential diagnosis of ICD shocks. See text for details.

ETABLE 41.7

Non–Device-Related Interventions to Reduce Shocks in ICD Patients

	SHOCKS FOR VT/VF	SHOCKS FOR AF/SVT
General Cardiac Care		
Prevent metabolic abnormalities (e.g. K^+)	X	
Prevent ischemia	X	
Optimize heart failure therapy	X	X
Maximize beta blocker dose	X	X
Nondevice Therapy for Arrhythmias		
Antiarrhythmic drugs (sotalol, amiodarone)	X	X
Catheter ablation	X	X
Neuraxial modulation	X	
Minimize Proarrhythmia		
From drugs	X	
From pacing	X	X
Lifestyle		
Minimize triggers in susceptible patients	X	X

AF, Atrial fibrillation; *SVT,* supraventricular tachycardia; *VF,* ventricular fibrillation; *VT,* ventricular tachycardia.

Because shocks for VT/VF or rapidly conducted AF are associated with increased mortality over weeks to months,[26] the clinician should not only diagnose and treat the immediate precipitant of shocks but also consider treatments to reduce delayed mortality. Thus, patients who present with a change in shock pattern should be reassessed for HF and ischemia.

The approach to shocks delivered for oversensing is guided by the cause of oversensing. T wave oversensing was once a common cause of inappropriate shocks in transvenous ICDs (**see Fig. 41.21**), but its frequency has been reduced by multiple sensing enhancements and programming options.[20] Despite

prescreening, it remains the most common cause of oversensing in subcutaneous ICDs. Shocks for SVT may be corrected by reprogramming (rate zones or SVT-VT discriminators) and treatment with beta blockers, antiarrhythmic drugs, or ablation. Most avoidable shocks for self-terminating VT may be prevented by strategic programming.

A patient with a *single shock* should be evaluated in person or by remote monitoring within 24 to 48 hours. In contrast, *repetitive shocks* constitute an emergency (**Fig. 41.23**). The cause must be determined, and VT/VF detection may be disabled using a programmer or magnet. Repetitive shocks for VT/VF may be caused by multiple unsuccessful shocks for a single episode or recurrent VT/VF after successful shock termination ("VT storm").

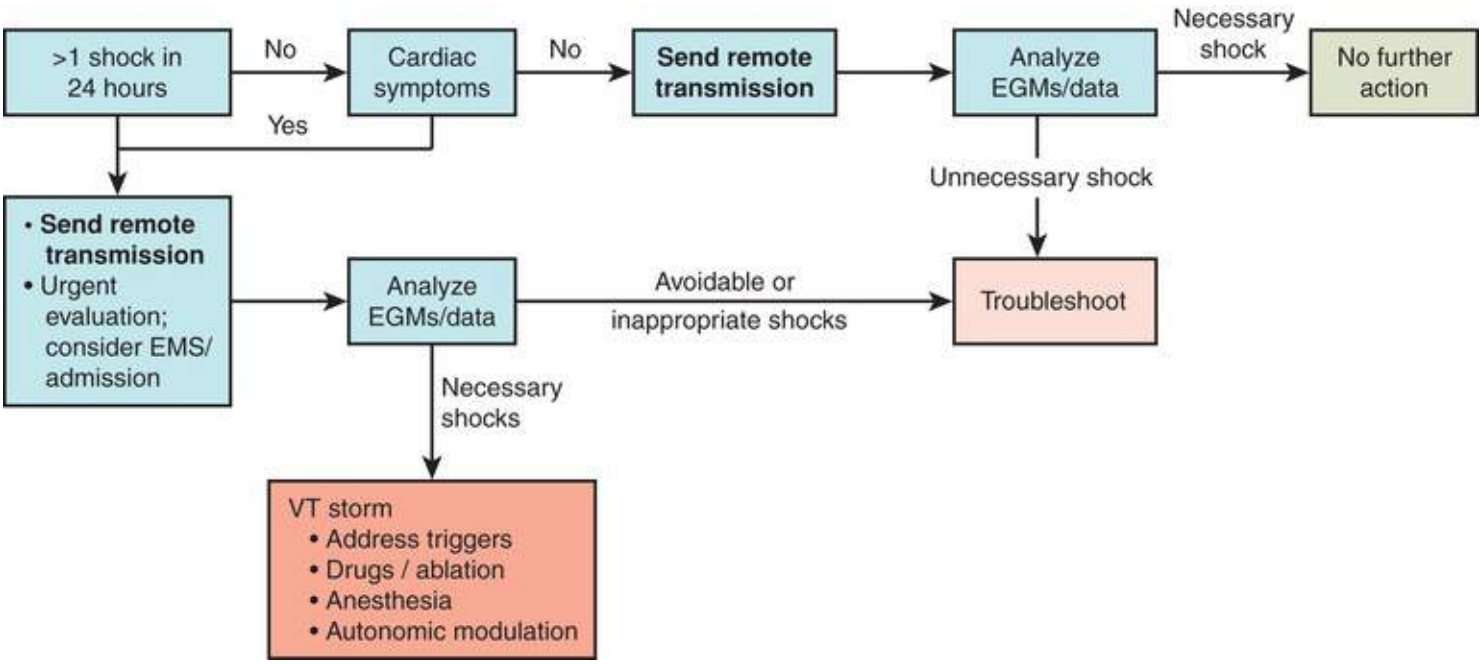

FIGURE 41.23 Approach to the patient with ICD shocks at home. Remote monitoring facilitates care of patients who receive shocks. In the absence of ongoing cardiac symptoms, a single appropriate shock (reviewed remotely) does not require further intervention. Multiple shocks or ongoing symptoms require urgent action to treat VT storm, treat SVT, or troubleshoot to prevent oversensing. (From Swerdlow CD, Friedman P. Implantable cardioverter-defibrillator: clinical aspects. In Zipes D, Jalife J, editors. Cardiac Electrophysiology: From Cell to Bedside. 7th ed. Philadelphia: Saunders Elsevier; 2018.)

Treatment of VT storm includes reversal of precipitating events, beta blockers, and antiarrhythmic therapy. Neuraxial interventions may also be useful.[28] Causes include acute ischemia, exacerbation of HF, metabolic abnormalities (e.g., hypokalemia, amiodarone-induced hyperthyroidism), and drug proarrhythmia or noncompliance.

Unsuccessful Shocks

Table 41.4 summarizes causes of unsuccessful shocks. If an ICD classifies a shock for VT/VF as unsuccessful, stored EGMs should be reviewed to determine if the shock truly failed to terminate VT/VF, or if the ICD misclassified effective therapy as ineffective (e.g., due to immediate arrhythmia recurrence). Because defibrillation success is probabilistic, occasionally shocks fail, but failure of two maximum-output shocks is rare if the safety margin is adequate. Shocks from chronic ICD systems fail to terminate true VT/VF because of both patient-related and ICD system–related causes. Many patient-related causes can be reversed, but system-related causes usually require operative intervention. ICD data should be

reviewed for clues to system-related causes, including excessive detection or charge times, evidence of lead or connection failure, mismatch between programmed and delivered shock strength, and out-of-range high-voltage impedance, suggesting a failure in lead components of the shock circuit. In the absence of a diagnosis, defibrillation testing should be performed.

TABLE 41.4

Causes of Unsuccessful ICD Shocks

Successful Termination of VT/VF Misclassified by the ICD
VT/VF recurs before the device determines the VT/VF episode has terminated.
Failure to terminate SVT (e.g., sinus tachycardia)
Postshock rhythm is SVT in the VT rate zone.
Patient-Related Factors
Metabolic (hyperkalemia)
Ischemia
Progression of heart failure
Some antiarrhythmic drugs (e.g., amiodarone, type IC)
Pleural or pericardial effusions
Device System–Related Reasons
Insufficient programmed shock strength
Battery depletion
Failure of generator component or lead
Device-lead connection problem
Lead dislodgment
Delayed detection resulting in a prolonged VT/VF that increases required shock strength

Failure to Deliver Therapy or Delayed Therapy

Delayed therapy or failure to deliver therapy can be caused by sensing problems, programmed detection parameters, or ICD system malfunction. In modern ICDs, clinically significant undersensing of VF is rare but may be caused by low-amplitude EGMs, rapidly varying EGM amplitudes (**see Fig. 41.20C**), drug effects, postshock tissue changes, and device-device or intradevice interactions.[20] Rarely, enhanced sensing features may classify VF as oversensing and withhold therapy. VF may be underdetected despite adequate sensing due to device inactivation or programming (sensitivity, rate, duration, SVT-VT discriminators). Lead, connector, or generator malfunction can also prevent shock delivery.

ICD Lead Failure: Presentation and Management

The serious consequences of ICD lead failure combined with reliability concerns for specific lead models and have focused efforts on early diagnosis.[17,29] Excluding leads with known high failure rates, the overall incidence of clinical failure is about 1.3 per 100 lead-years.[30]

Clinical Presentations

Pace-sense malfunctions account for most failures. Oversensing is the most common initial electrical abnormality with either conductor fracture or insulation breach.[17,29] Conductor fractures usually cause a characteristics pattern of oversensing[17] (**Fig. 41.24**). Unlike conductor fractures, insulation breaches themselves do not generate abnormal signals. Instead, oversensing occurs because external signals enter the conductor at the breach; EGM patterns vary, reflecting the source signal (**eFig. 41.16C, F**). Several enhanced sensing features incorporate specific features of lead-related oversensing to alert patients and physicians and, in some cases, withhold inappropriate shocks[20,29] (**see Fig. 41.20B**).

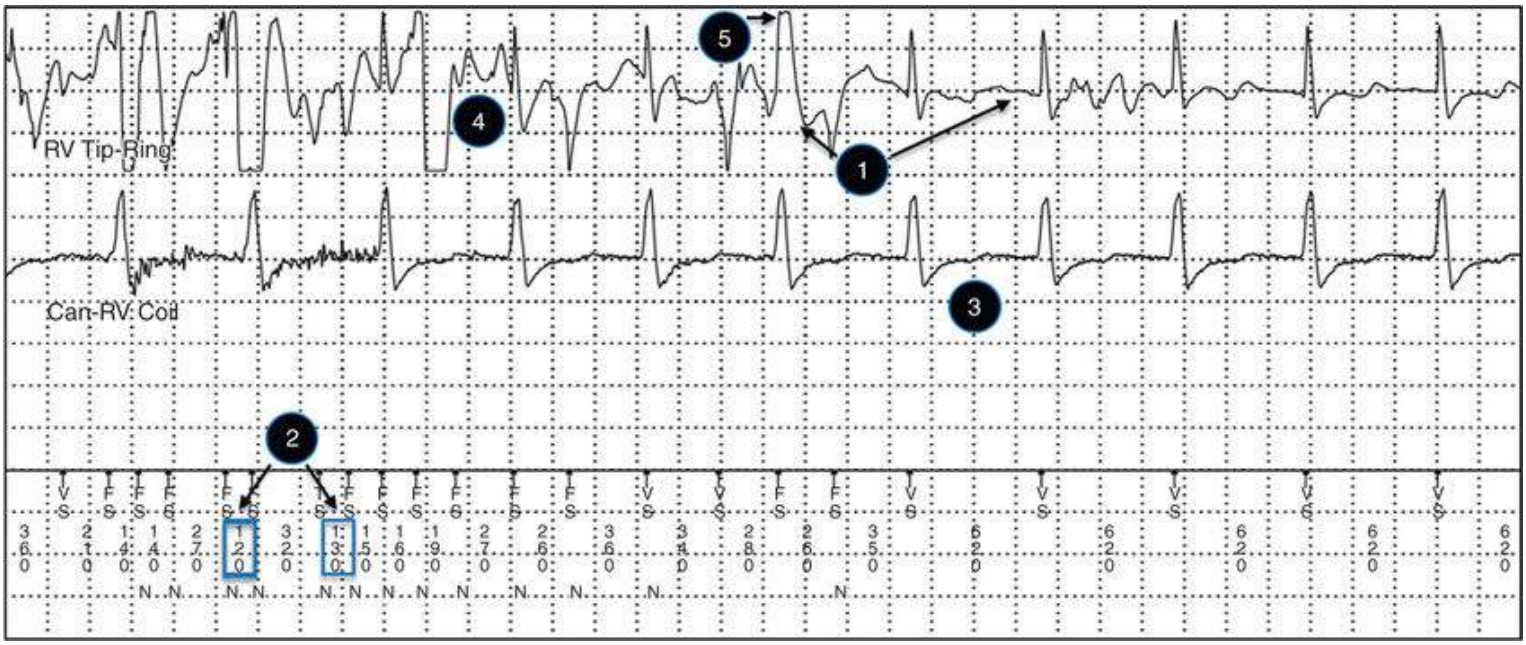

FIGURE 41.24 Characteristic features of EGM in conductor fracture or connection problem between DF1 lead and header: (1) intermittent nonphysiologic signals; (2) "nonphysiologic" intervals too short to correspond to successive ventricular depolarizations; (3) no abnormal signals on shock channel of dedicated sensing bipole; (4) variable amplitude, morphology, and frequency; (5) may saturate sensing amplifier. Enhanced sensing feature (Lead Noise Algorithm) prevents inappropriate detection of VF, classifying intervals as "N" (noise) on marker channel. High-frequency signal superimposed on shock channel probably is caused by pectoral myopotentials, which are a normal finding on EGMs, including the can (see eFig. 41.16E, F). (From Swerdlow CD, Friedman P. Implantable cardioverter-defibrillator: clinical aspects. In Zipes D, Jalife J, editors. Cardiac Electrophysiology: From Cell to Bedside. 7th ed. Philadelphia: Saunders Elsevier; 2018.)

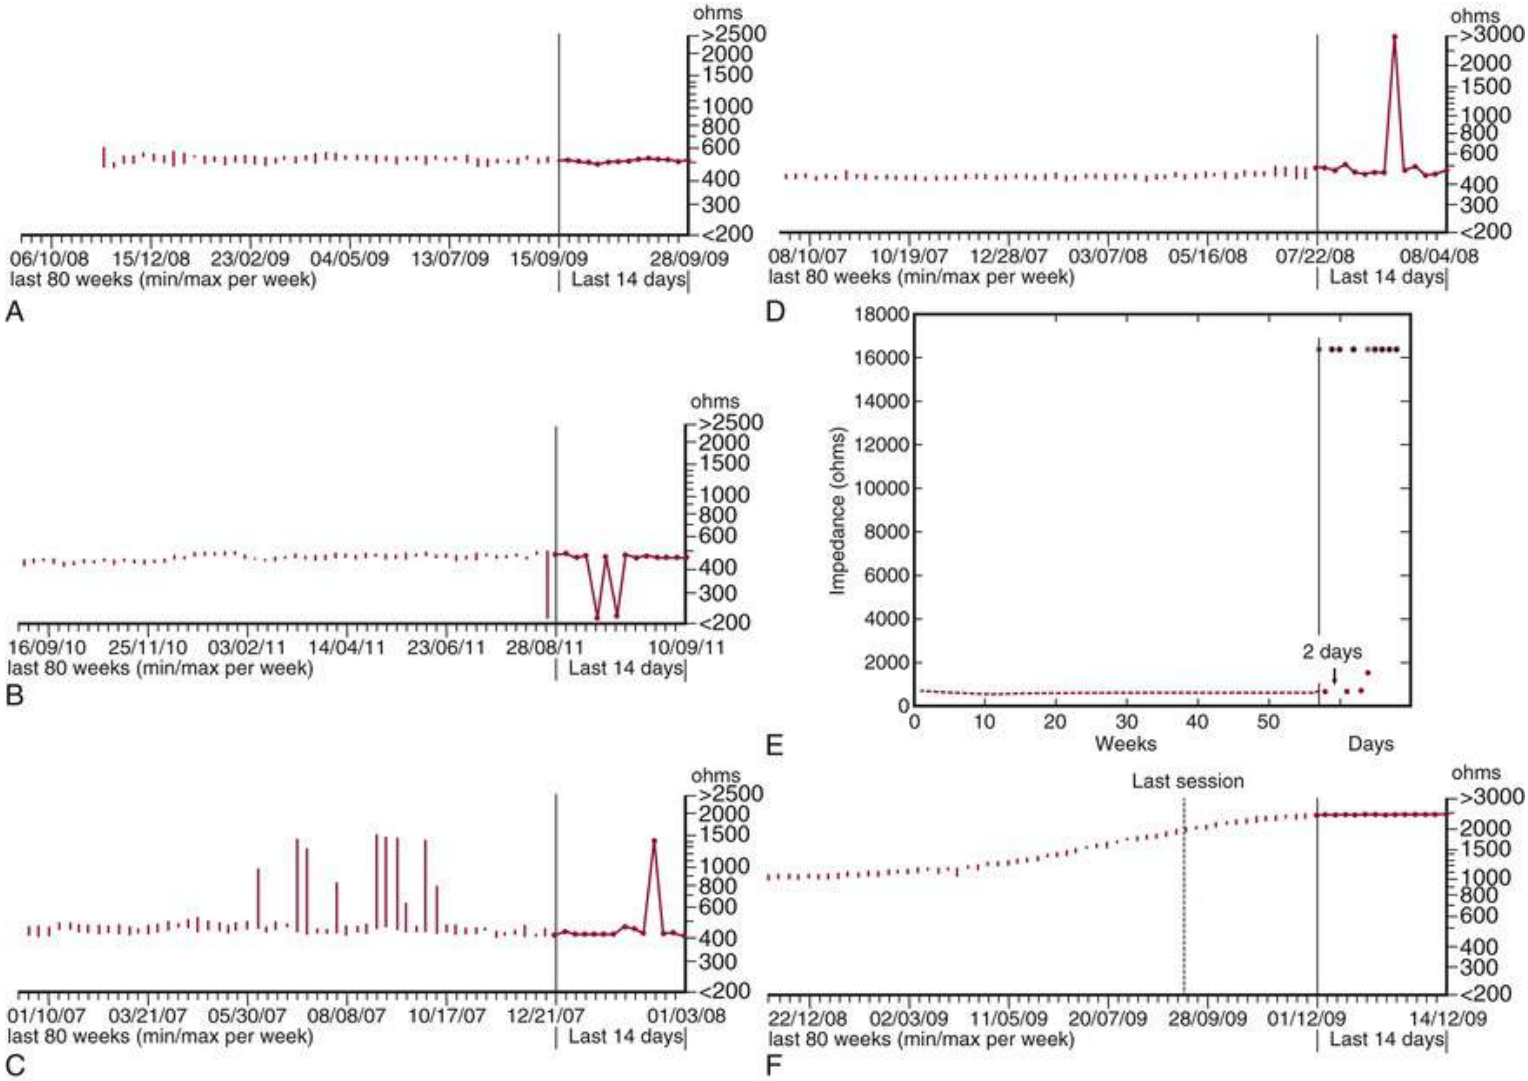
Pacemakers and ICDs periodically measure direct-current electrical resistance ("impedance") of the pacing circuit. Usually, pacing impedance is in the normal range when oversensing occurs. Pace-sense malfunctions can also present with pacing impedance changes, loss of capture, or abrupt decrease in R wave amplitude. Pacemaker lead failures present identically to failures of ICD pace-sense components, except that oversensing causes only inhibition of pacing, not inappropriate therapy for VF.

Shock-component malfunction presents with shock-impedance changes, abnormal signals on shock EGMs, or failed defibrillation shocks. Insulation breaches that cause high-voltage short circuits may also cause ICD generator failure.

Impedance and Impedance Trends in Diagnosis of Lead Failure

Conductor fractures may cause abrupt increases in impedance; conversely, insulation breaches may cause abrupt decreases in impedance. **eFig. 41.17** shows examples of pace-sense impedance trends in various conditions. Oversensing usually precedes impedance changes in pace-sense component failures, but impedance changes occur before or concurrently with oversensing in a minority of cases. When the cause of oversensing is in doubt, impedance abnormalities confirm the diagnosis of lead failure.

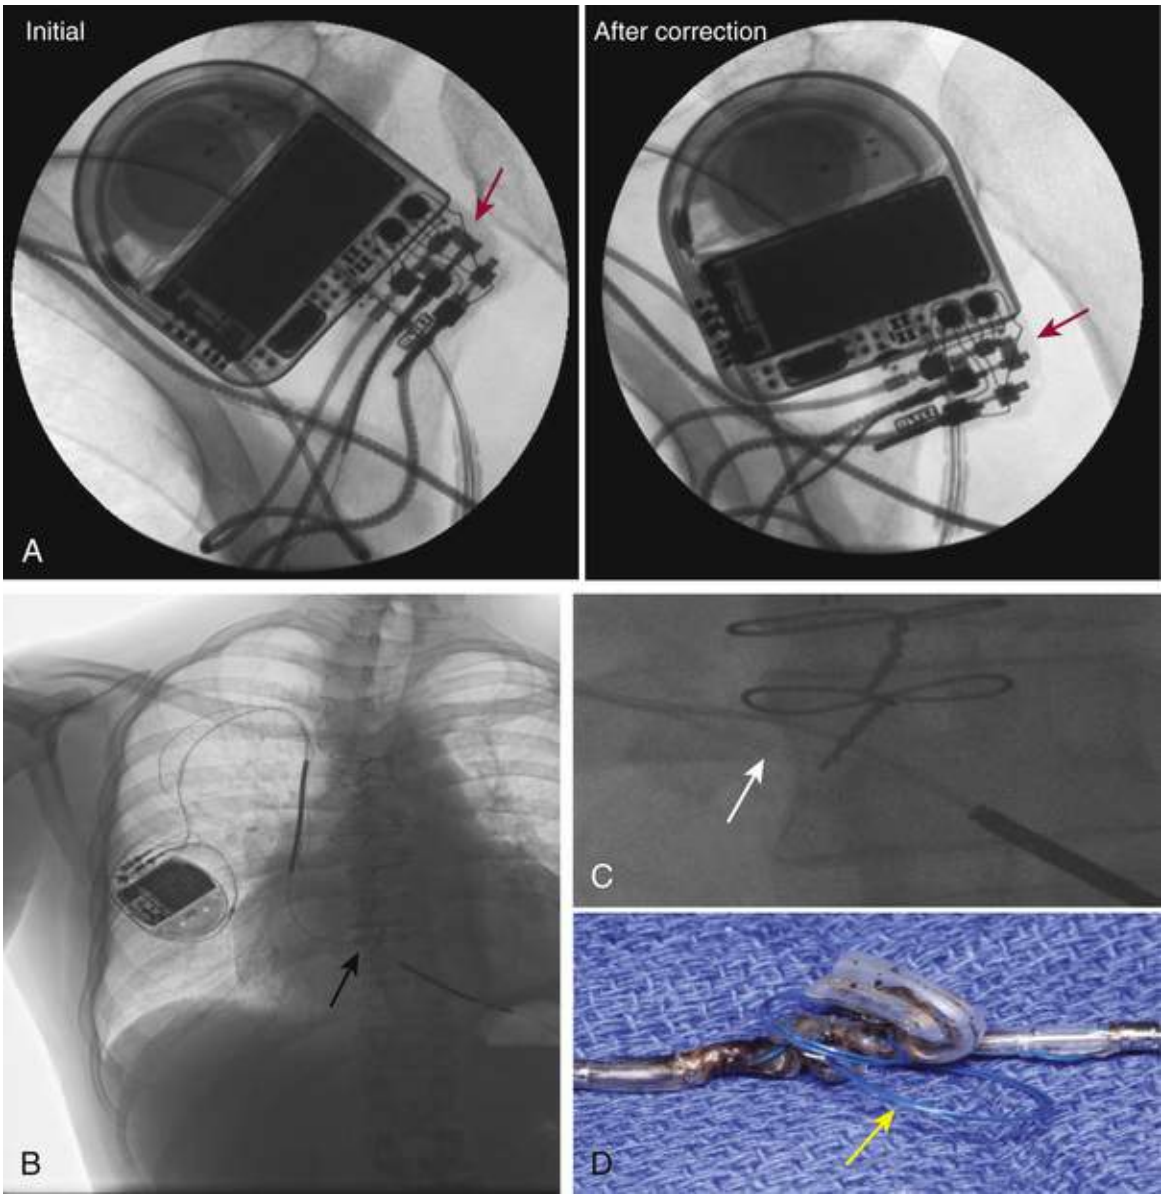


EFIGURE 41.17 Impedance trends for pace-sensing electrodes. To the *left* of the longest vertical line, data are displayed as *vertical bars* connecting weekly maximum and minimum impedance values. To the *right, black points* indicate daily values. An abrupt 50% to 75% relative increase in impedance is a highly specific indicator of an ICD system problem, either conductor fracture or connection problem between lead and header. Conversely, a gradual impedance increase without oversensing usually occurs at the electrode-myocardial interface, caused at least in some cases by calcium deposition in the form of hydroxyapatite; lead replacement is not indicated unless pacing or sensing is compromised. Occasionally, silicone insulation breaches present with low or decreasing pacing impedance. **A,** Normal impedance trend. Although this trend occurred in a normal lead, normal trends may occur with conductor fractures and insulation failures. **B,** Lead insulation failure showing a late, abrupt fall in impedance. **C,** Connection problem between the header and lead because of incomplete insertion of the pin. Highly variable impedances are seen beginning approximately 4 months after implantation, followed by approximately a 2-month return to baseline between early October and December 2007. **D,** Lead conductor fracture with a late, abrupt increase in impedance to highest reported value (>3000 Ω). **E,** Engineering-level display of stored data for another lead conductor fracture. Although the programmer displays impedance only up to a maximum value of 3000 Ω, impedance is measured up to 16,000 Ω. A late, abrupt increase in impedance to an open-circuit value is diagnostic of a conductor fracture. **F,** Gradual increase in impedance in a normally functioning lead, thought to be caused by changes at the electrode-myocardial interface.

Fractures of high-voltage conductors can present as abrupt increases in shock impedance. Low shock impedance occurs in some high-voltage insulation breaches. However, diagnosing high-voltage insulation breaches by painless measurements of shock impedance is challenging because high-voltage shocks above the insulating material's dielectric breakdown voltage can cause catastrophic short circuits even if low-voltage test pulses encounter intact insulation.

Imaging

The chest x-ray film is unrevealing in most cases of lead failure, but it should be inspected for lead conductor discontinuity, kinks or acute angles that identify stress points, and twisting suggesting “twiddler's syndrome.” It is important for excluding alternative causes of oversensing, such as lead dislodgment, abandoned leads or lead fragments that cause a lead-lead interaction, and incomplete insertion of DF-1 pins into the header (**eFig. 41.18A**). Cinefluoroscopy in multiple views is more sensitive than chest radiography for identifying “inside-out” insulation breaches that cause cable conductors to protrude outside the outer insulation (externalized cables; **eFig. 41.18B-D**).



EFIGURE 41.18 Radiography in evaluation of suspected lead failure. **A,** Intraoperative fluoroscopic images of a cardiac resynchronization ICD show incomplete insertion of the RV pace-sensing lead pin into the header. The ICD has been removed from the pocket to enhance image quality. Before revision, the lead connector pin was not advanced completely into the header (*red arrow*). The proximal connection between the ring electrode and the header was intermittent, which resulted in high impedance and oversensing causing pauses in the paced rhythm. After revision, the RV electrode is advanced completely into the header. **B to D,** Outer insulation breach of ICD lead resulting in "externalized" cables protruding out of the breach near the tricuspid valve. **B,** *Arrow* in chest radiograph indicates site of breach. These breaches typically are better seen on cine fluoroscopy. **C,** Magnified view. **D,** Photograph of extracted lead shows insulation breach with *blue* inner insulation (ethylene tetrafluoroethylene, ETFE, see Fig. 41.1) protruding from lead body. (**A,** From Swerdlow CD, Gillberg JM, Khairy P. Sensing and detection. In Ellenbogen KA, Kay GN, Lau CP, Wilkoff BL, editors. Clinical Cardiac Pacing, Defibrillation, and Resynchronization Therapy. 4th ed. Philadelphia: Saunders; 2011; **B-D,** From Swerdlow CD, Friedman PA, Asirvatham SJ, Hayes DL. Troubleshooting: interpreting diagnostic information. In Hayes DL, Friedman PA, editors. Cardiac Pacing and Defibrillation: A Clinical Approach. 3rd ed. West Sussex, UK: Wiley-Blackwell; 2014.)

Approach to the Patient

Fig. 41.25 summarizes the approach to patients with findings suggestive of lead failure. All lead-failure diagnostics have false positives, and the diagnosis of lead failure must be confirmed before surgical intervention to remove a failed lead.[29] Connection problems between the lead and header must be excluded (**eFig. 41.18**). System revision involves either abandoning or extracting the failed lead and inserting a replacement lead. Usually, lead abandonment is associated with lower procedural risk and

lead extraction with fewer long-term problems. The trade-offs depend on multiple factors related to the patient, operator/institution, specific lead model, and patient preference.[17,29,31]

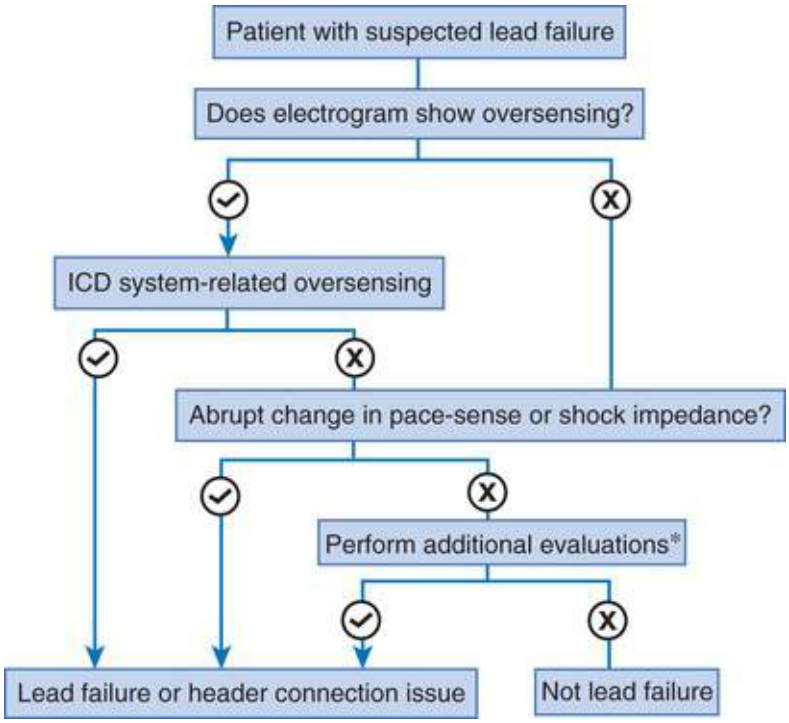


FIGURE 41.25 Deductive approach to suspected ICD lead failure. See text for details. *Additional evaluations include real-time, pace-sense electrograms with muscle exercise and pocket manipulation; shock EGMs; differential EGMs; and pacing and sensing thresholds. (From Swerdlow CD, Kalahasty G, Ellenbogen KA. Implantable cardiac defibrillator lead failure and management. J Am Coll Cardiol 2016;67(11):1358-68.)

Complications

Complications can be divided into early surgical complications and late complications related to the patient or pacemaker/ICD system (**eTable 41.8**).

ETABLE 41.8

Major Complications of Pacemakers and ICDs

Vascular Access
Pneumothorax
Hemopneumothorax
Vascular perforation
Placement of lead into left atrium or left ventricle via patent foramen ovale
Placement of lead into subclavian artery and retrograde across aortic valve
Lead Placement
Lead dislodgment
Lead microdislodgment
Cardiac perforation with hemopericardium (possible cardiac tamponade)
Extracardiac stimulation*: phrenic nerve, intercostal muscle, left hemidiaphragm
Tricuspid regurgitation
Subclavian or axillary vein thrombosis
Loose set screw
Device-Related Infection
Erosions
Pocket infection
Endocarditis
Bacteremia

*May indicate perforation of lead tip or screw.

Implant-Related Complications

Transvenous lead insertion may result in complications related to vascular access, lead placement, pocket integrity, and infection. Overall, major complications occur in about 4% to 5% of new implants[32] and 2% to 3% of generator changes.[33]

Vascular Access

Vascular access for transvenous leads can be complicated by pneumothorax and less often by hemothorax or injury to neurovascular structures. Rarely, failure to recognize inadvertent entry into the arterial system results in placement of a lead retrograde through the aorta into the left ventricle. There is also a risk of entry into the left atrium from the right atrium via a patent foramen ovale. An unexplained stroke should prompt echocardiographic examination to confirm that the atrial and ventricular leads are not in left-sided chambers. Upper extremity swelling on the side of the implant indicates thrombosis of the accessed vein. It usually resolves with elevation of the extremity and time, with or without anticoagulation.

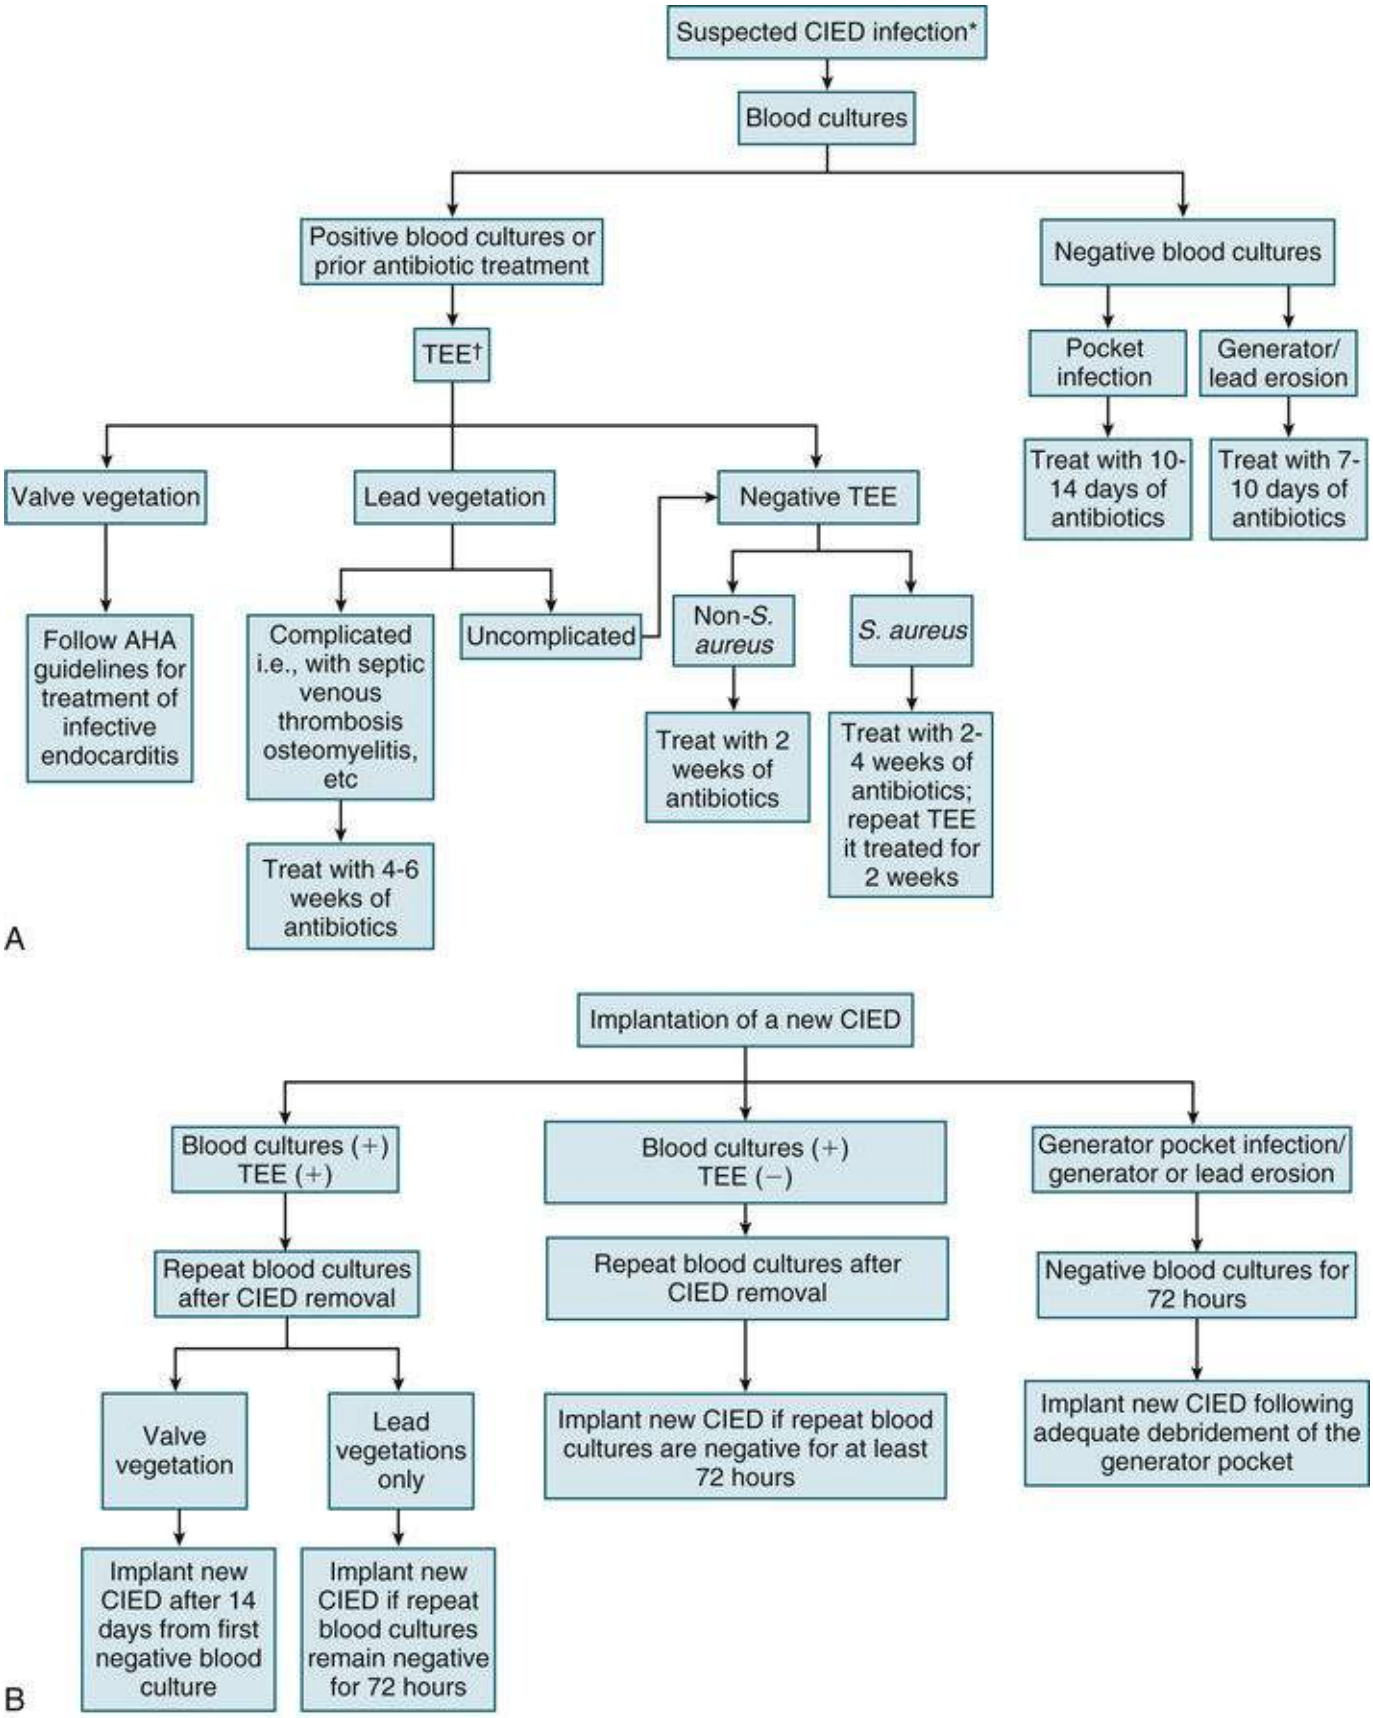
Lead Placement

The most common complication is dislodgment of the lead, and this usually requires prompt revision. Cardiac perforation may result in pericarditis, pericardial effusion, or cardiac tamponade but may also occur without clinical findings. A loose set screw or inadequate connection with the header may result in oversensing or failure to capture (**eFig. 41.18**).

Pacing may stimulate extracardiac nerves or muscles, including atrial stimulation of the right phrenic nerve or ventricular stimulation of the left hemidiaphragm. Intercostal muscle stimulation may indicate RV lead perforation. Lead placement can cause ventricular premature complexes due to mechanical effects, but these usually resolve within 24 hours. Rarely, RV leads may cause clinically significant tricuspid regurgitation.

CIED Infections

Infections may occur early after implant or may be delayed. Early infections usually are caused by skin organisms, such as staphylococci or streptococci. Antibiotic prophylaxis given immediately before device implant reduces the risk of perioperative infection.[34,35] Late infections may be caused by intraoperative contamination with indolent organisms or hematogenous spread. Pocket infections can present with pain, erythema, or purulent drainage; erosion may be caused by indolent infection (**eFig. 41.19**). Septic pulmonary emboli may be the first indication of systemic CIED infection. Treatment requires intravenous antibiotics and removal of both the generator and the leads. Recent scientific statements provide guidance based on factors that include clinical presentation, blood cultures, and presence or absence of lead or valve vegetations, as determined by echocardiography.[34,35]

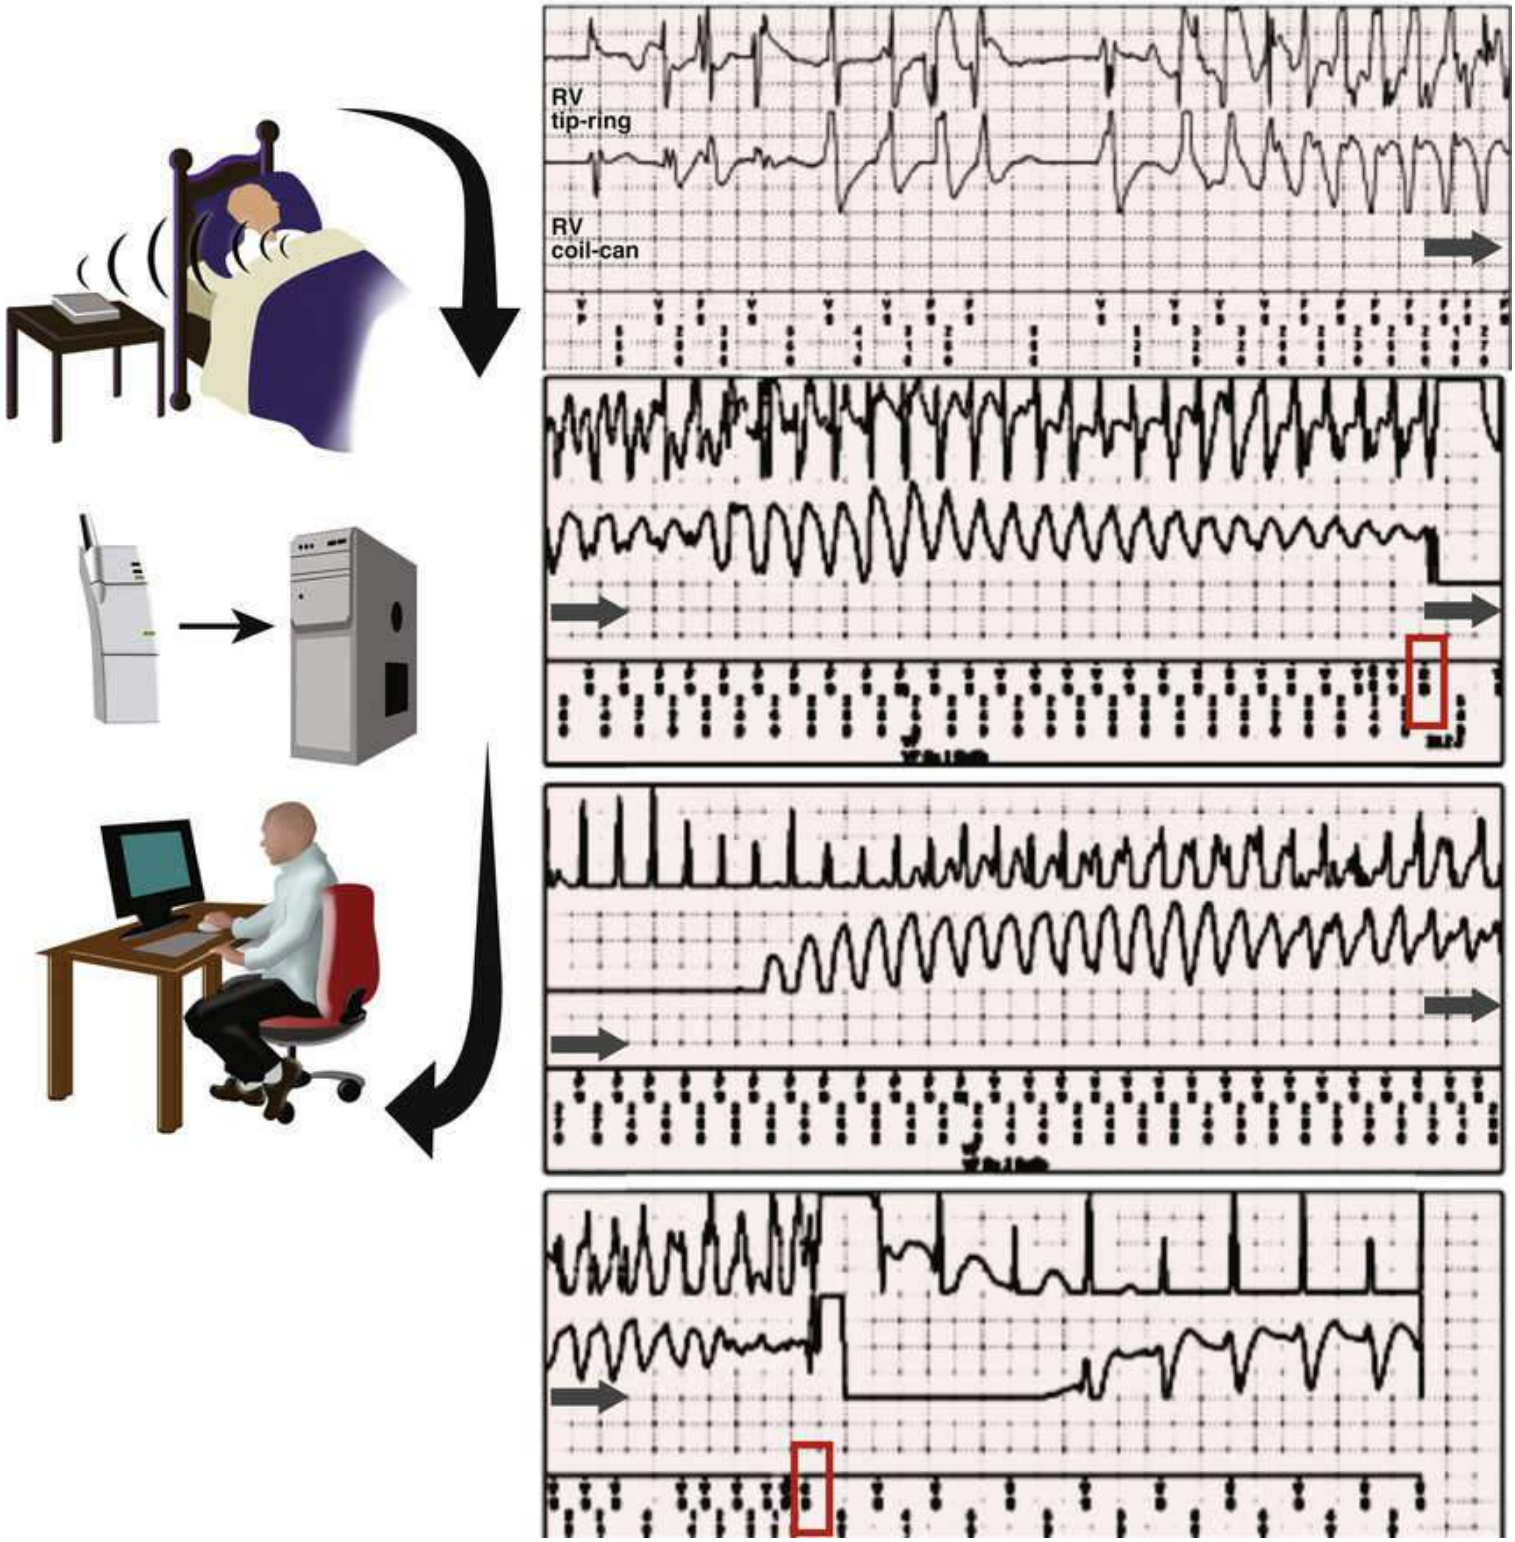


EFIGURE 41.19 Cardiac implantable electrical device (CIED) infection: approach to diagnosis, antibiotic therapy, and reimplantation. **A,** Diagnosis and management of adults with CIED infection. A history, physical examination, chest radiograph, ECG, and device interrogation are standard baseline procedures before CIED removal. *Duration of antibiotics should be counted from the day of device explantation. †Transesophageal electrocardiography. Treatment can be extended to 4 or more weeks if there are metastatic septic complications or sustained bloodstream infection despite CIED removal. **B,** Approach to implantation of a new device in patients after removal of an infected CIED. (From: Baddour LM, Epstein AE, Erickson CC, et al. Update on cardiovascular implantable electronic device infections and their management: a scientific statement from the American Heart Association. Circulation 2010;121(3):458-77.)

Follow-Up

Remote Monitoring

The convergence of Internet technology, improved telemetry, and enhanced CIED diagnostics permits remote monitoring of multiple device functions and improves patient management[36] (**eFig. 41.20**). Currently, most ICDs and many pacemakers use “wireless telemetry” to transmit stored data stored automatically to a home monitor, which then relays the data to a server via an Internet connection. By convention, *remote interrogation* refers to scheduled, routine device interrogation at a distance, corresponding to in-clinic interrogation; *remote monitoring* refers to automatic data transmission based on device-generated alerts.[36] Colloquially, “remote monitoring” includes both. Routine, scheduled transmissions include battery status, pacing and sensing thresholds, lead impedances, and detected arrhythmias. Patients can also initiate transmissions in response to symptoms. Health care providers log into a Web server to review alerts and transmitted data. ICDs and some pacemakers provide programmable alerts for system malfunction (e.g., suspected lead failure), potential programming errors (e.g., VF detection or therapy “off”), or high-risk arrhythmias. Alerts may be transmitted daily or even immediately. Alerts may also notify the patient through audible tones or generator vibration. A “lead integrity alert” reduces inappropriate shocks caused by lead failure.[29]



EFIGURE 41.20 Remote monitoring of pacemakers and ICDs. The drawings at the **left** illustrate the function of a remote monitoring network. Device diagnostics and EGMs are transmitted to a bedside monitor or wearable cellular unit that retransmits the data to a central server. The server prioritizes the data and sends the formatted report to the patient's health care provider. Continuous EGMs at the **right** show an example of a patient-initiated transmission that was reviewed from home within minutes of being sent by one of the authors (CDS). It shows a pause-dependent polymorphic VT that required two shocks for termination (*red boxes* on the marker channel). The patient's internist had recently increased the dose of diuretics, and the serum potassium concentration was 2.7 mEq/L. RV tip-ring, EGM recording between tip of lead and ring electrode on the lead; RV coil-can, EGM recording between coil in lead and can of ICD.

CIED Diagnostics for Atrial Fibrillation

Remote monitoring can be used to monitor comorbidities if relevant data are stored in the device or input into the local hub from another source. AF is an important comorbidity that can be monitored reliably by

CIEDs with an atrial lead. ICD patients with rapidly conducted AF have an increased risk of inappropriate shocks, and early diagnosis may permit treatment or reprogramming to prevent inappropriate therapy. Early treatment of new-onset, persistent AF may reduce exacerbations of HF. Alerts for AF facilitate early anticoagulation and adjustment of rate and rhythm control medications.[36] In CIED patients, asymptomatic AF episodes as short as 5 minutes are associated with an increased rate of stroke, although it is not clear if AF is causal. Present data are insufficient to determine if continuous device monitoring of patients with infrequent paroxysmal AF might permit safe withdrawal of anticoagulation or intermittent use of short-acting anticoagulants.

Common Clinical Issues in CIED Patients

Psychosocial Issues

ICD patients may experience anxiety about shocks, but they may also feel protected from the risk of sudden death. They may benefit from interventions such as counseling, education, and support groups.[37] It is important to provide patients with a plan for what to do when a shock occurs. **eTable 41.9** summarizes an approach consistent with the clinical approach in **Fig. 41.23**, which emphasizes that patient-initiated remote transmission is the most rapid and efficient approach to transfer information required for medical decision making to the clinician. ICD patients benefit from counseling after shocks occur.[37] This includes reviewing what triggered the shock and what intervention has been taken to mitigate the trigger, estimating the likelihood of future shocks after this intervention, explaining that shocks are one of multiple challenges of living with heart disease, and usually emphasizing the value of returning to normal activity.

ETABLE 41.9

Patient Plan for ICD Shocks

SHOCKS IN 24 HOURS	RESPONSE
First shock	Send remote transmission. Call immediately if cardiac symptoms,* otherwise within 24 hours.
Second shock	Send remote transmission. Call immediately.
Third shock	Send remote transmission. Receive medical care immediately.

*Chest pain, dyspnea, syncope.

A consensus statement addresses legal and ethical issues related to withdrawal of CIED therapy to reduce suffering at the end of a patient's life.[38] This is important because 20% of ICD patients receive painful shocks in their last weeks of life. A patient (or legally defined surrogate decision maker) has the right to request withdrawal of any medical therapy, including CIED therapy, even if such withdrawal allows the patient to die naturally from an underlying disease.

Lifestyle Issues

Driving

Pacemaker patients are not restricted from driving after the perioperative period. Guidelines for ICD patients recommend that patients refrain from driving for 6 months after each shock for VT/VF and for 6 months after ICD implant for secondary prevention.[39] Primary prevention patients are not restricted from driving personal cars (versus commercial vehicles).

Participation in Sports

Exercise improves health and quality of life but may induce VT/VF in patients with specific diseases.[40] Decisions regarding sports participation should be based on the patient's underlying disease, indication for ICD therapy (e.g., primary versus secondary prevention, risk of exercise-induced VT/VF), and risks of specific sports (e.g., ICD system damage in contact sports, risk of trauma with transient loss of consciousness).[40] Athletes with ICDs experience shocks for both VT/VF and SVT more frequently during sports than at rest, but the risk of injury or failure to terminate VT/VF is low.[41] Swimming presents the risk of drowning even if VT/VF is treated promptly.

Drug Interactions

Antiarrhythmic drugs are used in pacemaker patients to prevent AF and in ICD patients to prevent both AF and VT/VF. RCTs report reduction in VT/VF using either sotalol or the combination of amiodarone and beta blockers. However, antiarrhythmic and other drugs have important interactions with devices (**see eTable 41.1**). Beta blockers and other drugs that prolong AV conduction may increase RV pacing burden and thereby exacerbate HF. Antiarrhythmic drugs prescribed for VT/VF or AF (e.g., amiodarone) may slow the rate of VT and thus require decreasing the rate threshold to ensure that VT is detected.

Electromagnetic Interference

Ubiquitous electromagnetic waves can interfere with CIEDs, potentially causing temporary or permanent inactivation, inappropriate pacing or inhibition of pacing or shocks, and inappropriate detection of VT/VF.[42] EMI is less common with smaller, dedicated, bipolar sensing dipoles than with unipolar sensing (pacemakers) or integrated bipolar sensing (ICDs).

Nonmedical Sources

Clinically significant EMI is extremely rare for household appliances. Although the risk is extremely low, patients should hold activated digital cellular phones to the contralateral ear and should avoid carrying phones in the ipsilateral breast pocket. CIED patients may walk through airport metal detectors and electronic article surveillance devices at a normal pace. Prolonged exposure can inhibit pacing and detection of VT/VF, cause inappropriate detection of VT/VF, or (rarely) program VT/VF detection “off.”

Medical Sources

Medical sources of EMI are most frequently associated with electrosurgery (electrocautery) or magnetic resonance imaging (MRI).

Perioperative Management of CIED Patients.

A consensus statement requires preoperative determination of pacemaker dependency, device model, type of lead, and plans to use electrocautery to inform management[43] (**eTable 41.10**). The arterial pulse must be monitored intraoperatively. Intraoperative management strategies may include magnet application or perioperative reprogramming. When a magnet is placed over a pacemaker, it paces asynchronously. In contrast, a magnet placed over an ICD disables detection of VT/VF but does not alter pacing mode.

ETABLE 41.10

Perioperative Management of Pacemakers and ICDs

Preoperative Evaluation
Determine if electrosurgery will be used; if so, determine operative site in relation to pulse generator. Determine type and model of cardiac implantable electrical device (CIED) and leads (history, identification card, chest radiograph). Assess whether patient is pacemaker dependent. Assess device function if full check not performed within 6 months.
Preoperative Preparation
Apply magnet or reprogram if surgical site above umbilicus. Pacemaker and ICD reprogramming: disable rate-responsive pacing; consider increasing pacing output if high-risk surgery, metabolic shifts likely. ICD reprogramming: disable VT/VF therapies; reprogram to asynchronous or triggered mode. (In ICDs, magnet application does not result in asynchronous pacing.) Position dispersive grounding pad to minimize current near generator (e.g., apply to shoulder contralateral to device for head and neck surgery).
Intraoperative Management
Monitor the ECG and the peripheral pulse (arterial line, plethysmography, pulse oximetry). Use transcutaneous pacing and defibrillation pads (anterior-posterior position) for pacemaker-dependent patients if surgical site permits. Use bipolar cautery, ultrasonic (harmonic) scalpel, or short bursts of monopolar electrosurgery.
Interrogate Before Discharge from Telemetry *if*:
Device was reprogrammed preoperatively. Intraoperative power-on-reset likely (e.g., cardiothoracic surgery). Patient experienced clinically significant intraoperative arrhythmia. Pacing/sensing thresholds may have changed because of intraoperative hypotension or metabolic abnormalities. CIED cannot be evaluated within 1 month after procedure (including remote monitoring).

The risk of oversensing is greatest for monopolar electrocautery delivered between a pen and a remote dispersive ground electrode, or when the surgical site is in proximity to the device or sensing electrodes.[43] If the surgical incision and dispersive ground pad are both below the umbilicus, the risk of EMI is low. Rate-adaptive sensors should be disabled.

Magnetic Resonance Imaging.

MRI exposes CIED patients to risks resulting from mechanical forces generated by the static magnetic field, heat and current flow in the leads induced by the radiofrequency fields, and current induced by gradient magnetic fields.[44] MRI-conditional pacemaker and ICD systems employ pulse generators and leads designed to permit safe imaging under specific MRI conditions when programmed to fixed rate (VOO, DOO) or nonpacing (ODO) modes.[44] MRI of patients with standard CIEDs may be performed safely by implementing rigorous risk mitigation strategies.[42]

Other Medical Procedures and Devices.

When external cardioversion is required, defibrillation pads should be placed at least 8 inches (20 cm) from the pulse generator. In ICD patients, cardioversion of AF should be performed through the device whenever possible. Ionizing radiation therapy can damage CIED circuitry, and CIEDs should be shielded or moved to the contralateral side. Left-ventricular assist devices (LVADs) cause specific forms of EMI.[42]

Guidelines

Cardiac Pacemakers and Cardioverter-Defibrillators

Charles D. Swerdlow, Paul J. Wang, and Douglas P. Zipes

The American College of Cardiology/American Heart Association/Heart Rhythm Society (ACC/AHA/HRS) guidelines for the use of cardiac pacemakers, implantable cardioverter-defibrillators (ICDs), and cardiac resynchronization therapy (CRT) were most recently updated in 2008.[1] ACC, AHA, and the European Society of Cardiology (ESC), along with HRS, collaborated on guidelines for the

management of patients with ventricular arrhythmias and the prevention of sudden cardiac death (SCD) in 2006.[2] Similar guidelines for cardiac pacing and CRT were published by ESC in 2007.[3]

As with other ACC/AHA guidelines, these use the standard ACC/AHA classification system for indications:

Class I: Conditions for which there is evidence and/or general agreement that the test is useful and effective
Class II: Conditions for which there is conflicting evidence and/or a divergence of opinion about the usefulness or efficacy of performing the test
Class IIa: Weight of evidence/opinion in favor of usefulness or efficacy
Class IIb: Usefulness or efficacy less well established by evidence/opinion
Class III: Conditions for which there is evidence and/or general agreement that the test is not useful or effective and in some cases may be harmful

Three levels are used to rate the evidence on which recommendations have been based:

Level A recommendations are derived from data from multiple randomized clinical trials.
Level B recommendations are derived from a single randomized trial or nonrandomized studies.
Level C recommendations are based on the consensus opinion of experts.

Indications for Permanent Pacing

Acquired Atrioventricular Block

For patients with complete or second-degree atrioventricular (AV) block, the ACC/AHA guidelines consider permanent pacing to be appropriate when the abnormality causes symptoms and is not precipitated by a drug whose use can be discontinued (**Table 41G.1**) or a condition that is likely to be reversible, such as acute inferior myocardial infarction (MI) with a narrow QRS complex. Examples of symptoms include fatigue, syncope or presyncope, seizures, congestive heart failure, and confusional states. In asymptomatic patients, pacing is indicated for those at high risk for the development of complications, such as patients with periods of asystole of 3 seconds or longer or an escape rate of less than 40 beats/min or those who have specific high-risk conditions.

TABLE 41G.1

Indications for Pacing in Patients with Atrioventricular (AV) Block

Class I
1. Third-degree or advanced second-degree AV block at any anatomic level associated with any one of the following conditions: a. Symptoms (including heart failure) or ventricular arrhythmias attributable to AV block. *(Level of evidence: C.)* b. Arrhythmias and other medical conditions requiring drugs that result in symptomatic bradycardia. *(Level of evidence: C.)* c. Documented periods of asystole >3.0 second, any escape rate <40 beats/min, or any escape rhythm below the AV junction in awake, asymptomatic patients in sinus rhythm. *(Level of evidence: C.)* d. A documented period of asystole >5 second in awake, asymptomatic patients in atrial fibrillation. *(Level of evidence: C.)* e. After catheter ablation of the AV junction. *(Level of evidence: C.)* f. Postoperative AV block that is not expected to resolve after cardiac surgery. *(Level of evidence: C.)* g. Neuromuscular diseases, such as myotonic muscular dystrophy, Kearns-Sayre syndrome, Erb (limb-girdle) muscular dystrophy, and peroneal muscular atrophy, with or without symptoms of bradycardia. *(Level of evidence: B.)*
2. Symptomatic second-degree AV block regardless of type or site of block. *(Level of evidence: B.)*
3. Asymptomatic third-degree AV block at any anatomic site with an average awake ventricular rate >40 beats/min in patients with cardiomegaly or left ventricular dysfunction or if the site of block is below the AV node. *(Level of evidence: B.)*
4. Second- or third-degree AV block during exercise in the absence of myocardial ischemia. *(Level of evidence: C.)*
Class IIa
1. Persistent third-degree AV block at any anatomic site with an average ventricular rate >40 beats/min in asymptomatic adult patients in the absence of cardiomegaly. *(Level of evidence: C.)*
2. Asymptomatic second-degree AV block at the intra- or infra-His levels found at electrophysiologic study. *(Level of evidence: B.)*
3. First- or second-degree AV block with symptoms similar to those of pacemaker syndrome or hemodynamic compromise. *(Level of evidence: B.)*
4. Asymptomatic type II second-degree AV block with a narrow QRS complex. When type II second-degree AV block occurs with a wide QRS complex, including isolated right bundle branch block, pacing becomes a class I recommendation. *(Level of evidence: B.)*
Class IIb
1. Neuromuscular diseases such as myotonic muscular dystrophy, Erb (limb-girdle) dystrophy, and peroneal muscular atrophy with any degree of AV block (including first-degree AV block), with or without symptoms of bradycardia. *(Level of evidence: B.)*
2. AV block as a result of drug use or toxicity when the block is expected to recur even after cessation of use of the drug. *(Level of evidence: B.)*
Class III
1. Asymptomatic first-degree AV block. *(Level of evidence B.)*
2. Asymptomatic type I second-degree AV block at the supra-His (AV node) level or another site or not known to be intra- or infra-Hisian by electrophysiologic study. *(Level of evidence: C.)*
3. AV block expected to resolve and unlikely to recur (e.g., drug toxicity, Lyme disease, or transient increases in vagal tone or during hypoxia in sleep apnea in the absence of symptoms). *(Level of evidence: B.)*

The guidelines do not support pacing for patients with asymptomatic first-degree or type I second-degree AV block, and do not support the use of pacing for patients with hypoxia and sleep apnea syndrome in the absence of symptoms.

Chronic Bifascicular and Trifascicular Block

Syncope is common in patients with chronic bifascicular or trifascicular block, but the risk for SCD or progression to complete heart block varies in patient subsets. Guidelines for pacing in these settings (**Table 41G.2**) include alternating bundle branch block as a class I indication because it indicates abnormal and unstable conduction in all three fascicles. The guidelines also support pacing in patients with markedly abnormal infranodal conduction at electrophysiologic study (EPS), even if they are asymptomatic (class IIa). Pacing is not supported for patients without symptoms, even if first-degree AV block is also present.

TABLE 41G.2

Indications for Pacing in Patients with Chronic Bifascicular and Trifascicular Block

Class I
1. Advanced second-degree AV block or intermittent third-degree AV block. *(Level of evidence: B.)*
2. Type II second-degree AV block. *(Level of evidence: B.)*
3. Alternating bundle branch block. *(Level of evidence: C.)*
Class IIa
1. Syncope not demonstrated to be caused by AV block when other probable causes, specifically ventricular tachycardia, have been excluded. *(Level of evidence: B.)*
2. Incidental finding at electrophysiologic study of a markedly prolonged H-V interval (≥100 msec) in asymptomatic patients. *(Level of evidence: B.)*
3. Incidental finding at electrophysiologic study of pacing-induced infra-His block that is not physiologic. *(Level of evidence: B.)*
Class IIb
1. Neuromuscular diseases such as myotonic muscular dystrophy, Erb (limb-girdle) dystrophy, and peroneal muscular atrophy with bifascicular block or any degree of fascicular block, with or without symptoms of bradycardia. *(Level of evidence: C.)*
Class III
1. Fascicular block without AV block or symptoms. *(Level of evidence: B.)*
2. Fascicular block with first-degree AV block without symptoms. *(Level of evidence: B.)*

Acute Myocardial Infarction

Symptoms do not play a role in appropriateness for pacing in patients with acute MI because of the high risk for SCD in some post-MI patients with conduction system disturbances (**Table 41G.3**). The guidelines emphasize that the requirement for temporary pacing after acute MI does not automatically indicate a need for permanent pacing. However, permanent pacemakers are supported in patients with transient (presumed) infranodal AV block and associated bundle branch block, one of the rare times that transient AV block is judged to be an indication for permanent pacing. The usefulness of permanent pacemakers for patients with advanced AV block at the AV node level is less clear (class IIb).

TABLE 41G.3

Indications for Permanent Pacing After Acute Myocardial Infarction

Class I
1. Permanent ventricular pacing is indicated for
a. Persistent second-degree AV block in the His-Purkinje system with alternating bundle branch block or third-degree AV block within or below the His-Purkinje system after ST-segment elevation myocardial infarction. *(Level of evidence: B.)*
b. Transient second- or third-degree infranodal AV block and associated bundle branch block. If the site of block is uncertain, an electrophysiologic study may be necessary. *(Level of evidence: B.)*
c. Persistent and symptomatic second- or third-degree AV block. *(Level of evidence: C.)*
Class IIb
1. Permanent ventricular pacing may be considered for persistent second- or third-degree transient AV block at the AV node level, with or without symptoms. *(Level of evidence: B.)*
Class III
1. Transient AV block without intraventricular conduction defects. *(Level of evidence: B.)*
2. Transient AV block with isolated left anterior fascicular block. *(Level of evidence: B.)*
3. Acquired new bundle branch block or fascicular block without AV block. *(Level of evidence: B.)*
4. Asymptomatic first-degree AV block with bundle branch or fascicular block. *(Level of evidence: B.)*

Sinus Node Dysfunction

As for patients with acquired AV block, pacing is indicated for those with symptoms caused by bradycardia that is not the result of a drug whose use can be discontinued (**Table 41G.4**). Pacing is discouraged in asymptomatic patients, even when resting heart rates are lower than 40 beats/min, and in symptomatic patients when symptoms cannot be proved to be caused by bradycardia. A class IIa recommendation supports pacing in patients with syncope of unexplained origin when major abnormalities in sinus node function are demonstrated at electrophysiologic testing.

TABLE 41G.4

Indications for Pacing in Patients with Sinus Node Dysfunction

Class I
1. Symptomatic bradycardia or frequent symptomatic sinus pauses. *(Level of evidence: C.)* 2. Symptomatic chronotropic incompetence. *(Level of evidence: C.)* 3. Symptomatic bradycardia that results from required drug therapy. *(Level of evidence: C.)*
Class IIa
1. Sinus node dysfunction occurring with a heart rate <40 beats/min when a clear association between significant symptoms consistent with bradycardia and the actual presence of bradycardia has not been documented. *(Level of evidence: C.)* 2. Syncope of unexplained origin when clinically significant sinus node dysfunction is discovered or provoked during electrophysiologic testing. *(Level of evidence: C.)*
Class IIb
1. Minimally symptomatic patients with a chronic heart rate <40 beats/min while awake. *(Level of evidence: C.)*
Class III
1. Sinus node dysfunction in asymptomatic patients. *(Level of evidence: C.)* 2. Sinus node dysfunction in patients with symptoms that are clearly documented in the absence of bradycardia. *(Level of evidence: C.)* 3. Sinus node dysfunction with symptomatic bradycardia caused by nonessential drug therapy. *(Level of evidence: C.)*

Prevention and Termination of Tachyarrhythmias

In some patients with long-QT syndrome, continuous pacing can prevent recurrent tachyarrhythmias. In addition, paroxysmal reentrant tachyarrhythmias can be terminated in some patients through programmed stimulation and short bursts of rapid pacing. However, the guidelines do not provide support for the routine use of antitachycardia pacemakers without extensive testing before implantation (**Table 41G.5**), but continue to consider bradycardia pacing appropriate (class I indication) for patients with sustained pause-dependent ventricular tachycardia (VT, unrelated to a drug whose use can be discontinued), with or without a prolonged QT interval, if the efficacy of temporary pacing has been demonstrated (**Table 41G.6**). However, some patients have or are at risk for other types of VT. In these patients an ICD may be more appropriate.

TABLE 41G.5

Indications for Pacemakers to Terminate Tachycardia

Class IIa
1. Symptomatic recurrent supraventricular tachycardia that is reproducibly terminated by pacing in the unlikely event that catheter ablation and/or drugs fail to control the arrhythmia or produce intolerable side effects. *(Level of evidence: C.)*
Class III
1. The presence of accessory pathways with the capacity for rapid anterograde conduction. *(Level of evidence: C.)*

TABLE 41G.6

Indications for Pacemakers to Prevent Tachycardia

Class I
1. Pause-dependent sustained ventricular tachycardia with or without a prolonged QT interval. *(Level of evidence: C.)*
Class IIa
1. Pacing is reasonable for patients with congenital long-QT syndrome considered to be at high risk. *(Level of evidence: C.)*
Class IIb
1. Prevention of symptomatic, drug-refractory recurrent atrial fibrillation in patients with coexisting sinus node dysfunction. *(Level of evidence: B.)*
Class III
1. Frequent or complex ventricular ectopic activity without sustained ventricular tachycardia in patients without long-QT syndrome. *(Level of evidence: C.)* 2. Torsades de pointes ventricular tachycardia secondary to reversible causes. *(Level of evidence: A.)*

Carotid Sinus Syndrome and Neurocardiogenic Syncope

The only class I indication for permanent pacing is recurrent syncope caused by carotid sinus stimulation

in the absence of any drug that depresses the sinus node or AV conduction (**Table 41G.7**). Pacing is discouraged in patients without symptoms or in those who have syncope without bradycardia.

TABLE 41G.7

Indications for Pacing in Patients with Neurally Mediated Reflex Syncope

Class I
1. Recurrent syncope caused by carotid sinus hypersensitivity, defined as minimal carotid sinus pressure inducing ventricular asystole of >3 seconds in patients not receiving medications that depress the sinus node or AV conduction. *(Level of evidence: C.)*
Class IIa
1. Syncope in the absence of a definite provocative event with a pause of ≥3 seconds with carotid massage. *(Level of evidence: C.)*
Class IIb
1. Recurrent symptomatic neurocardiogenic syncope with a cardioinhibitory response during tilt-table testing. *(Level of evidence: B.)*
Class III
1. A cardioinhibitory response during carotid sinus stimulation without symptoms or with vague symptoms. *(Level of evidence: C.)* 2. Situational vasovagal syncope in which avoidance behavior is effective. *(Level of evidence: C.)*

Hypertrophic Cardiomyopathy

The guidelines minimize indications for pacing in patients with hypertrophic cardiomyopathy (HCM) unless they have associated sinus node dysfunction or AV block that would fulfill related indications for pacing (**Table 41G.8**). A class IIb indication permits pacing in medically refractory symptomatic patients with HCM and a significant resting or provoked left ventricular (LV) outflow tract gradient. Pacing should really be considered only if the patient is truly refractory to pharmacologic therapy.

TABLE 41G.8

Pacing in Patients with Hypertrophic Cardiomyopathy

Class IIb
1. Medically refractory symptomatic patients with significant resting or provoked LV outflow tract obstruction. *(Level of evidence: A.)*
Class III
1. Asymptomatic patients or those whose symptoms are medically controlled. *(Level of evidence: C.)* 2. Symptomatic patients without LV outflow tract obstruction. *(Level of evidence: C.)*

Cardiac Transplantation

Table 41G.9 details these indications.

TABLE 41G.9

Indications for Pacing After Cardiac Transplantation

Class I
1. Persistent symptomatic or inappropriate bradycardia that is not expected to resolve. *(Level of evidence: C.)*
Class IIb
1. Relative bradycardia is recurrent or prolonged and is limiting rehabilitation or hospital discharge. *(Level of evidence: C.)* 2. Syncope after transplantation without a documented bradyarrhythmia. *(Level of evidence: C.)*

Cardiac Resynchronization Therapy

For guidelines on CRT, **see Chapter 27**.

Selection of Pacemakers

The guidelines provide recommendations and decision trees to help physicians match patients' needs to

the technology implanted and to anticipate future needs of the patient. In keeping with the guidelines, elderly patients should receive devices according to the same indications as for younger patients (**Table 41G.10**).

TABLE 41G.10

Indications for Permanent Pacemaker in Children, Adolescents, and Patients with Congenital Heart Disease

Class I
1. Advanced second- or third-degree AV block associated with symptomatic bradycardia, ventricular dysfunction, or low cardiac output. *(Level of evidence: C.)*
2. Sinus node dysfunction with correlation of symptoms during age-inappropriate bradycardia. The definition of bradycardia varies with the patient's age and expected heart rate. *(Level of evidence: B.)*
3. Postoperative advanced second- or third-degree AV block that is not expected to resolve or that persists at least 7 days after cardiac surgery. *(Level of evidence: B.)*
4. Congenital third-degree AV block with a wide QRS escape rhythm, complex ventricular ectopy, or ventricular dysfunction. *(Level of evidence: B.)*
5. Congenital third-degree AV block in an infant with a ventricular rate <55 beats/min or with congenital heart disease and a ventricular rate <70 beats/min. *(Level of evidence: C.)*
Class IIa
1. Congenital heart disease and sinus bradycardia for prevention of recurrent episodes of intra-atrial reentrant tachycardia; sinus node dysfunction may be intrinsic or secondary to antiarrhythmic treatment. *(Level of evidence: C.)*
2. Congenital third-degree AV block beyond the first year of life with an average heart rate <50 beats/min and abrupt pauses in ventricular rate that are 2 or 3 times the basic cycle length or associated with symptoms as a result of chronotropic incompetence. *(Level of evidence: B.)*
3. Sinus bradycardia with complex congenital heart disease and a resting heart rate <40 beats/min or pauses in ventricular rate >3 seconds. *(Level of evidence: C.)*
4. Congenital heart disease and impaired hemodynamics as a result of sinus bradycardia or loss of AV synchrony. *(Level of evidence: C.)*
5. Unexplained syncope in a patient with previous congenital heart surgery complicated by transient complete heart block and a residual fascicular block after a careful evaluation to exclude other causes of syncope. *(Level of evidence: B.)*
Class IIb
1. Transient postoperative third-degree AV block that reverts to sinus rhythm with a residual bifascicular block. *(Level of evidence: C.)*
2. Congenital third-degree AV block in asymptomatic children or adolescents with an acceptable rate, a narrow QRS complex, and normal ventricular function. *(Level of evidence: B.)*
3. Asymptomatic sinus bradycardia after biventricular repair of congenital heart disease with a resting heart rate <40 beats/min or pauses in ventricular rate >3 seconds. *(Level of evidence: C.)*
Class III
1. Transient postoperative AV block with return of normal AV conduction in an otherwise asymptomatic patient. *(Level of evidence: B.)*
2. Asymptomatic bifascicular block with or without first-degree AV block after surgery for congenital heart disease in the absence of previous transient complete AV block. *(Level of evidence: C.)*
3. Asymptomatic type I second-degree AV block. *(Level of evidence: C.)*
4. Asymptomatic sinus bradycardia with the longest relative risk interval <3 seconds and a minimum heart rate >40 beats/min. *(Level of evidence: C.)*

Implantable Cardioverter-Defibrillator Therapy

The 2008 guidelines group all indications together; that is, they no longer separate primary and secondary indications (**Table 41G.11**). The strongest evidence for use of ICDs for “secondary prevention” is in patients with LV dysfunction who have been resuscitated from ventricular fibrillation (VF), hemodynamically unstable VT, or VT with syncope and who remain at risk for future cardiac arrests. There is also strong evidence supporting the use of ICDs for “primary prevention” in patients at least 40 days after MI who have depressed LV function with ejection fraction (EF) of less than 30% to 40% and in patients with nonischemic dilated cardiomyopathy who have LVEF of less than 30% to 35%.

TABLE 41G.11

Indications for Implantable Cardioverter-Defibrillator Therapy

Class I
1. Survivors of cardiac arrest secondary to ventricular fibrillation (VF) or hemodynamically unstable sustained ventricular tachycardia (VT) after evaluation to define the cause of the event and to exclude any completely reversible causes. *(Level of evidence: A.)*
2. Structural heart disease and spontaneous sustained VT, whether hemodynamically stable or unstable. *(Level of evidence: B.)*
3. Syncope of undetermined origin with clinically relevant, hemodynamically significant sustained VT or VF induced at electrophysiologic study. *(Level of evidence: B.)*
4. Left ventricular ejection fraction (LVEF) <35% because of previous myocardial infarction (MI) in patients at least 40 days after MI and in New York Heart Association (NYHA) Functional Class II or III. *(Level of evidence: A.)*
5. Nonischemic dilated cardiomyopathy in patients who have an LVEF ≤35% and are in NYHA Functional Class II or III. *(Level of evidence: B.)*
6. LV dysfunction because of previous MI in patients who are at least 40 days after MI, have an LVEF <30%, and are in NYHA Functional Class I. *(Level of evidence: A.)*
7. Nonsustained VT because of previous MI, LVEF <40%, and inducible VF or sustained VT at electrophysiologic study. *(Level of evidence: B.)*
Class IIa
1. Unexplained syncope, significant LV dysfunction, and nonischemic dilated cardiomyopathy. *(Level of evidence: C.)*
2. Sustained VT and normal or near-normal ventricular function. *(Level of evidence: C.)*
3. Patients with hypertrophic cardiomyopathy and (a) a family history of sudden death presumably caused by hypertrophic cardiomyopathy in one or more first-degree relatives, (b) LV wall thickness ≥30 mm, or (c) one or more unexplained syncopal episodes in the last 6 months. *(Level of evidence: C.)*
4. Selected patients with hypertrophic cardiomyopathy and either nonsustained VT (particularly those <30 years of age) or an abnormal blood pressure response with exercise* in the presence of other established risk markers† or potential risk modifiers.‡ *(Level of evidence: C.)*
5. Arrhythmogenic right ventricular dysplasia/cardiomyopathy in patients who have 1 or more risk factors for sudden cardiac death. *(Level of evidence: C.)*
6. Long-QT syndrome in patients who are experiencing syncope and/or VT while receiving beta blockers. *(Level of evidence: B.)*
7. Nonhospitalized patients awaiting transplantation. *(Level of evidence: C.)*
8. Brugada syndrome in patients who have had syncope or documented VT that has not resulted in cardiac arrest. *(Level of evidence: C.)*
9. Catecholaminergic polymorphic VT in patients who have syncope and/or documented sustained VT while receiving beta blockers. *(Level of evidence: C.)*
10. Cardiac sarcoidosis, giant cell myocarditis, or Chagas disease. *(Level of evidence: C.)*
Class IIb
1. Nonischemic heart disease in patients with an LVEF ≤35% and in NYHA Functional Class I. *(Level of evidence: C.)*
2. Long-QT syndrome and risk factors for sudden cardiac death. *(Level of evidence: B.)*
3. Syncope and advanced structural heart disease in patients in whom thorough invasive and noninvasive investigations have failed to define a cause. *(Level of evidence: C.)*
4. Familial cardiomyopathy associated with sudden death. *(Level of evidence: C.)*
5. LV noncompaction. *(Level of evidence: C.)*
6. Patients with hypertrophic cardiomyopathy and either an abnormal blood pressure response to exercise* or isolated bursts of nonsustained VT in the absence of any other risk factors† or risk modifiers‡ for sudden cardiac death. *(Level of evidence: C.)*
Class III
1. Patients who do not have a reasonable expectation of survival with acceptable functional status for at least 1 year, even if they meet the ICD implantation criteria specified in the class I, IIa, and IIb recommendations. *(Level of evidence: C.)*
2. Incessant VT or VF. *(Level of evidence: C.)*
3. Significant psychiatric illnesses that may be aggravated by device implantation or may preclude systematic follow-up. *(Level of evidence: C.)*
4. Drug-refractory congestive heart failure in patients who are not candidates for cardiac transplantation or CRT-D. *(Level of evidence: C.)*
5. Syncope of undetermined cause in a patient without inducible ventricular tachyarrhythmias and without structural heart disease. *(Level of evidence: C.)*
6. When VF or VT is amenable to surgical or catheter ablation (e.g., atrial arrhythmias associated with Wolff-Parkinson-White syndrome, right ventricular or LV outflow tract VT, idiopathic VT, or fascicular VT in the absence of structural heart disease). *(Level of evidence: C.)*
7. Ventricular tachyarrhythmias caused by a completely reversible disorder in the absence of structural heart disease (e.g., electrolyte imbalance, drugs, trauma). *(Level of evidence: B.)*

*Defined either as failure to increase by 20 mm Hg or greater or as a drop of 20 mm Hg or greater.

†*Established risk markers:* Sudden death presumably caused by hypertrophic cardiomyopathy in one or more first-degree relatives, LV wall thickness of 30 mm or greater, one or more unexplained syncopal episodes in the last 6 months, nonsustained VT, abnormal blood pressure response to exercise.

‡*Potential risk modifiers:* Resting LV outflow tract gradient of 30 mm Hg or greater, late gadolinium enhancement on cardiac magnetic resonance imaging, LV apical aneurysm.

CRT-D, Cardiac resynchronization therapy defibrillator.

However, it is important to recognize the conceptual difference between class I indications for pacing ICDs and those for ICDs for primary prevention. Many class I indications for pacing relieve serious symptoms that occur frequently in day-to-day life. In contrast, class I ICD indications for primary prevention address the risk for infrequent but catastrophic events, and the decision to implant an ICD should include consideration of the presence of severe comorbid conditions, which could limit benefit from the ICD. In contrast, pacing is almost never withheld from patients with persistent symptomatic bradycardia because of comorbidities.

Expert Consensus Statement on Use of ICD Therapy

Accompanying the previous guidelines, an expert consensus statement on the use of ICD therapy was published and approved by HRS/ACC/AHA to expand the guidelines to include “Patients Who Are Not

Included or Not Well Represented in Clinical Trials." The following is extracted from that statement.[4]

Patient Population #1: Patients with an abnormal troponin level (or other biomarker) for myocardial infarction who do not fulfill criteria for MI, and who previously satisfied primary prevention or secondary prevention criteria for ICD implantation.

In patients with abnormal cardiac biomarkers not thought to be caused by an MI and who otherwise would be candidates for implantation on the basis of primary prevention or secondary prevention criteria, implantation of an ICD is recommended. *This statement clarifies the guidelines for primary prevention ICD implantation in the absence of criteria for MI.*

Patient Population #2: Patients within 40 days of acute MI who have known left ventricular dysfunction and who have previously satisfied criteria for implantation of a primary prevention ICD.

Implantation of an ICD with in the first 40 days following acute MI in patients with preexisting systolic ventricular dysfunction (who would have qualified for a primary prevention ICD) is not recommended. *Although the patient meets criteria for ICD otherwise, multiple randomized controlled trials (RCTs) have found no benefit in the 40 days after MI.*

Patient Population #3: Patients within 40 days of an acute MI who also have an indication for permanent pacemaker implantation.

In patients who, within 40 days of an MI, require nonelective permanent pacing, who also would meet primary prevention criteria for implantation of an ICD, and in whom recovery of LV function is uncertain or not expected, implantation of an ICD with appropriately selected pacing capabilities is recommended. *If a pacemaker were implanted, it is likely that an ICD would need to be implanted at a later date, exposing the patient to the risk of a second operation.*

Patient Population #4: Patients within 40 days of an MI who subsequently present sustained or hemodynamically significant ventricular tachyarrhythmias.

In patients who, within 40 days of an MI, develop sustained (or hemodynamically significant) ventricular tachyarrhythmias more than 48 hours after an MI and in the absence of ongoing ischemia, implantation of an ICD is recommended. *The waiting period of 40 days after MI applies only to primary prevention indications for an ICD, not to the secondary prevention indication of sustained or hemodynamically significant ventricular arrhythmias.*

In patients who, within 40 days of an MI, develop sustained (or hemodynamically significant) VT more than 48 hours after an MI that can be treated by ablation, implantation of an ICD can be useful.

In patients who, within 40 days of an MI, develop sustained (or hemodynamically significant) ventricular tachyarrhythmias where there is clear evidence of an ischemic etiology with coronary anatomy amenable to revascularization (and appropriately treated), implantation of an ICD is not recommended. *Ischemic VT/VF should be treated with revascularization, not an ICD.*

Patient Population #5: Patients who, within 40 days of an MI (but >48 hours), present with syncope likely due to ventricular tachyarrhythmia, and in whom there is no evidence of ongoing ischemia.

In patients who, within 40 days of an MI, present with syncope thought to be caused by ventricular tachyarrhythmia (by clinical history, documented NSVT, or EPS), implantation of an ICD can be useful. *This is another example that the waiting period of 40 days after MI applies only to primary prevention indications for an ICD, not to secondary prevention indications.*

Patient Population #6: Patients within 40 days of an MI who have a previously implanted ICD that requires elective replacement for battery depletion.

In patients within 40 days of an MI and who have an ICD that requires elective replacement due to battery depletion, after careful assessment of comorbidities and the current clinical situation, replacement of the ICD generator is recommended. *Elective replacement MI is indicated even when, within 40 days of MI, the battery status jeopardizes device performance. This circumstance should occur rarely if patients are followed by remote monitoring.*

Patient Population #7: Patients with significant left ventricular dysfunction within 40 days following an acute MI who are also listed for heart transplantation or who undergo implantation of a left ventricular assist device.

ICD implantation in patients within 40 days of an MI who have been listed for heart transplant or implanted with an LVAD is not recommended. *Listing for transplant or LVAD implantation within 40 days of MI is not an ICD indication.*

Patient Population #8A: Patients within 90 days of revascularization who have known left ventricular dysfunction and who have previously satisfied criteria for implantation of a primary prevention ICD.

In patients who are within 90 days of revascularization and who previously qualified for the implantation of an ICD for primary prevention of SCD, and who have undergone revascularization that is unlikely to result in an improvement in LVEF greater than 0.35, and who are not within 40 days after an acute MI, implantation of an ICD can be useful. *An RCT showed no benefit of ICD implantation with epicardial leads after surgical revascularization. ICD implantation has not been studied within 90 days of percutaneous revascularization.*[5]

Patient Population #8B: Patients within 90 days of revascularization who have previously satisfied criteria for implantation of a secondary prevention ICD (resuscitated from cardiac arrest due to VT/VF).

In patients within 90 days of revascularization who have previously qualified for the implantation of an ICD for secondary prevention of SCD (resuscitated from cardiac arrest due to ventricular tachyarrhythmia

not caused by acute ischemia or other reversible cause) and have abnormal LV function, implantation of an ICD is recommended. *Similar to the post-MI waiting period, the postrevascularization waiting period applies only to primary prevention indications for an ICD.*

In patients within 90 days of revascularization who have previously qualified for the implantation of an ICD for secondary prevention of SCD (resuscitated from cardiac arrest due to ventricular tachyarrhythmia) that is unlikely related to myocardial ischemia/injury and have normal LV function, implantation of an ICD is recommended.

In patients within 90 days of revascularization who have previously qualified for the implantation of an ICD for secondary prevention of SCD (resuscitated from cardiac arrest due to ventricular tachyarrhythmia) that was not related to acute myocardial ischemia/injury and who were subsequently found to have coronary artery disease that is revascularized with normal LV function, implantation of an ICD can be useful. *Again, the postrevascularization waiting period applies only to primary prevention indications for an ICD.*

In patients within 90 days of revascularization who were resuscitated from cardiac arrest due to ventricular tachyarrhythmia that was related to acute myocardial infarction/injury, with normal LV function, and who undergo complete coronary revascularization, an ICD is not recommended. *Acute ischemic VF in the setting of acute MI is never an indication for an ICD.*

Patient Population #9: Patients within 90 days of revascularization who also have an indication for permanent pacemaker (PPM) implantation.

In patients within 90 days of revascularization who require nonelective permanent pacing, who would also meet primary prevention criteria for implantation of an ICD, and in whom recovery of LV function is uncertain or not expected, implantation of an ICD with appropriately selected pacing capabilities is recommended. *Similar to the post-MI recommendation, if a pacemaker were implanted, it is likely that an ICD would need to be implanted at a later date, exposing the patient to the risk of a second operation.*

Patient Population #10: Patients within 90 days of revascularization who subsequently present sustained or hemodynamically significant ventricular tachyarrhythmia.

In patients within 90 days of revascularization with structural heart disease and sustained (or hemodynamically significant) ventricular tachyarrhythmia that was not clearly related to acute myocardial infarction/ischemia, implantation of an ICD is recommended.

In patients who, within 90 days of revascularization, develop sustained (or hemodynamically significant) VT that can be treated by ablation therapy, implantation of an ICD can be useful. *This is consistent with the principle that postrevascularization criteria apply only to primary prevention indications.*

Patient Population #11: Patients within 90 days of revascularization who present with syncope likely caused by ventricular tachyarrhythmia.

In patients within 90 days of revascularization who present with syncope thought to be caused by ventricular tachyarrhythmia (by clinical history or documented NSVT, or EPS),implantation of an ICD can

be useful. *This consensus also applies the principle that postrevascularization criteria apply only to primary prevention indications.*

Patient Population #12: Patients within 90 days of revascularization who have a previously implanted ICD that requires elective replacement because of battery depletion.

In patients within 90 days of revascularization with an ICD that requires replacement because of battery depletion, after careful assessment of comorbidities and the current clinical situation, replacement of the ICD generator is recommended.

Patient Population #13: Patients within 90 days of revascularization who are also listed for heart transplantation or who undergo implantation of a ventricular assist device.

In patients within 90 days of revascularization who have been listed for heart transplant or implanted with a ventricular assist device, and who are not within 40 days of an acute MI, implantation of an ICD can be useful. *Unlike other parallels between post-MI and postrevascularization restrictions on primary prevention ICDs, this restriction does not apply solely because of revascularization.*

Patient Population #14: Patients less than 9 months from the initial diagnosis of nonischemic cardiomyopathy (NICM) who have significant left ventricular dysfunction and heart failure symptoms.

Implantation of an ICD for primary prevention is not recommended within the first 3 months after initial diagnosis of NICM. If recovery of LV function is unlikely, implantation of an ICD for primary prevention can be useful between 3 and 9 months after initial diagnosis of NICM. *This consensus supports a 3-month waiting period after diagnosis for primary prevention implants if recovery is unlikely (e.g., extensive scar and no improvement with medical therapy at 3 months).*

Patient Population #15: Patients less than 9 months from the initial diagnosis of NICM who meet criteria for primary prevention ICD who also have an indication for PPM implantation.

In patients less than 9 months from the initial diagnosis of NICM who require nonelective permanent pacing, who would meet primary prevention criteria for implantation of an ICD, and in whom recovery of LV function is uncertain or not expected, implantation of an ICD with the appropriately selected pacing abilities is recommended. *ICD implant for primary prevention is recommended even within the first 9 months of diagnosis of NICM when there is a permanent pacing indication.*

Patient Population #16: Patients less than 9 months from the initial diagnosis of NICM who also have sustained or hemodynamically significant ventricular tachyarrhythmia.

In patients less than 9 months from the initial diagnosis of NICM with sustained (or hemodynamically significant) ventricular tachyarrhythmia, implantation of an ICD is recommended. *Again, waiting periods do not apply to implantation of secondary prevention ICDs.*

Patient Population #17: Patient less than 9 months from the initial diagnosis of NICM who present with syncope likely caused by ventricular tachyarrhythmia.

In patients less than 9 months from the initial diagnosis of NICM with syncope thought to be caused by a ventricular tachyarrhythmia (by clinical history or documented NSVT), implantation of an ICD can be useful. *This is another example of a secondary prevention indication.*

Patient Population #18: Patients less than 9 months from the initial diagnosis of NICM who are also listed for heart transplantation or who undergo implantation of a ventricular assist device.

In patients <9 months from the initial diagnosis of NICM who have been listed for heart transplant or implanted with an LVAD, implantation of an ICD can be useful.

Cardiac Arrest and Sudden Cardiac Death

Robert J. Myerburg, Jeffrey J. Goldberger

Perspective

Sudden cardiac arrest (SCA), and its common consequence sudden cardiac death (SCD), is a major public health problem because of its frequency and demographics. With current estimates for out-of-hospital SCDs still in the range of 390,000 per year in the United States alone,[1,2] plus an additional 200,000 in-hospital cardiac arrests,[3] its impact is defined by the “rule of the 50s”[2]: SCD accounts for 50% of all cardiovascular deaths[4]; approximately 50% of all SCDs are unexpected first expressions of a cardiac disorder[5]; and SCD often strikes during the victim's productive years, accounting for up to 50% of years of potential life lost from heart disease.[6] Despite recognition of an association between forewarning symptoms of chest pain or syncope and SCD dating to Hippocrates around 400 BC, the description of a “shrunken and withered” artery to the heart in a victim of SCD in the late 1490s by Da Vinci, and an epidemiologic survey in Rome by Lancisi at the request of Pope Clement XI in 1706, advances in prediction, prevention, and management of unexpected SCA and SCD did not begin to emerge until approximately 50 years ago. It is anticipated that the major insights into causes, pathophysiology, and preventive and management strategies developed during the past few decades will continue to evolve.

Definitions

Sudden cardiac death is natural death from cardiac causes heralded by abrupt loss of consciousness within 1 hour of the onset of an acute change in cardiovascular status (**Table 42.1**). Preexisting heart disease may or may not have been known to be present, but the time and mode of death are unexpected. This definition incorporates the key elements of natural, rapid, and most importantly, unexpected death by a cardiac cause or mechanism. It consolidates previous definitions that have conflicted, mainly because

the most useful operational definition of SCD in the past differed for clinicians, cardiovascular epidemiologists, pathologists, and scientists attempting to define pathophysiologic mechanisms. As the epidemiology, clinical expression, causes, and mechanisms began to be understood, these differences merged.

TABLE 42.1

Terms Related to Sudden Cardiac Death

TERM	DEFINITION	QUALIFIERS	MECHANISMS
Sudden cardiac death	Sudden, irreversible cessation of all biologic functions as a consequence of cardiac arrest	None	—
Cardiac arrest	Abrupt cessation of cardiac mechanical function, leading to death in the absence of reversal by a prompt intervention	Rare spontaneous reversions; the likelihood of successful intervention is related to the mechanism of arrest, clinical setting, and prompt return of spontaneous circulation	VF, pulseless VT, PEA, asystole, extreme bradycardia, mechanical factors
Cardiovascular collapse	Sudden loss of effective blood flow because of cardiac and/or peripheral vascular factors that may reverse spontaneously (e.g., neurocardiogenic syncope, vasovagal syncope) or require interventions (e.g., cardiac arrest)	Nonspecific term; includes SCA and its consequences and transient non–life-threatening conditions that usually revert spontaneously	Same as cardiac arrest, plus vasodepressor-induced syncope or other causes of transient loss of blood flow

PEA, Pulseless electrical activity; *SCA,* sudden cardiac arrest; *VF,* ventricular fibrillation, *VT,* ventricular tachycardia.

To satisfy clinical, scientific, legal, and social considerations, four temporal elements must be considered: (1) prodromes, (2) onset, (3) cardiac arrest, and (4) biologic death (**Fig. 42.1**). Because the proximate cause of SCA is an abrupt disturbance in cardiovascular function resulting in loss of consciousness due to cessation of cerebral blood flow, any definition must recognize the brief interval between onset of the mechanism *directly* responsible for cardiac arrest and the consequent loss of blood flow. The 1-hour definition primarily refers to the duration of the “terminal event,” which defines the interval between the onset of symptoms signaling the pathophysiologic disturbance leading to cardiac arrest and the onset of the cardiac arrest itself. Based on human centrifuge studies carried out during the early years of the U.S. space program, the time between abrupt cessation of cerebral blood flow and loss of consciousness can be 10 seconds or less.

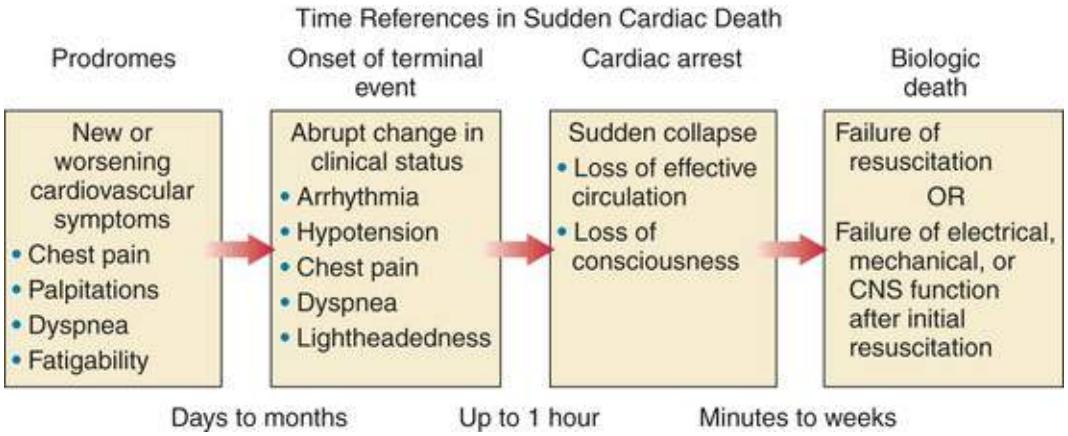

FIGURE 42.1 Sudden cardiac death (SCD) viewed from four temporal perspectives: (1) prodromes, (2) onset of the terminal event, (3) cardiac arrest, and (4) progression to biologic death. Individual variability of the components influences clinical expression. Some victims experience no prodromes, with onset leading almost instantaneously to cardiac arrest; others may have an onset that lasts up to 1 hour before clinical arrest. Other patients may live days to weeks after the cardiac arrest before biologic death, often because of irreversible brain damage and dependence on life support. These factors influence interpretation of the 1-hour definition. The two most relevant clinical factors are onset of the terminal event and the clinical cardiac arrest itself; legal and social considerations focus on the time of biologic death. *CNS,* Central nervous system.

Prodromes, occurring weeks or months before an event, are generally predictors of an impending cardiac event, but not specific for SCA itself. The same premonitory signs and symptoms may be more specific for imminent cardiac arrest when they begin abruptly. Sudden *onset* of chest pain, dyspnea, or palpitations and other symptoms of arrhythmias often precede the onset of cardiac arrest and define the 1-hour onset of the terminal event that brackets the *cardiac arrest*. The fourth element, *biologic death,* was an immediate consequence of cardiac arrest in the past and usually occurred within minutes. However, the generally accepted clinical-pathophysiologic definition of up to 1 hour between onset of the terminal event and biologic death requires qualifications for specific circumstances. For example, since the development of community-based interventions and life support systems, patients may now remain biologically alive for a long period after the onset of a pathophysiologic process that has caused irreversible damage and will ultimately lead to death. In this circumstance, the causative pathophysiologic and clinical event is the cardiac arrest itself rather than the factors responsible for the delayed biologic death. Thus, death remains defined biologically, legally, and literally as an absolute and irreversible event timed to cessation of all biologic functions, but most studies link the definition of SCD to the cardiac arrest rather than to a biologic death that occurs during hospitalization after cardiac arrest or within 30 days. Finally, forensic pathologists studying unwitnessed deaths continue to use the definition of sudden death for a person known to be alive and functioning normally 24 hours before, and this remains appropriate within obvious limits. Among the precautions is the recognition that not all sudden deaths are cardiac in origin.[7]

Epidemiology

Epidemiologic Overview

Epidemiologic studies of SCD are difficult to interpret for both theoretical and practical reasons. There are persisting inconsistencies about the definition and challenges in accessing data and adjudicating individual cases in datasets, in determining pathophysiologic mechanisms, and in making distinctions between population risk and individual risk.[8] In addition, SCA leading to SCD has short-term dynamics

superimposed on a long-term static or dynamic substrate, which introduces unusual epidemiologic complexities, including long-term risk prediction based on the evolution of atherogenesis, myocardial hypertrophy, and ventricular muscle dysfunction over time and modulation by transient (short-term) variables such as ischemia, hemodynamic shifts, atherosclerotic plaque disruption and thrombosis, and autonomic variations. The differences between chronic disease evolution and transient events call for different forms of epidemiologic modeling (**Table 42.2A**). Furthermore, the emerging field of genetic epidemiology adds another dimension for consideration, and there is a need to focus on *interventional epidemiology*, a term coined to define the population dynamics of therapeutic outcomes.

TABLE 42.2

Pathophysiologic Epidemiology and Power Cascade for Indicators of Risk for Sudden Cardiac Death

STRATEGY	EXAMPLES	MEASURES	POWER
A. Power Cascade for Risk Prediction			
Conventional risk factors	Framingham risk index	Prediction of evolution of disease	High for the population Low for the individual
Anatomic disease screening	Coronary calcium score and CT angiography	Identification of abnormal coronary arteries	High for anatomic identification Low for individual event prediction
Clinical risk profiling	Ejection fraction, stress testing, imaging techniques	Extent of disease	High for small, high-risk subgroups Low for large, low-risk subgroups
Transient risk predictors	Inflammatory markers; thrombotic cascade	Prediction of unstable plaques; acute changes in vascular status	Uncertain feasibility
Personalized risk predictors	Familial/genetic profiles	Individual SCD expression	Uncertain clinical precision; in evolution
B. Pathophysiologic Epidemiology			
Substrate-based risk	Coronary heart disease State of epicardial and intramyocardial vessels Myocardial infarction Myopathy, infiltration, inflammation, valvulopathy Hypertrophy; myocardial fibrosis		
Expression-based risk	Left ventricular dysfunction and heart failure Metabolic abnormalities Autonomic fluctuations		
Mechanism-based causes	VF/pulseless VT PEA Asystole		

In reference to risk for SCD from coronary heart disease, clinical categories ranging from general population risk to personalized risk profiling are paralleled by the partition of risk predictors into the pathophysiologic categories of substrate-based risk and expression-based risk[2,9] (**Table 42.2B**). *Substrate-based risk* refers to prediction of the evolution or identification of vascular or myocardial substrates that establish risk for SCD (i.e., atherogenesis, scar patterns, remodeling) and to quantification of these risks. It should not be perceived as limited to anatomic features because risk substrates may exist at a molecular level. In contrast, *expression-based risk* refers to the identification of mechanisms and pathways that contribute to the clinical manifestation of the risk established by the substrate. This category includes plaque transition and acute coronary syndromes (plaque disruption and thrombogenesis) and their potential for specific expression as an arrhythmic event in susceptible individuals. The arrhythmogenic category of risk can also be viewed to include modifiers of molecular-based risk that drive individual expression.

Incidence and the Population Burden of Sudden Cardiac Death

The worldwide incidence of out-of-hospital cardiac arrest (OHCA) leading to SCD is difficult to

estimate because numbers vary as a function of the prevalence of coronary heart disease in different countries[10] (**see Chapter 1**). The annual number of out-of-hospital SCDs in the United States is derived from multiple sources, such as retrospective death certificate data, American Heart Association (AHA) statistical updates based on data from the National Center for Health Statistics,[1] and national extrapolations from a large emergency rescue experience in one community[11] and a community-wide multisource data set from another.[12] Recently, data from large surveillance studies, such as the Resuscitation Outcomes Consortium (ROC), are contributing additional insight into the subtleties of data collection and interpretation.[13]

Statistical analyses from the same death certificate data sources have ranged from fewer than 250,000 SCDs annually when the etiologic definition is limited to coronary heart disease (*International Classification of Diseases,* ninth edition [ICD-9], classifications 410 to 414) to more than 460,000 SCDs per year when all causes are included.[9,10,14] Extrapolations from the two community-based sources set nationwide figures at fewer than 200,000 SCDs annually.[11,12] Because these broad ranges and the reported regional differences in incidence and outcomes of cardiac arrest[15] suggest that an accurate number can be found only by performing carefully designed prospective epidemiologic surveillance studies, the most widely cited estimates remain in the range of 390,000 SCDs annually, as suggested in the 2016 AHA statistical update.[1] These figures suggest an overall incidence of between one and two deaths per 1000 persons in the general population. The annual number of emergency medical services (EMS)–assessed OHCAs in the United States is 356,000, among whom 347,500 are adults over age 18 years.[1]

The temporal definition of sudden death strongly influences epidemiologic data. Retrospective death certificate studies have demonstrated that a temporal definition of sudden death of less than 2 hours after the onset of symptoms results in 12% to 15% of all natural deaths being defined as “sudden” and almost 90% of all natural sudden deaths having cardiac causes. In contrast, application of a 24-hour definition of sudden death increases the fraction of all natural deaths falling into the sudden category to more than 30% but reduces the proportion of all sudden natural deaths resulting from cardiac causes to 75%.

Prospective studies have demonstrated that approximately 50% of all deaths caused by coronary heart disease are sudden and unexpected and occur shortly (instantaneous to 1 hour) after the onset of symptoms. Because coronary heart disease is the dominant cause of both sudden and nonsudden cardiac deaths in the United States, the fraction of total cardiac deaths that are sudden is similar to the fraction of deaths from coronary heart disease that are sudden, although there does appear to be geographic variation in the fraction of coronary deaths that are sudden.[14,15] It is also of interest that the age-adjusted decline in mortality from coronary heart disease in the United States during the past half-century has not changed the fraction of coronary deaths that are sudden and unexpected,[16,17] even though there may be a decline in out-of-hospital deaths relative to emergency department deaths. Furthermore, the decreasing age-adjusted mortality does not imply a decrease in absolute numbers of cardiac or sudden deaths, because of the growth and aging of the U.S. population and the increasing prevalence of chronic heart disease,[14] including heart failure. It appears that the cumulative SCD burden in absolute numbers is not tracking the age-adjusted decrease in cardiac deaths that has been evolving during the past 40 to 50 years.[18] The figures previously cited suggest that SCD numbers have not decreased, although the landscape of SCD over time is further complicated by the suggested shift of mechanisms of out-of-hospital SCA from ventricular tachyarrhythmias to pulseless electrical activity or asystole, in part because of implantable

cardioverter-defibrillator (ICD) efficacy.[19]

Population Pools, Risk Gradients, and Time Dependence of Risk

Four factors are of primary importance for identification of populations at risk and consideration of strategies for prevention of SCD: (1) the absolute numbers and event rates (incidence) among population subgroups (**Fig. 42.2A**), (2) the clinical subgroups in which SCDs occur (**Fig. 42.2B**), (3) competing risks, and (4) the time dependence of risk.

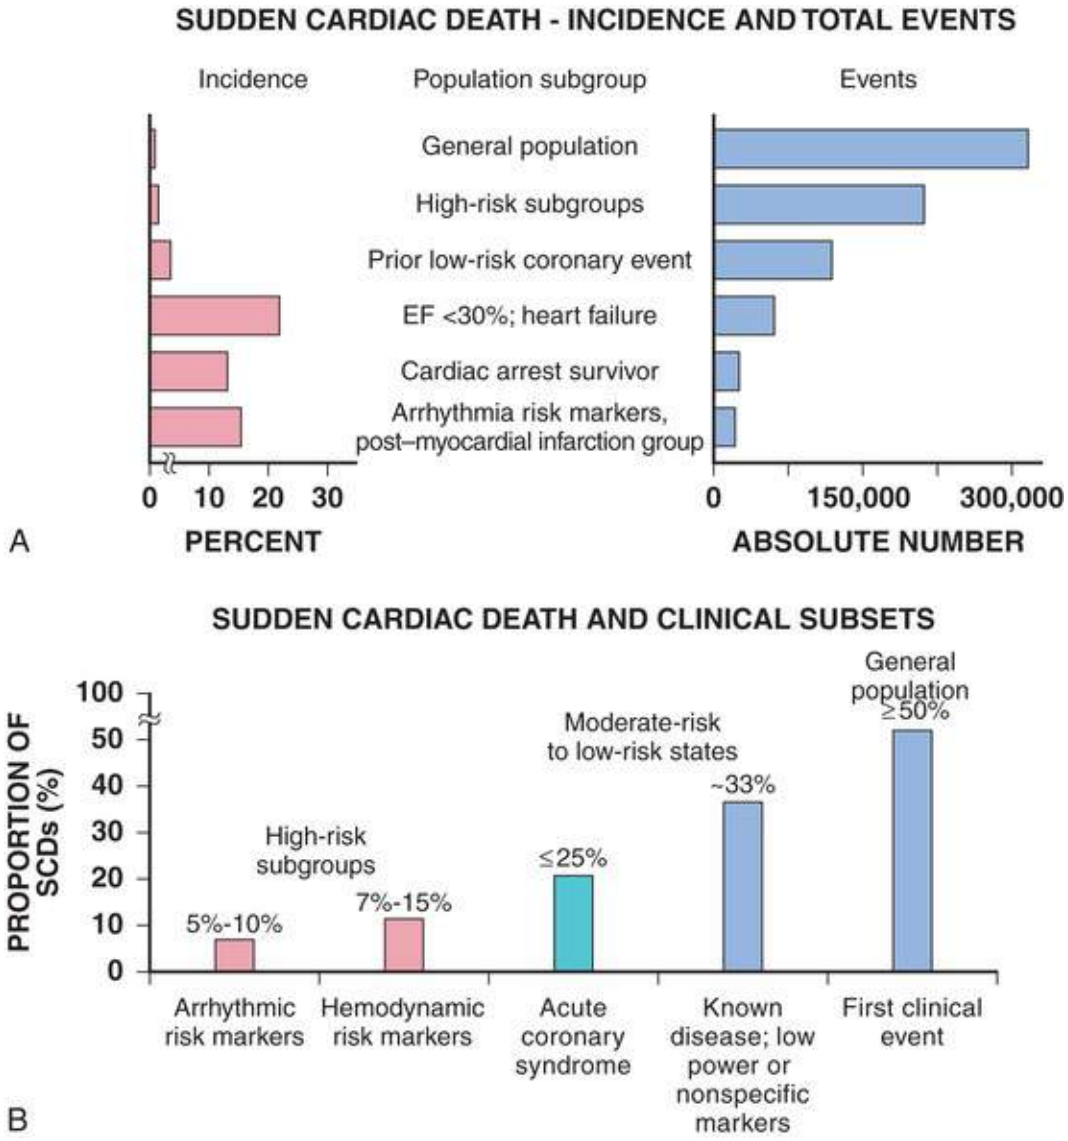

FIGURE 42.2 Impact of population subgroups and time from events on the clinical epidemiology of sudden cardiac death (SCD). **A,** Estimates of incidence (percent per year) and the total number of events per year for the general adult population in the United States and for increasingly high-risk subgroups. The overall adult population has an estimated incidence of sudden death of 0.1% to 0.2% per year, which accounts for a total of more than 300,000 events per year. With the identification of increasingly powerful risk factors, the incidence increases progressively, but this is accompanied by a progressive decrease in the total number of events represented by each group. The inverse relationship between incidence and the total number of events results from the progressively smaller denominator pool in the highest subgroup categories. In contrast to earlier iterations of this incidence profile, the magnitude of risk in the heart failure category exceeds that in the high-risk post–myocardial infarction and post–primary cardiac arrest groups. Successful interventions in larger population subgroups require identification of specific markers to increase the ability to identify specific patients who are at particularly high risk for a future event. (*Note:* The horizontal axis for the incidence figures is not linear and should be interpreted accordingly.) **B,** Distribution of the clinical status of victims at the time of SCD. Approximately 50% of all cardiac arrests caused by coronary heart disease occur as the first clinically manifested event, and up to an additional 30% occur in the clinical setting of known disease in the absence of strong risk predictors. Less than 25% of victims have high-risk markers based on arrhythmic or hemodynamic parameters. *EF,* Ejection fraction. (**A,** Modified from Myerburg RJ, Kessler KM, Castellanos A. Sudden cardiac death: structure, function, and time-dependence of risk. Circulation 1992;85[Suppl I]:I2; **B,** modified from Myerburg RJ. Sudden cardiac death: exploring the limits of our knowledge. J Cardiovasc Electrophysiol 2001;12:369.)

Population and Subgroup Risk Versus Individual Risk Assessment

When the estimated 390,000 SCDs that occur annually in the United States are viewed as a global figure for an unselected adult population 35 years and older, the overall incidence is calculated to be in the range of 0.1% to 0.2% per year (1 to 2 per 1000 population; **Fig. 42.2A**). This general population

includes the large proportion of SCDs that occur as a first clinical manifestation of previously unrecognized heart disease, as well as SCDs that can be predicted with somewhat greater accuracy in higher-risk subgroups (**Fig. 42.2B**). Because it is impractical to plan an intervention designed for the general population that would be applied to the 999 per 1000 who do not have an event to reach and possibly influence the 1 per 1000 who will experience an event, better risk profiling is needed to identify smaller high-risk subsets in whom interventions are practical. **Fig. 42.2A** highlights this problem by expressing the incidence (percent per year) of SCD among various subgroups and comparing the incidence figures with the total number of events that occur annually in each subgroup. Thus, despite the large absolute number at risk in the general population and the impact of preventive interventions on populations risk for coronary artery disease (CAD), the precise ability to identify these individuals for targeted therapy for SCD prevention is an unmet challenge.[2] The cost and risk-to-benefit uncertainties limit the nature of such broad-based interventions and demand a higher resolution of risk identification.[20] Two fundamental approaches to this challenge can be followed: (1) a general population strategy targeting prevention of acquired risk factors, such as obesity (primordial prevention), and primary prevention by control of manifest risk factors,[21] and (2) a more focused individual risk strategy based on identification and intervention in small subsets of the general population with a high density of risk (**Fig. 42.3**).

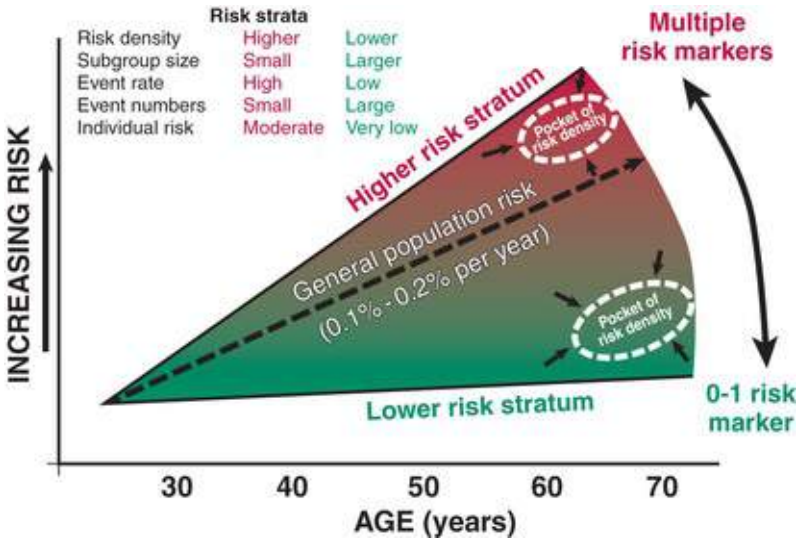

FIGURE 42.3 Stratification of risk as a continuum across the population. The mean risk in the general population is demonstrated as a continuum across four decades. The mean risk of approximately 0.1% to 0.2% per year is bracketed by extremes of higher and lower risk strata, with the larger absolute numbers accumulated in the lower risk strata. Potentially identifiable subgroups with varying risk densities populate each range of risk. The ability to identify high–risk density subgroups within the general population would contribute to better individual risk prediction. (Modified from Myerburg RJ, Junttila MJ. Sudden cardiac death caused by coronary heart disease. Circulation 2012;125:1043.)

On moving from the total adult population to a subgroup at higher risk because of the presence of selected coronary risk factors, there may be a 10-fold or greater increase in the annual incidence of events, with the magnitude dependent on the number and types of risk factors operating in specific subgroups. The size of the denominator pool, however, remains very large, and implementation of interventions remains problematic, even at this heightened level of risk. Higher resolution is desirable and can be achieved by identification of more specific subgroups. However, the corresponding absolute number of deaths becomes progressively smaller as the subgroups become more focused (see **Fig. 42.2A**), thus limiting the potential benefit of interventions to a much smaller fraction of the total number of

patients at risk. Up to half of all SCDs attributable to coronary heart disease are first clinical events,[8] and another 20% to 30% occur in subgroups of patients with known coronary heart disease who are profiled to be at relatively low risk for SCD on the basis of current clinically available markers (**see Fig. 42.2B**). The principle of a high proportion of SCDs occurring as first events or in previously asymptomatic individuals applies to the less common causes as well.[22]

Biologic and Clinical Time-Dependent Risk

Temporal elements in risk for SCD have been analyzed in the context of both biologic and clinical chronology. In the former, epidemiologic analyses of risk for SCD in populations have identified three patterns: diurnal, day of the week, and seasonal. General patterns of heightened risk during the morning hours, on Mondays, and during the winter months have been described.[18] An exception to the diurnal risk pattern is SCD in sleep apnea, in which the risk tends to be nocturnal.[23]

Ambient temperature is an environmental factor associated with risk for SCD. Both excessive cold[18] and excessive heat[24] have been linked to risk for cardiac arrest, although the studies did not determine whether temperature extremes are associated with ventricular tachyarrhythmias versus other mechanisms of cardiac arrest. However, significant cooling of the core temperature can lengthen the time course of repolarization of ventricular myocardium and prolong the QT interval, whereas sweating associated with increases in core temperature can alter electrolyte balance. Elevated temperature is a risk for SCA in patients with Brugada syndrome (**see Chapters 33 and 39**). Another environmental variable, transient ambient air pollution conditions, has been correlated with an increased incidence of ventricular arrhythmias stored in ICD memories,[18] but the question of whether these are cardiac arrest equivalents is uncertain.

In the longer-term clinical paradigm, risk for SCD is not linear as a function of time after changes in cardiovascular status.[16,17,25] Survival curves after major cardiovascular events, which identify risk for both SCD and total cardiac death, usually demonstrate that the most rapid rate of attrition occurs during the first 6 to 18 months after an index event. Thus, there is a time dependence of risk that focuses the potential opportunity for maximum efficacy of an intervention during the early period after a cardiovascular event. Curves that have these characteristics have been generated from among survivors of OHCA, new onset of heart failure, and unstable angina and from patients with recent myocardial infarction (MI) and low ejection fraction or heart failure. For the latter, however, early nonarrhythmic deaths also contribute a large proportion of the fatal events. Even though the rate of attrition decreases after the early spike in mortality, a secondary delayed increase in risk occurs in post-MI patients 2 to 5 years after an index event, probably related to ventricular remodeling and heart failure.

Age, Race, Sex, and Heredity

Age

The incidence of sudden death has two peak ages: within the first year of life (including sudden infant death syndrome [SIDS]; **see Chapter 75**) and between 45 and 75 years of age. Among the general populations of infants younger than 1 year and middle-aged or older adults, the incidence is surprisingly similar.[26] In adults older than 35 years, the incidence of SCD is in the range of 1 per 1000 persons per year (**Fig. 42.4A**), with an age-related increase in risk over time as the prevalence of coronary heart disease increases in parallel with advancing age.[16]

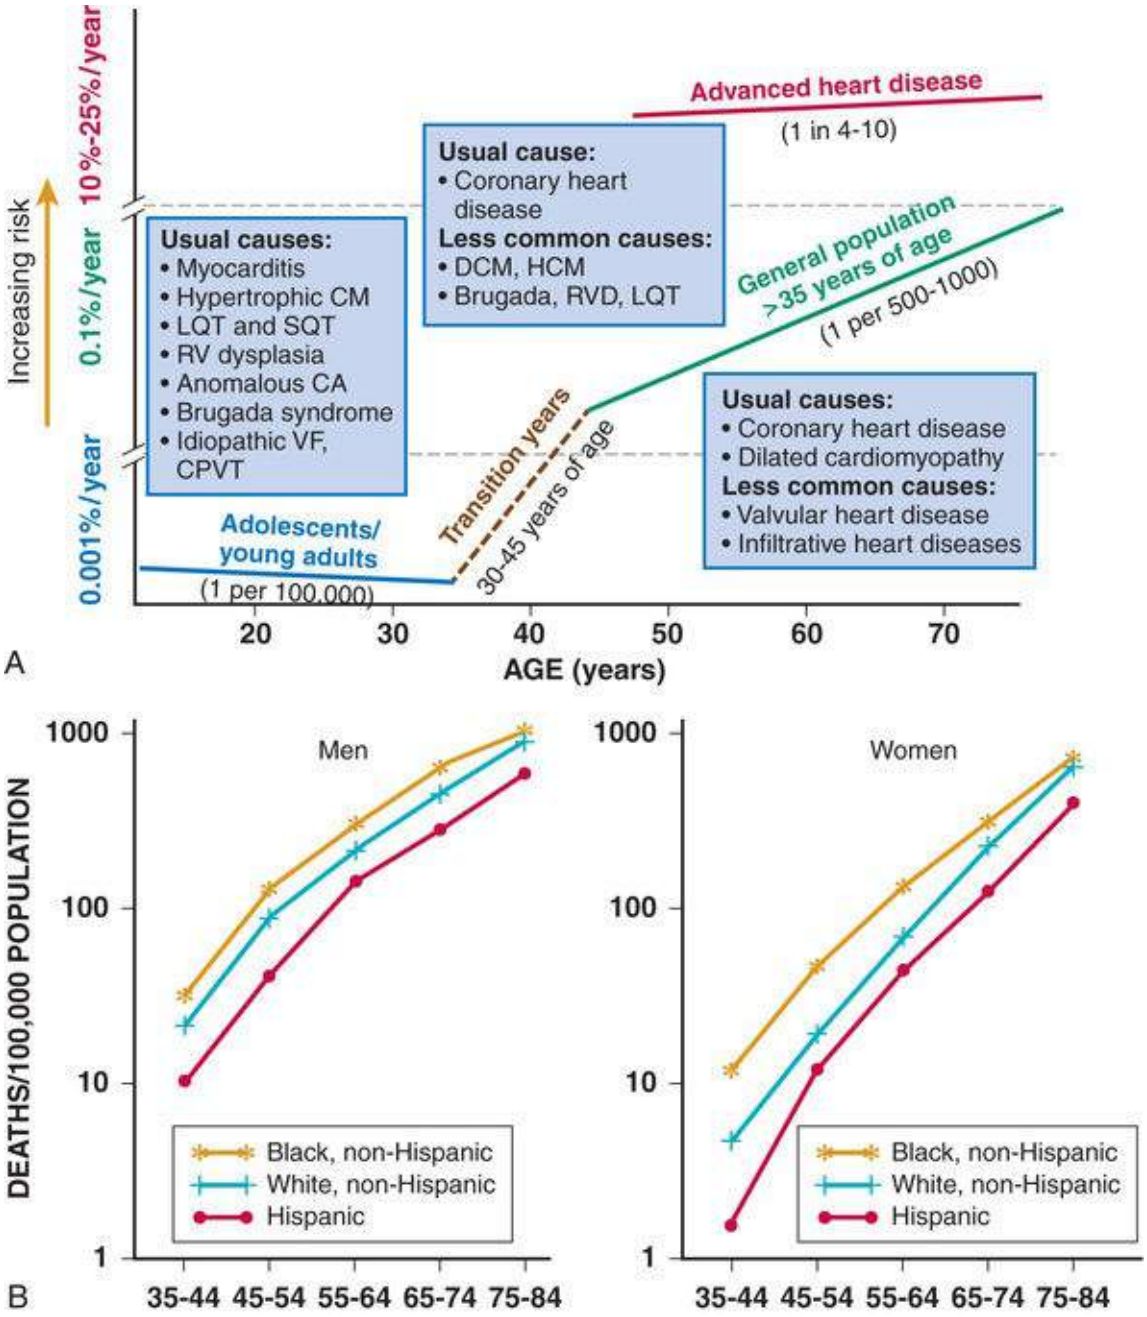

FIGURE 42.4 Age-, sex-, and race-specific risks for sudden cardiac death (SCD). **A,** Age-related and disease-specific risk for SCD. For the general population 35 years and older, the risk for SCD is 0.1% to 0.2% per year (1/500 to 1000 population), with a wide spread in subgroup risk based on the number and power of individual risk factors. Causes are dominated by coronary heart disease and, to a lesser extent, nonischemic cardiomyopathy in this age range. The risk for SCD increases dramatically beyond age 35 years and continues to increase past age 70. In patients older than 30 with advanced structural heart disease and markers of high risk for cardiac arrest, the event rate may exceed 25% per year, and the age-related risk is attenuated. In adolescents and adults younger than 30, the overall risk for SCD is 1/100,00 population or 0.001% per year, with a variety of causes such as inherited structural and electrical disorders, developmental defects, and myocarditis dominating. In adolescents and young adults at risk for SCD from specific identified causes, it is difficult to ascertain the risk in individual patients because of variable expression of the disease state (see text for details). In the transition range from 30 to 45 years of age, the relative frequency of the uncommon disease yields to the dominance of coronary heart disease and nonischemic cardiomyopathy, but both groups of potential causes must be entertained because many of the rare disorders are expressed in that age range. **B,** SCD risk as a function of age, sex, and race or culture (white, black, and Hispanic). *CA,* Cardiac arrest; *CM,* cardiomyopathy; *CPVT,* catecholaminergic polymorphic ventricular tachycardia; *DCM,* dilated CM; *HCM,* hypertrophic CM; *LQT,* long QT syndrome; *RV,* right ventricular; *RVD,* RV dysplasia; *SQT,* short QT syndrome; *VF,* ventricular fibrillation. (**B,** Data modified from Gillum RF. Sudden cardiac death in Hispanic Americans and African Americans. Am J Public Health 1997;87:1461.)

An evaluation of the lifetime risk of SCD resulting from CAD in the Framingham population

demonstrated a significant decrease in the lifetime risk for the population at age 75 and older, compared to populations at 45 and 55 years, with the difference most prominent in men.[27]

The incidence in infants is 73 per 100,000 person-years and is most often associated with complex congenital heart disease. The incidence in children, adolescents, and adults younger than 30 is approximately 6 per 100,000 person-years,[18,26] or 1% of the risk in middle-aged and older adults (**Fig. 42.4A**). One study demonstrated that approximately 40% of SCDs in this age category were unexplained, based on the absence of an autopsy or premortem clinical diagnosis, but postmortem genetic studies identified a likely cause in 27% of such cases that underwent studies.[28] Defined causes of SCD and CAD etiologies were more common in the 30- to 35-year-old subgroup.

In contrast to incidence, however, the proportion of deaths caused by coronary heart diseases that are sudden and unexpected decreases with advancing age. In the 20- to 39-year age-group, approximately 75% of the deaths attributable to coronary heart disease in men are sudden and unexpected, with the proportion falling to approximately 60% in the 45- to 54-year age-group and hovering close to 50% thereafter. Age also influences the proportion of any cardiovascular cause among all causes of natural sudden death in that the proportion of coronary deaths and of all cardiac causes of death that are sudden is highest in the younger age-groups, whereas the fraction of total sudden natural deaths that result from any cardiovascular cause is higher in the older age-groups. At the other end of the age range, only 19% of sudden natural deaths in children between 1 and 13 years have cardiac causes; the proportion increases to 30% in the 14- to 21-year age-group.

In the transition age range between adolescence and young adulthood (to 25 years) and in the middle and older ages (beginning at 35 years), coronary heart disease emerges to its position as the dominant cause of SCD. However, rare disorders, such as hypertrophic cardiomyopathy, Brugada syndrome, long-QT syndrome, and right ventricular dysplasia, are significant contributors to the distribution of causes of SCD in this age-group. In one study, myocardial fibrosis of unknown etiology was a significant cause in this group.[29]

Race

A number of studies comparing racial differences in the relative risk for SCD in whites and blacks with coronary heart disease in the United States had yielded conflicting and inconclusive data. However, the most recent studies demonstrate a higher risk for cardiac arrest and SCD in blacks than in whites[30] (**see Fig. 42.4B**). SCD rates in Hispanic populations were lower. These differences were observed across all age-groups.

Sex

SCD syndrome has a large preponderance in men relative to women during the young adult and early middle-age years because of the protection that women enjoy from coronary atherosclerosis before menopause (**see Fig. 42.4B**). Various population studies have demonstrated a fourfold to sevenfold greater incidence of SCD in men than in women before 65 years of age, at which point the difference decreases to 2 : 1 or less, and continues to decrease with advancing age. As risk for coronary events increases in postmenopausal women, risk for SCD increases proportionately, but men remain at higher risk than women across the entire age spectrum.[27,31] Even though the overall risk for SCD is much lower in younger women, CAD is the most common cause of SCD in women older than 40 years, and the classic coronary risk factors, including cigarette smoking, diabetes, use of oral contraceptives, and hyperlipidemia, all influence risk in women[32] (**see Chapter 89**). Data from the Nurses' Health Study

suggest that a healthy lifestyle, defined as no cigarette smoking, a low body mass index, regular exercise, and a healthy diet, reduces the risk for SCD in women by as much as 46% to more than 90%, depending on the number of low-risk markers present.[18] Women are 50% less likely to have severe left ventricular dysfunction and 66% less likely to have known coronary heart disease before SCD[33] and are therefore less likely to be profiled as high risk and more likely to have SCD as a first cardiac event.

Heredity

Familial patterns of risk for SCD, which result from known or suspected genetic variations, are emerging as important factors for risk profiling. This concept is generally applicable in regard to both disease development and SCD expression in the common acquired disorders and in a specific sense to inherited arrhythmogenic conditions associated with SCD. The various genetic associations can be separated into four categories (**Table 42.3**): uncommon inherited primary arrhythmic syndromes (e.g., long-QT syndromes, Brugada syndrome, catecholaminergic polymorphic ventricular tachycardia or fibrillation; **see Chapter 33**), uncommon inherited structural diseases associated with risk for SCD (e.g., hypertrophic cardiomyopathy, right ventricular dysplasia; **Chapters 77 and 78**), "acquired" or induced risk for arrhythmias (e.g., drug-induced long QT interval or proarrhythmia, electrolyte disturbances), and common acquired diseases associated with risk for SCD (e.g., coronary heart disease, nonischemic cardiomyopathies; **Chapters 59 and 60**). Genetic variants mapped to loci on many chromosomes are being defined as the molecular bases for these entities and associations.

TABLE 42.3
Genetic Contributors to Risk for Sudden Cardiac Death

Genetically Based Primary Arrhythmia Disorders
Congenital long–QT interval syndrome, short-QT syndrome Brugada syndrome Catecholaminergic polymorphic VT/VF Nonsyndromic VT/VF
Inherited Structural Disorders With Risk for Arrhythmic SCD
Hypertrophic cardiomyopathy Right ventricular dysplasia/cardiomyopathy
Genetic Predisposition to Induced Arrhythmias and SCD
Drug-induced "acquired" long–QT interval syndrome (drugs, electrolytes) Electrolyte and metabolic arrhythmogenic effects
Genetic Modulation of Complex Acquired Diseases
Coronary artery disease, acute coronary syndromes Congestive heart failure, dilated cardiomyopathies

The multiple specific mutations at gene loci–encoding ion channel proteins associated with the various inherited arrhythmia syndromes (**see Chapter 33**) represent a major advance in the understanding of a genetic and pathophysiologic basis for these causes of sudden death. In addition, the role of modifier genes and mutation specificity in the severity of clinical phenotypes in long–QT interval syndromes[34-36] and structural diseases such as hypertrophic cardiomyopathy[37] is of increasing interest. These observations may provide screening tools for individuals at risk, as well as the potential to devise specific therapeutic strategies. A study of screening electrocardiograms (ECGs) for long-QT syndrome (LQTS) in children entering first grade and repeated in the seventh grade, with subsequent genetic testing in children who were positive, suggested that the incidence of inherited LQTS was considerably higher (approximately 1 in 1000) by age 12 years (seventh grade) than earlier estimates from studies based on diagnoses from general clinical expressions.[38] Moreover, the cumulative risk of SCA among those with unrecognized or untreated LQTS was reported to be 13% before age 40 years.[39,40] In addition, gene loci identified by genome-wide association studies may also serve as candidates for investigation of the role

of low-penetrance mutations or polymorphisms in SCD caused by more common conditions, such as coronary heart disease.[41] At this time, the hope for common variants linked to common syndromes such as SCD apparently will be superseded by multiple rare-variant associations.

To the extent that SCD is an expression of underlying coronary heart disease, hereditary factors that contribute to risk for coronary heart disease operate nonspecifically for the SCD syndrome. Various studies have identified mutations and relevant polymorphisms along multiple steps of the cascade, from atherogenesis to plaque destabilization, thrombosis, and arrhythmogenesis, each of which is associated with increased risk for a coronary event[18,42] (**Fig. 42.5**). Integration of these individual markers may provide more powerful individual risk prediction in the future. In addition, several studies have suggested that SCD as the initial expression of coronary heart disease demonstrates familial clustering,[9] including general population surveillance studies, family histories of cardiac arrest survivors in the community, studies of ventricular fibrillation (VF) during acute MI, and postmortem evaluation of SCD cases (**Table 42.4**).

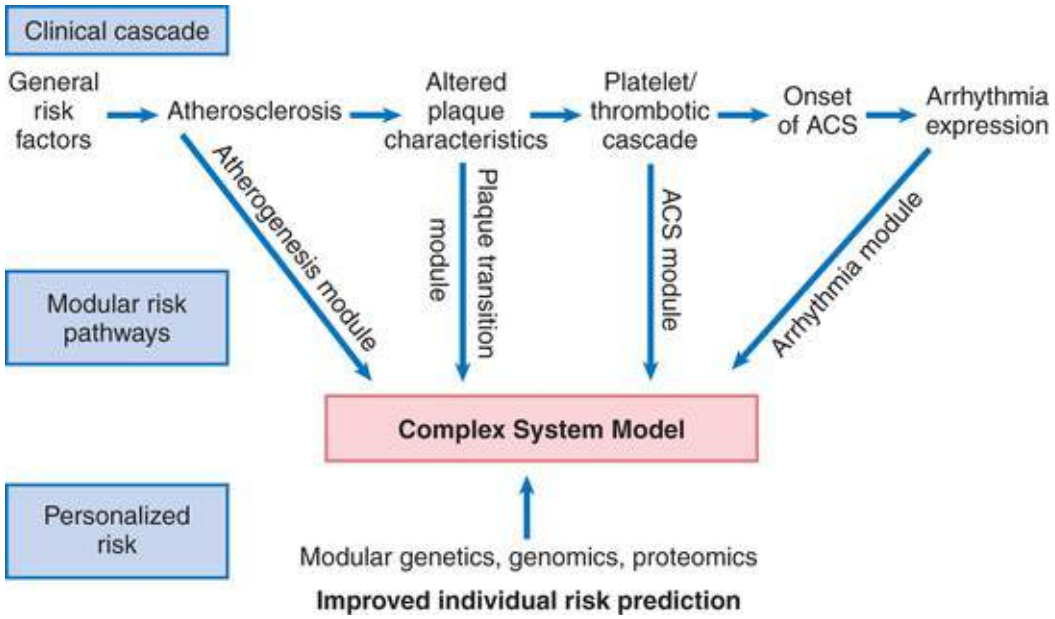

FIGURE 42.5 Coronary atherosclerosis heart disease cascade and genetic imprints on the progression to SCD. The cascade from conventional risk factors for coronary atherosclerosis to arrhythmogenesis in SCD related to coronary heart disease includes initiation and development, progression to an active state, initiation of acute coronary syndromes (*ACS*), and finally, progression to the specific expression of life-threatening arrhythmias. Multiple factors enter at each level, including specific risk based on the genetic profiles of individual patients. Individual risk based on genetic profiles has been identified for atherogenesis, plaque evolution, the thrombotic cascade, and arrhythmia expression. Stepwise integration of these characteristics for individuals through genetics, genomics, proteomics, and biologic system analyses offers the hope of a field of molecular epidemiology that may lead to higher single-patient probabilities for individual SCD risk prediction. (Modified from Myerburg RJ, Junttila MJ. Sudden cardiac death caused by coronary heart disease. Circulation 2012;125:1043.)

Risk Factors for Sudden Cardiac Death

General Risk Profile

Risk prediction for SCD is far more challenging than simply profiling risk for CAD by means of the conventional risk factors for coronary atherogenesis (**see Chapters 33 and 34**). Although the latter is useful for identifying levels of population risk and some aspects of individual risk, it is not sufficient for distinguishing individual patients at risk for SCD from those at risk for other manifestations of coronary heart disease (**see Chapters 56 to 61**), and there have been careful analyses of the complexities and considerations of new approaches to clinically applicable, individual risk assessment.[4,43]

Multivariate analyses of selected risk factors (e.g., age, diabetes mellitus, systolic blood pressure, heart rate, electrocardiographic abnormalities, vital capacity, relative weight, cigarette consumption, serum cholesterol level) have determined that approximately 50% of all SCDs occur in the 10% of the population in the highest-risk decile on the basis of multiple risk factors (**Fig. 42.6**). Thus the interactions of multiple risk factors potentiate the sum of the individual risks. Comparison of risk factors in victims of SCD with those in people who develop any manifestation of CAD does not provide useful patterns, by either univariate or multivariate analysis, to distinguish SCD victims from the overall pool. However, a history of diabetes mellitus and a tendency to longer QTc intervals on random ECGs are suggested as potential markers of interest for prediction of SCD.[44] Although angiographic and hemodynamic patterns discriminate SCD risk from non-SCD risk only under limited conditions, familial clustering of SCD as a specific manifestation of the disease may lead to the identification of specific genetic abnormalities that predispose to SCD.[9]

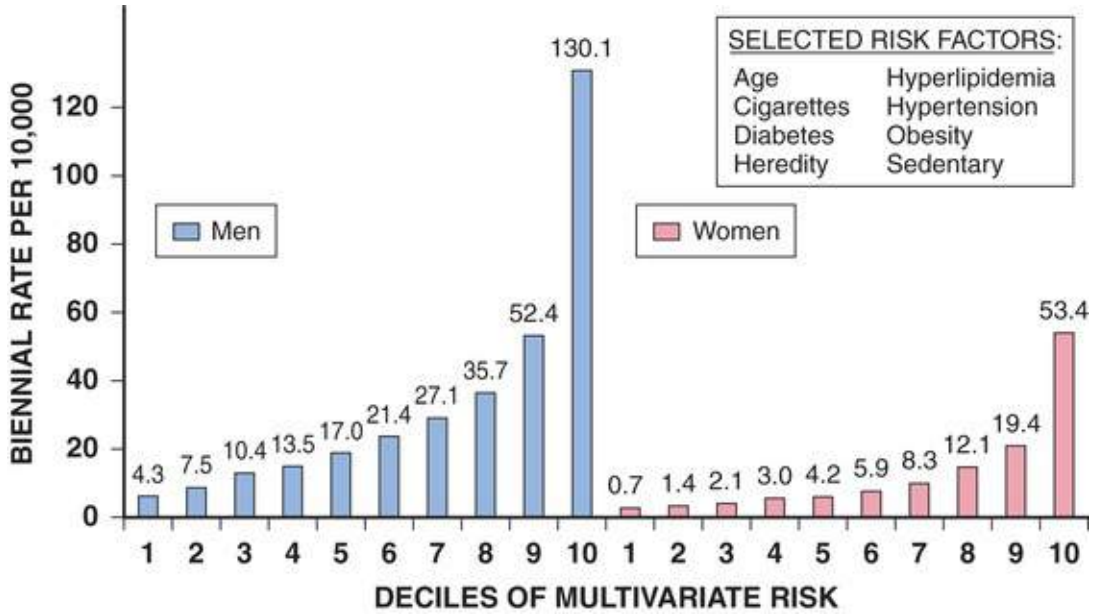

FIGURE 42.6 Risk for sudden death by decile of multivariate risk—the Framingham Study. Selected risk variables are shown. (Modified from Kannel WB, Shatzkin A. Sudden death: lessons from subsets in population studies. J Am Coll Cardiol 1985;5[Suppl 6]:141B. Reprinted by permission of the American College of Cardiology.)

Hypertension is a clearly established risk factor for coronary heart disease and also emerges as a highly significant risk factor in the incidence of SCD (**see Chapters 46 and 47**). However, increasing systolic blood pressure levels have no influence on the ratio of sudden deaths to total coronary heart disease deaths. No relationship has been observed between cholesterol concentration and the proportion of coronary deaths that were sudden. Neither the electrocardiographic pattern of left ventricular hypertrophy nor nonspecific ST-T wave abnormalities influence the proportion of total coronary deaths that are sudden and unexpected. Only intraventricular conduction abnormalities are suggestive of a disproportionate number of SCDs, an old observation reinforced by data from some device trials that suggest the importance of QRS duration as a risk marker. Low vital capacity also suggests a disproportionate risk for sudden versus total coronary deaths. This is of interest because such a relationship was particularly striking in the Framingham Study in analysis of data from women who had died suddenly.

The conventional risk factors used in early studies of SCD are risk factors for the evolution of CAD. The rationale is based on two facts: (1) CAD has been considered the structural basis for 80% of SCDs in the United States, and (2) coronary risk factors are easy to identify because they tend to be present continuously over time (**see Fig. 42.5**). Two recent observations modify this rationale. First, evolving evidence indicates that the anatomic consequences of CAD may not account for as large a proportion of SCDs in adults as previously estimated, with hypertension, left ventricular hypertrophy, and myocardial fibrosis identified as dominant anatomic and pathophysiologic factors.[29] Second, a 10-year longitudinal study of clinical associations identified in hospitalized OHCA victims demonstrated a trend toward decreasing structural heart disease associations, paralleled by an increasing dominance of risk factor markers.[45] However, many of the risk factors specific for triggering fatal arrhythmias are dynamic pathophysiologic events and occur transiently.[9,18] Transient pathophysiologic events are being modeled epidemiologically in an attempt to express and use them as clinical risk factors for both profiling and intervention.[2] Nonetheless, data suggest that longitudinal and transient risk predictors may have their power blunted by clinical interventions, such as percutaneous coronary intervention during acute coronary syndromes and post-MI beta-blocker therapy.[46,47]

Identification of specific clinical markers of risk for SCD as a specific expression of both coronary

heart disease and other cardiovascular disorders has been a goal for many years.[16,17] Left ventricular ejection fraction has been the most popular of such markers for clinical trials and patient profiling. However, its sensitivity limitations and inability to identify the large subgroup in which SCD is the first expression of heart disease have encouraged investigators to seek additional markers. For example, exercise data from a large cohort of men observed for years after a stress test demonstrated that a profile of higher resting heart rates, smaller increments in rate during exercise, and lower decrement in heart rate during the first minute after exercise predicted higher risk for SCD during follow-up.[48] In addition, a number of electrocardiographic indicators (e.g., microvolt T wave alternans, indices of QT duration/dispersion), genetic profiles, and other indices of the extent of disease are also predictive.

Functional Capacity and Sudden Death

The Framingham Study demonstrated a striking relationship between functional classification and death during a 2-year follow-up. However, the proportion of deaths that were sudden did not vary with the functional classification, with a range of 50% to 57% in all groups, including those free of clinical heart disease and those in functional class IV. Other studies have also suggested that patients with heart failure and better functional capacity are at lower risk for dying, as expected, but that a higher proportion of such deaths are sudden.[18]

Lifestyle and Psychosocial Factors (see Chapter 96)

A strong association has been found between cigarette smoking and all manifestations of coronary heart disease. The Framingham Study demonstrated that cigarette smokers have a twofold to threefold increase in risk for sudden death in each decade of life at entry between 30 and 59 years, and that this is one of the few risk factors in which the proportion of deaths attributable to coronary heart disease that are sudden increases in association with the risk factor. The excess risk for SCD in current smokers with coronary heart disease was not observed in former smokers, whose risk was similar to that of those who never smoked.[49] In addition, in a study of 310 OHCA survivors, the recurrent cardiac arrest rate was 27% at 3 years of follow-up in those who continued to smoke versus 19% in those who stopped.

Conversely, light to moderate alcohol consumption was associated with a reduced risk for SCD in male physicians.[18] Obesity is a second factor that appears to influence the proportion of coronary deaths that occur suddenly. With increasing relative weight, the percentage of coronary heart disease deaths that were sudden in the Framingham Study increased linearly from a low of 39% to a high of 70%. Total coronary heart disease deaths increased with increasing relative weight as well.

Associations between levels of physical activity and SCD have been studied with variable results. Epidemiologic observations have suggested a relationship between low levels of physical activity and increased risk for death from coronary heart disease. The Framingham Study, however, showed an insignificant relationship between low levels of physical activity and the incidence of sudden death, but a high proportion of sudden to total cardiac deaths with higher levels of physical activity. An association between acute physical exertion and the onset of MI has been suggested, particularly in individuals who are habitually physically inactive. A subsequent case-crossover cohort study confirmed this observation for SCD by demonstrating a 17-fold relative increase in SCD associated with vigorous exercise versus lower-level activity or inactive states.[50] However, the absolute risk for events was very low (one event per 1.5 million exercise sessions). Habitual vigorous exercise greatly attenuated risk. In contrast, SCD has a higher incidence in young athletes than in young nonathletic individuals in the same age range (**see Chapter 53**). A clue that intensity of exercise may play a role in SCA risk comes from an observation in

college athletes, suggesting that Division 1 basketball players are at higher risk than Division 2 or 3 athletes.[51] Information about physical activity relationships in various clinical settings, such as overt and silent disease states, is still lacking.

The magnitude of recent life changes (health, work, home, family) and personal and social factors has been related to MI and SCD. There is an association with significant elevations in life change scores during the 6 months before a coronary event, and the association is particularly striking in victims of SCD. Women who died suddenly less often were married, had fewer children, and had greater educational discrepancies with their spouses than did age-related controls living in the same neighborhood. A history of psychiatric treatment, including phobic anxieties,[18] cigarette smoking, and greater quantities of alcohol consumption than in controls also characterized the sudden death group. After controlling for other major prognostic factors, the risk for sudden and total deaths and other coronary events is affected by social and economic stress. Alteration of modifiable lifestyle factors has been proposed as a strategy to reduce the risk for SCD in patients with coronary heart disease, although studies of pharmacologic and psychotherapeutic treatment of depression after MI failed to demonstrate an effect on event rates, even though the symptoms of depressive states improved.[18] Behavioral changes (e.g., inactivity) secondary to depression appeared to relate more closely to event rates than did depression itself. Acute psychosocial stressors have been associated with a higher risk for cardiovascular events, including SCD.[52] The risk appears to cluster around the time of the stress and seems to occur in victims with preexisting risk, with the stressor simply advancing the time of an impending event. The possibility of physical stress–induced coronary plaque disruption has also been suggested.

Left Ventricular Ejection Fraction in Chronic Ischemic Heart Disease

A marked reduction in the left ventricular ejection fraction (EF) is the most powerful of the known predictors of total mortality and SCD in patients with chronic ischemic heart disease, as well as in those at risk for SCD from other causes (see later). Increased mortality, independent of other risk factors, is measurable with EF higher than 40%, but the greatest rate of change in mortality occurs at levels between 30% and 40%. An EF of 30% or lower is the single most powerful independent predictor of SCD but has low sensitivity and specificity.[53] Nonetheless, relying on a low EF as the sole major predictor limits the predictive power because of the large number of SCDs that occur at low incidence rates among the very large subset of patients with normal or moderately reduced EF and unrecognized disease.[54] There are emerging implications that left ventricular volume and other structural evaluations of the left ventricle (e.g., infarct size, degree of fibrosis) may be a better predictor of cardiac events than EF alone.[55,56]

Ventricular Arrhythmias in Chronic Ischemic Heart Disease

Most forms of ambient ventricular ectopic activity—premature ventricular complexes (PVCs) and short runs of nonsustained ventricular tachycardia (VT)—have a benign prognosis in the absence of structural heart disease (**see Chapters 37 and 61**). An exception is the polymorphic forms of nonsustained VT that occur in patients without structural heart disease but who can have a molecular, functional, drug-related, or electrolyte-related basis for high-risk arrhythmias. When present in the coronary-prone age-groups, however, PVCs select a subgroup with a higher probability of CAD and SCD. Exercise-induced PVCs and short runs of nonsustained VT indicate some level of risk for SCD, even in the absence of recognizable structural heart disease. However, the data available to support this hypothesis are conflicting, with the possible exception of polymorphic runs of nonsustained VT. Additional data suggest that PVCs and nonsustained VT during both the exercise and the recovery phases of a stress test are

predictive of increased risk. Arrhythmias in the recovery phase, previously thought to be benign, appear to predict higher risk than do arrhythmias in the exercise phase, and there is a gradient of risk with increasing severity of arrhythmias.

The occurrence of PVCs in MI survivors, particularly if frequent and having complex forms such as repetitive PVCs, predicts an increased risk for SCD and total mortality during long-term follow-up. Data are conflicting on the role of measures of frequency and forms of ventricular ectopic activity as discriminators of risk, but most studies have cited a frequency cutoff of 10 PVCs per hour as a threshold level for increased risk. Several investigators have emphasized that the most powerful predictors among the various forms of PVCs are runs of nonsustained VT, although this relationship is now questioned. Many of the reported studies have been based on a single ambulatory monitor sample recorded 1 week to several months after the onset of acute MI, and the duration of the samples has ranged from 1 to 48 hours. Other studies have suggested that ambulatory ventricular arrhythmias in patients with heart failure do not specifically predict an increased risk for death.

The results of the Cardiac Arrhythmia Suppression Trial (CAST; **see Chapter 36**), which was designed to test the hypothesis that suppression of PVCs by antiarrhythmic drugs alters the risk for SCD after MI, were surprising for two reasons: mortality in the randomized placebo group was lower than expected, and mortality among patients in the encainide and flecainide arms exceeded control rates by more than threefold. Subgroup analysis has demonstrated increased risk for patients with nonsustained VT and EF of 30% or less in the placebo group, but excess risk in the treated group was still observed. The excess mortality rates may be accounted for by the occurrence of ischemic events in the presence of drug. No adverse effect (other than short-term proarrhythmic risk at initiation of therapy) was observed with the other drug in the study (moricizine), and no long-term benefit emerged with further study. The SWORD (Survival with Oral *d*-Sotalol) study, a comparison of *d*-sotalol with placebo in a post-MI population with a low mortality rate, also demonstrated excess risk in the drug-treated group. Whether the conclusions from CAST, CAST II, and SWORD extend beyond the drug studies or to other diseases remains to be learned.

Left ventricular (LV) dysfunction is the major modulator of risk implied by chronic PVCs after MI. The risk for death predicted by post–MI PVCs is enhanced by the presence of LV dysfunction, which appears to exert its influence most strongly in the first 6 months after infarction. Delayed deterioration of LV function, probably because of remodeling after MI, may increase the risk further.

Emerging Markers of Risk for Sudden Cardiac Death

Additional risk markers with independent or added predictive power are being studied for risk profiling. These include techniques such as microvolt T wave alternans,[57] contrast-enhanced magnetic resonance imaging (MRI) of the infarction as well as noninfarct patterns of fibrosis seen on MRI delayed hyperenchancement,[58] measures of QT variability,[59] derivatives of heart rate variability methods,[60] sympathetic imaging with 11C-hydroxyephedrine or I-*m*-iodobenzylguanidine (MIBG),[61] and studies of familial clustering of SCD as an expression of coronary heart disease[4] and for potential genetic risk profiling.[9] These techniques are all in early clinical application.

Causes of Sudden Cardiac Death

Coronary Artery Abnormalities

Diseases of the coronary arteries and their consequences have been estimated to account for at least 80%

of SCDs in Western countries, but recent observations are beginning to suggest that the magnitude of this excess burden may be decreasing.[62] Coronary artery disease is also the most common cause in many areas of the world where the prevalence of atherosclerosis is lower. In this regard, it is anticipated that as third-world countries improve access to health care for communicable disease in the earlier years of life, coronary atherosclerosis and its consequences will emerge as a larger problem.[63]

Despite the established dominant relationship between coronary atherosclerosis and SCD, complete understanding of SCD requires recognition that less common and often rare coronary vascular disorders may be identifiable before death and may have therapeutic implications (**Table 42.5**). Many of these entities are relatively more common causes of SCD in adolescents and young adults, in whom the prevalence of coronary heart disease–related SCDs is much lower before age 30 years[28] (**see Fig. 42.4A**).

TABLE 42.5

Causes of and Contributing Factors in Sudden Cardiac Death

I. Coronary artery abnormalities
- A. Coronary atherosclerosis
  1. Chronic coronary atherosclerosis with acute or transient myocardial ischemia—thrombosis, spasm, physical stress
  2. Acute myocardial infarction, onset and early phase
  3. Chronic atherosclerosis with a change in myocardial substrate, including previous myocardial infarction
- B. Congenital abnormalities of coronary arteries
  1. Anomalous origin from the pulmonary artery
  2. Other coronary arteriovenous fistula
  3. Origin of a left coronary artery from the right or noncoronary sinus of Valsalva (lower incidence; higher risk)
  4. Origin of the right coronary artery from the left sinus of Valsalva (higher incidence; lower risk)
  5. Hypoplastic or aplastic coronary arteries
  6. Coronary-intracardiac shunt
- C. Coronary artery embolism
  1. Aortic or mitral endocarditis
  2. Prosthetic aortic or mitral valves
  3. Abnormal native valves or left ventricular mural thrombus
  4. Platelet embolism
- D. Coronary arteritis
  1. Polyarteritis nodosa, progressive systemic sclerosis, giant cell arteritis
  2. Mucocutaneous lymph node syndrome (Kawasaki disease)
  3. Syphilitic coronary ostial stenosis
- E. Miscellaneous mechanical obstruction of the coronary arteries
  1. Coronary artery dissection in Marfan syndrome
  2. Coronary artery dissection in pregnancy (primarily labor/delivery)
  3. Prolapse of aortic valve myxomatous polyps into the coronary ostia
  4. Dissection or rupture of the sinus of Valsalva
- F. Functional obstruction of the coronary arteries
  1. Coronary artery spasm with or without atherosclerosis
  2. Myocardial bridges

II. Hypertrophy of the ventricular myocardium
- A. Left ventricular hypertrophy associated with coronary heart disease
- B. Hypertensive heart disease without significant coronary atherosclerosis
- C. Hypertrophic myocardium secondary to valvular heart disease
- D. Hypertrophic cardiomyopathy
  1. Obstructive
  2. Nonobstructive
- E. Primary or secondary pulmonary hypertension
  1. Advanced chronic right ventricular overload
  2. Pulmonary hypertension in pregnancy (highest-risk peripartum)

III. Myocardial diseases and dysfunction, with or without heart failure
- A. Chronic congestive heart failure
  1. Ischemic cardiomyopathy
  2. Idiopathic dilated cardiomyopathy, acquired
  3. Hereditary dilated cardiomyopathy
  4. Alcoholic cardiomyopathy
  5. Hypertensive cardiomyopathy
  6. Postmyocarditis cardiomyopathy
  7. Peripartum cardiomyopathy
  8. Idiopathic fibrosis
- B. Acute and subacute cardiac failure
  1. Large acute myocardial infarction

VI. Congenital heart disease
- A. Congenital aortic (potentially high risk) or pulmonic (low risk) valve stenosis
- B. Congenital septal defects with Eisenmenger physiology
  1. Advanced disease
  2. During labor and delivery
- C. Late after surgical repair of congenital lesions (e.g., tetralogy of Fallot)

VII. Electrophysiologic abnormalities
- A. Abnormalities of the conducting system
  1. Fibrosis of the His-Purkinje system
     a. Primary degeneration (Lenègre disease)
     b. Secondary to fibrosis and calcification of the "cardiac skeleton" (Lev disease)
     c. Postviral conducting system fibrosis
     d. Hereditary conducting system disease
  2. Anomalous pathways of conduction (Wolff-Parkinson-White syndrome, short refractory period bypass)
- B. Abnormalities of repolarization
  1. Congenital abnormalities in duration of the QT interval
     a. Congenital long–QT interval syndrome
     (1) Romano-Ward syndrome (without deafness)
     (2) Jervell and Lange-Nielsen syndrome (with deafness)
     b. Congenital short–QT interval syndrome
  2. Acquired (or provoked) long–QT interval syndromes
     a. Drug effect (with genetic predisposition?)
     (1) Cardiac, antiarrhythmic
     (2) Noncardiac
     (3) Drug interactions
     b. Electrolyte abnormality (response modified by genetic predisposition?)
     c. Toxic substances
     d. Hypothermia
     e. Central nervous system injury, subarachnoid hemorrhage
  3. Brugada syndrome—right bundle branch block and ST-segment elevations in the absence of ischemia
  4. Early repolarization syndrome
- C. Ventricular fibrillation of unknown or uncertain cause
  1. Absence of identifiable structural or functional causes
     a. "Idiopathic" ventricular fibrillation
     b. Short-coupled torsades de pointes, polymorphic ventricular tachycardia
     c. Nonspecific fibrofatty infiltration in a previously healthy victim (variation of right ventricular dysplasia?)
  2. Sleep-death in Southeast Asians (see VIIB3, Brugada syndrome)
     a. Bangungut
     b. Pokkuri
     c. Lai-tai

VIII. Electrical instability related to neurohumoral and central nervous system influences
- A. Catecholaminergic polymorphic ventricular tachycardia
- B. Other catecholamine-dependent arrhythmias
- C. Central nervous system related
  1. Psychic stress, emotional extremes (takotsubo syndrome)
  2. Auditory related
  3. "Voodoo death" in primitive cultures
  4. Diseases of the cardiac nerves
  5. Arrhythmia expression in congenital long–QT interval syndrome

IX. Sudden cardiac death in the young

2. Myocarditis, acute or fulminant
3. Acute alcoholic cardiac dysfunction
4. Takotsubo syndrome (uncertain risk for sudden death)
5. Ball valve embolism in aortic stenosis or prosthesis
6. Mechanical disruptions of cardiac structures
    a. Rupture of the ventricular free wall
    b. Disruption of the mitral apparatus
    (1) Papillary muscle
    (2) Chordae tendineae
    (3) Leaflet
    c. Rupture of the interventricular septum
7. Acute pulmonary edema in noncompliant ventricles

IV. Inflammatory, infiltrative, neoplastic, and degenerative processes
A. Viral myocarditis, with or without ventricular dysfunction
1. Acute phase
2. Postmyocarditis interstitial fibrosis
B. Myocarditis associated with the vasculitides
C. Sarcoidosis
D. Progressive systemic sclerosis
E. Amyloidosis
F. Hemochromatosis
G. Idiopathic giant cell myocarditis
H. Chagas disease
I. Cardiac ganglionitis
J. Arrhythmogenic right ventricular dysplasia, right ventricular cardiomyopathy
K. Neuromuscular diseases (e.g., muscular dystrophy, Friedreich ataxia, myotonic dystrophy)
L. Intramural tumors
1. Primary
2. Metastatic
M. Obstructive intracavitary tumors
1. Neoplastic
2. Thrombotic

V. Diseases of the cardiac valves
A. Valvular aortic stenosis/insufficiency
B. Mitral valve disruption
C. Mitral valve prolapse
D. Endocarditis
E. Prosthetic valve dysfunction

A. Sudden cardiac death in newborns
1. Complex congenital heart disease
2. Neonatal myocarditis
B. Sudden infant death syndrome
1. Immature respiratory control function
2. Long–QT interval syndrome
3. Congenital heart disease
4. Myocarditis
C. Sudden death in children
1. Eisenmenger syndrome, aortic stenosis, hypertrophic cardiomyopathy, pulmonary atresia
2. After corrective surgery for congenital heart disease
3. Myocarditis
4. Genetic disorders of electrical function (e.g., long–QT interval syndrome)
5. No identified structural or functional cause

X. Miscellaneous
A. Sudden death during extreme physical activity (seek predisposing causes)
B. Commotio cordis—blunt chest trauma
C. Mechanical interference with venous return
1. Acute cardiac tamponade
2. Massive pulmonary embolism
3. Acute intracardiac thrombosis
D. Cardiorespiratory arrest secondary to mechanical asphyxia
E. Dissecting aneurysm of the aorta
F. Toxic and metabolic disturbances (other than the QT interval effects listed above)
1. Electrolyte disturbances
2. Metabolic disturbances
3. Proarrhythmic effects of antiarrhythmic drugs
4. Proarrhythmic effects of noncardiac drugs
G. Mimics sudden cardiac death
1. “Café coronary”
2. Acute alcoholic states (“holiday heart”)
3. Acute asthmatic attacks
4. Air or amniotic fluid embolism

Atherosclerotic Coronary Artery Disease

The structural and functional abnormalities of the coronary vasculature as a result of coronary atherosclerosis interact with the electrophysiologic alterations that result from the myocardial impact of an ischemic burden (**see Chapters 58 to 62**). The relationship between the vascular and myocardial components of this pathophysiologic model, as well as its modulation by hemodynamic, autonomic, genetic, and other influences, establishes multiple patterns of risk derived from the fundamental disease state[2] (**Fig. 42.7**). Risk is modulated by multiple factors that can be either transient or persistent, and transient modulations may interact with persistent changes. The myocardial component of this pathophysiologic model is not static over time, and the term *persistent* must be viewed with caution because of the gradual effects of remodeling after an initial ischemic event and the effects of recurrent ischemic episodes. SCA and SCD resulting from transient ischemia or acute MI differ in physiology and prognosis from the risk for SCA implied by a previous MI with or without subsequent ischemic cardiomyopathy. In general, the short-term risk for life-threatening events is associated more closely with acute ischemia or the acute phase of MI, and longer-term risk is associated more with transient ischemia, myocardial scarring, remodeling, ischemic cardiomyopathy, and heart failure.

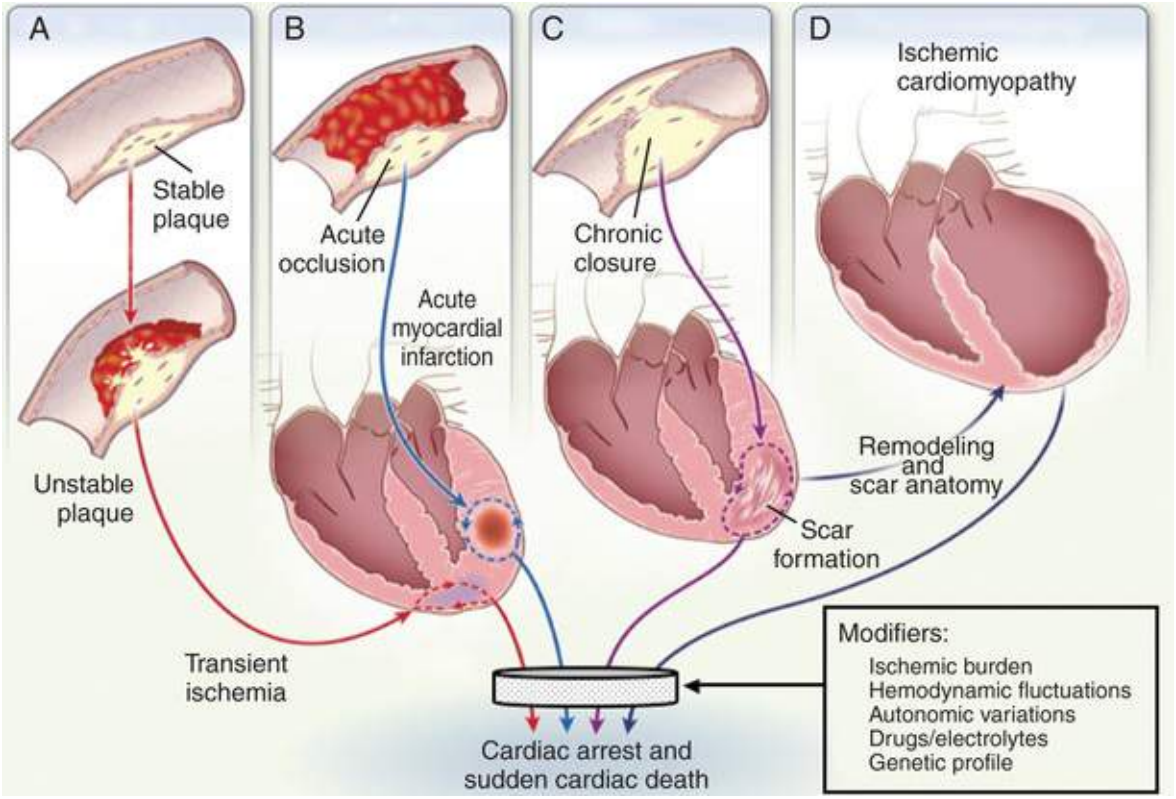

FIGURE 42.7 Pathophysiology of ventricular tachyarrhythmias in coronary heart disease. The short- and long-term risks for the development of VT or VF and recurrent events are related to the presence of transient or persistent physiologic factors. VT/VF caused by transient ischemia **(A)** and the acute phase (24 to 48 hours) of MI **(B)** are not predictive of recurrent events if the recurrent ischemia is preventable. In contrast, VT/VF associated with healed MI, with or without acute transient ischemia **(C),** is associated with risk for recurrence. Longstanding ischemic cardiomyopathy **(D),** especially when accompanied by heart failure, establishes a substrate associated with risk for VT/VF and recurrences over time. A series of modifying influences contribute to individual expression. (Modified from Myerburg RJ. Implantable cardioverter-defibrillators after myocardial infarction. N Engl J Med 2008;359:2245.)

Nonatherosclerotic Coronary Artery Abnormalities

Nonatherosclerotic coronary artery abnormalities include congenital lesions, coronary artery embolism, coronary arteritis, and mechanical abnormalities of the coronary arteries. Among the congenital lesions, anomalous origin of a left coronary artery (LCA) from the pulmonary artery is relatively common and associated with increased mortality in infancy and early childhood without surgical treatment (**see Chapters 53 and 75**). The early risk for SCD is not excessively high, but patients who survive to adolescence and young adulthood without surgical intervention are at risk for SCD. Other forms of coronary arteriovenous fistulas are much less common and associated with a low incidence of SCD.

Anomalous Origin of Coronary Arteries from the Wrong Sinus of Valsalva

These anatomic variants are associated with an increased risk for SCD, particularly during exercise. When the anomalous artery passes between the aortic and the pulmonary artery root, the takeoff angle of the anomalous ostium creates a slitlike opening of the vessel that reduces the effective cross-sectional area for blood flow. The less common origin of the LCA from the right sinus of Valsalva is a higher-risk variant, but the LCA origin from the left sinus of Valsalva, while lower risk, accounts for a proportion of SCDs that should not be ignored, based on the incidence of this anomaly.[64] Congenitally hypoplastic, stenotic, or atretic LCAs are uncommon abnormalities associated with a risk for MI in young persons, but not for SCD.

Embolism to the Coronary Arteries.

Coronary artery emboli occur most frequently in aortic valve endocarditis and from thrombotic material on diseased or prosthetic aortic or mitral valves. Emboli can also originate from left ventricular mural thrombi or as a consequence of surgery or cardiac catheterization. Symptoms and signs of myocardial ischemia or MI are the most common manifestations. In each of these categories, SCD results from the electrophysiologic consequences of embolic ischemia.

Coronary Arteritis.

Mucocutaneous lymph node syndrome (Kawasaki disease; **see Chapter 94**) carries a risk for SCD in association with coronary arteritis. Polyarteritis nodosa and related vasculitis syndromes can cause SCD, presumably because of coronary arteritis, as can coronary ostial stenosis in syphilitic aortitis. The latter has become a rare manifestation of syphilis.

Mechanical Obstruction of Coronary Arteries.

Several types of mechanical abnormalities are listed among the causes of SCD. Coronary artery dissection, with or without dissection of the aorta, occurs in Marfan syndrome (**see Chapter 75**) and has also been reported after trauma and in the peripartum period of pregnancy. Among the rare mechanical causes of SCD is prolapse of myxomatous polyps from the aortic valve into the coronary ostia, as well as dissection or rupture of a sinus of Valsalva aneurysm with involvement of the coronary ostia and proximal coronary arteries. Deep myocardial bridges over coronary arteries have been reported in association with SCD occurring during strenuous exercise, possibly caused by dynamic mechanical obstruction (**see Chapter 53**). Scattered fibrosis in the distribution of the affected vessel is typically seen at postmortem examination and suggests a chronic or intermittent ischemic burden over time. Deep bridging seems to be more common in association with hypertrophic cardiomyopathy. However, the more common superficial bridges in the absence of other disorders are of less concern, and SCD associated with this anatomy is uncommon.

Coronary Artery Spasm.

This may cause serious arrhythmias and SCD (**see Chapter 58**). Coronary artery spasm is usually associated with some degree of concomitant coronary atherosclerotic disease. Painless myocardial ischemia, associated with either spasm or fixed lesions, is recognized as a mechanism of previously unexplained sudden death. Based on absence of markers of risk for a high rate of recurrence, patients with documented life-threatening arrhythmias associated with vasospastic angina should receive either medical therapy or ICD, or both.[65] Different patterns of silent ischemia (e.g., totally asymptomatic, post-MI, mixed silent/anginal patterns) may have different prognostic implications. In post-MI patients, silent ischemia has been correlated with an increased risk for SCD.[66]

Ventricular Hypertrophy and Hypertrophic Cardiomyopathy

Left ventricular hypertrophy is an independent risk factor for SCD, is associated with many causes of SCD, and may be a physiologic contributor to mechanisms of potentially lethal arrhythmias. Underlying states resulting in LV hypertrophy include hypertensive heart disease with or without atherosclerosis, valvular heart disease, obstructive and nonobstructive hypertrophic cardiomyopathy (HCM; **see Chapters 53 and 78**), primary pulmonary hypertension with right ventricular hypertrophy, and advanced right ventricular overload secondary to congenital heart disease. Each of these conditions is associated with risk for SCD, and patients with severely hypertrophic ventricles may be particularly susceptible to

arrhythmic death.

Risk for SCD in patients with obstructive and nonobstructive HCM was identified in the early clinical and hemodynamic descriptions of this entity. In patients who have obstructive HCM, up to 70% of all deaths are sudden. However, survivors of cardiac arrest in this group may have a better long-term outcome than survivors with other causes, and reports have suggested that the risk for primary cardiac arrest and SCD in those with HCM is lower than previously thought.

A substantial proportion of patients with obstructive and nonobstructive HCM have a family history of affected relatives or premature SCDs of unknown cause. Genetic studies have confirmed autosomal dominant inheritance patterns, but with much allele and phenotypic heterogeneity. Most of the mutations are at loci that encode elements in the contractile protein complex, the most common being beta-myosin heavy chain and cardiac troponin T, which together account for more than half of identified abnormalities. The genetics of HCM is characterized by a large number of private mutations with variable expression. Possible interaction with modifier genes may account for variable expression among carriers of a specific variant, although a number of HCM variants thought to cause disease in the black population may actually be benign variants unique to the black population that are missed because of underrepresentation of blacks in control populations.[67]

Specific clinical markers have not been especially predictive of SCD in individual patients, although young age at onset, a strong family history of SCD, magnitude of the left ventricular mass, septal thickness greater than 3 cm, ventricular arrhythmias, a fall in blood pressure during exercise, and worsening symptoms (especially syncope) appear to indicate higher risk. Both a substantial provocable gradient, regardless of the resting gradient, and a high resting gradient alone identify high risk for SCD.[68] The mechanism of SCD in patients with HCM was initially thought to involve outflow tract obstruction, possibly a result of catecholamine stimulation, but later data have focused on lethal arrhythmias as the common mechanism of sudden death in HCM. Risk may also be suggested by nonsustained VT on ambulatory recording, inducibility of potentially lethal arrhythmias during programmed electrical stimulation, or a fall in blood pressure during exercise. Rapid or polymorphic symptomatic nonsustained VTs, or both, have better predictive power.

The pathogenesis of the arrhythmias in HCM is discussed in **Chapters 34 and 78**. Patients with nonobstructive HCM, such as the diffuse, the midcavitary, and to a lesser extent the apical variety, are also at risk for SCD, which suggests that an electrophysiologic mechanism secondary to the hypertrophied muscle itself plays a major role. In athletes younger than 35 years, HCM is the most common cause of SCD, in contrast to athletes older than 35, in whom coronary heart disease is the most common cause.

Nonischemic Cardiomyopathy and Systolic and Diastolic Heart Failure

The advent of therapeutic interventions that provide better long-term control of congestive heart failure has improved the long-term survival of these patients (**see Chapters 21, 25, and 77**). However, the proportion of patients with heart failure who die suddenly is substantial, especially among those who appear clinically stable (i.e., functional class I or II).[18] The mechanism of SCD may be tachyarrhythmic (VT or VF) or nonshockable bradyarrhythmias or asystole. The absolute risk for SCD increases with

deteriorating LV function, but the ratio of sudden to nonsudden deaths is inversely related to the extent of functional impairment.[18] In patients with cardiomyopathy who have good functional capacity (classes I and II), total mortality risk is considerably lower than in those with functional classes III and IV, but a higher probability exists that a death will be sudden (**Fig. 42.8**). Unexplained syncope has been observed to be a powerful predictor of SCD in patients who have functional class III or IV symptoms, regardless of the cause of cardiomyopathy. Ambulatory ventricular arrhythmias do not appear to identify specific risk for SCD in such patients.

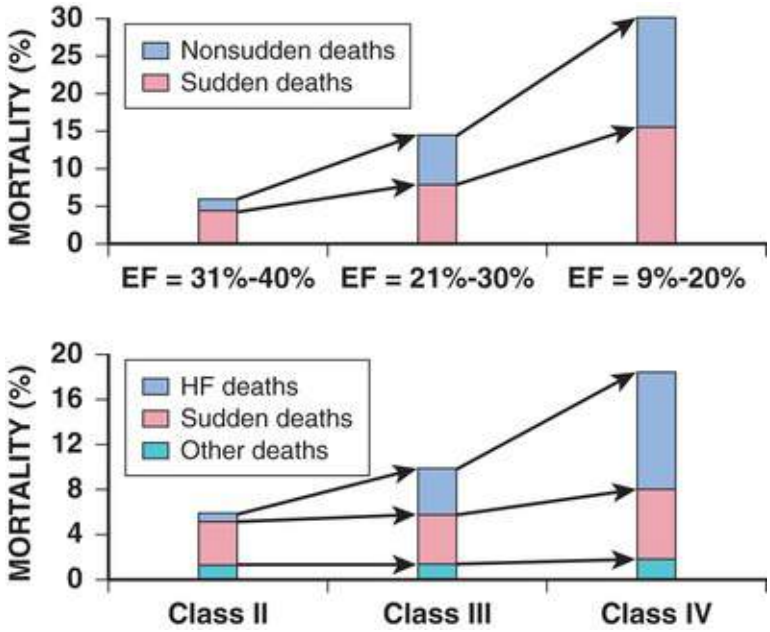

FIGURE 42.8 Risk for SCD related to left ventricular ejection fraction (*EF*) and functional classification in heart failure (*HF*). The relative probability of death being sudden is higher and absolute mortality risk is lower in patients with higher EF and better functional capacity. (Modified from Cleland JG, Chattopadhyay S, Khand A, et al. Prevalence and incidence of arrhythmias and sudden death in heart failure. Heart Fail Rev 2002;7:229, with permission from Springer Science and Business Media.)

Heart failure with a preserved EF carries a risk for mortality over time similar to that of heart failure with a reduced EF (**see Chapter 26**). Although risk for SCD in heart failure patients with a preserved EF may parallel that associated with systolic heart failure, possibly modulated by other risk factors,[69] additional studies are needed to clarify this relationship and its implication for medical practice.

An interaction between post-MI ventricular arrhythmia and depressed EF in determining risk for SCD has been described, but the strongest association between chronic heart failure and SCD is ischemic cardiomyopathy. The prevalence of ischemic cardiomyopathy had been increasing because of better acute MI survival statistics coupled with late remodeling. Other causes include “idiopathic” fibrosis,[29] alcoholic, and postmyocarditis cardiomyopathies; peripartum cardiomyopathy (**see Chapter 90**); and the familial pattern of dilated cardiomyopathy, often associated with lamin A/C mutations.[70] Other gene loci have also been implicated. A residual group of undefined causes have been classified as “idiopathic myocarditis.”

Acute Heart Failure

All causes of acute cardiac failure, in the absence of prompt interventions, can result in SCD as a result of the circulatory failure itself or secondary arrhythmias (**see Chapters 23 and 24**). The electrophysiologic

mechanisms involved may be caused by acute stretching of ventricular myocardial fibers or the His-Purkinje system, based on experimentally demonstrated arrhythmogenic effects. However, the roles of neurohumoral mechanisms and acute electrolyte shifts have not been fully evaluated. Causes of acute cardiac failure associated with SCD include massive acute MI, acute myocarditis, acute alcoholic cardiac dysfunction, acute pulmonary edema in any form of advanced heart disease, and a number of mechanical causes of heart failure, such as massive pulmonary embolism, mechanical disruption of intracardiac structures secondary to infarction or infection, and ball valve embolism in aortic or mitral stenosis (**see Table 42.5**).

Inflammatory, Infiltrative, Neoplastic, and Degenerative Diseases of the Heart.

Almost all diseases in this category have been associated with SCD, with or without concomitant cardiac failure. Acute viral myocarditis with LV dysfunction is frequently associated with cardiac arrhythmias, including potentially lethal arrhythmias[71] (**see Chapters 77 and 81**). Serious ventricular arrhythmias or SCD can occur in patients with myocarditis in the absence of clinical evidence of LV dysfunction.[72] In a report of 19 SCDs in 1,606,167 previously screened U.S. Air Force recruits, 8 of 19 victims (42%) had evidence of myocarditis (5 nonrheumatic, 3 rheumatic) at postmortem examination, and 15 of 19 (79%) had their cardiac arrests during strenuous exertion. Of myocarditis-related SCDs in a study from Sweden, 68% of victims had no premortem symptoms[22] (**Fig. 42.9**), and most data available suggest a bias toward victims younger than 35, both for absolute numbers and for percentages of SCD caused by myocarditis. Focal myocarditis can be associated with SCD and may be missed on autopsy depending on the extent of the cardiac evaluation. Giant cell myocarditis and acute necrotizing eosinophilic myocarditis are particularly virulent for both myocardial damage and arrhythmias.[71] Viral myocarditis can also cause damage isolated to the specialized conducting system and result in a propensity to arrhythmias; the rare association of this process with SCD has been reported. Varicella in adults is a rare cause of striking conduction system disorders, largely involving the intraventricular specialized conducting tissue with very prolonged QRS complexes and nonspecific patterns. LV function is usually preserved, and its relationship to SCD is unclear.

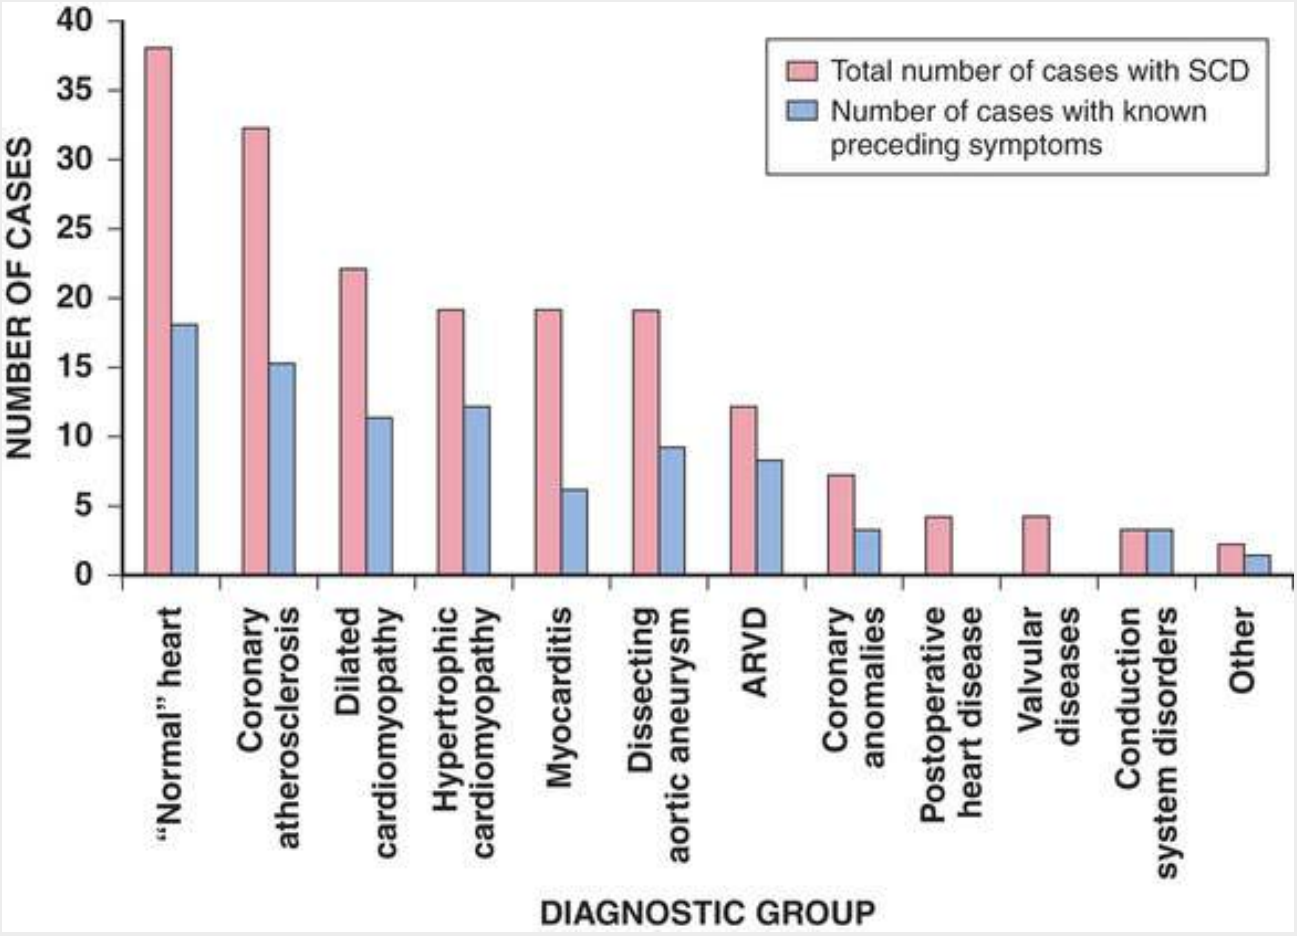

FIGURE 42.9 SCD in adolescents and young adults in Sweden. The frequency of preceding symptoms in 181 cases of SCD in persons 15 to 35 years old is shown by diagnostic group. *ARVD,* Arrhythmogenic right ventricular dysplasia. (Modified from Wisten A, Forsberg H, Krantz P, Messner T. Sudden cardiac death in 15-35-year olds in Sweden during 1992-99. J Intern Med 2002;252:529.)

Myocardial involvement in collagen-vascular disorders, tumors, chronic granulomatous diseases, infiltrative disorders, and protozoan infestations varies widely, but SCD can be the initial or terminal manifestation of the disease process in all cases. Among the granulomatous diseases, sarcoidosis stands out because of the frequency of associated SCD. SCD was the terminal event in 67% of deaths attributable to sarcoid heart disease. The risk for SCD has been related to the extent of cardiac involvement, but ambient arrhythmias, such as nonsustained VT, may indicate risk in such patients with lesser degrees of cardiac involvement. In a report of the pathologic findings in nine patients who died of progressive systemic sclerosis, eight who died suddenly had evidence of transient ischemia and reperfusion histologically, thus suggesting that this might represent spasm caused by Raynaud-like involvement of the coronary vessels. Amyloidosis of the heart can also cause sudden death (**see Chapter 77**). An incidence of 30% has been reported, and diffuse involvement of ventricular muscle or the specialized conducting system may be associated with SCD. Cardiac involvement can occur in both acquired and inherited forms. In the latter, variants in the transthyretin gene (TTR) are often identified.[73] TTR-associated cardiac amyloid tends to express later in life, almost always after age 50, and observed in up to 4% of the black population, with or without the disease.

Arrhythmogenic Right Ventricular Dysplasia or Cardiomyopathy.

ARVD/C is associated with a high incidence of ventricular arrhythmias, including polymorphic nonsustained VT and VF and recurrent sustained monomorphic VT (**see Chapters 33 and 39**). Although symptomatic monomorphic VT has been well recognized in this syndrome for many years, the risk for SCD had been unclear and thought to be relatively low until the risks associated with the disease were

clarified by a number of subsequent studies. In a high proportion of victims, perhaps as many as 80%, the first manifestation of ARVD/C is “unexplained” syncope or SCD. SCD is often exercise related, and in some areas of the world where HCM screening has excluded affected athletes from competition, ARVD/C has emerged as the most common cause of sports-related SCD. Moderate- to high-level competitive sports participation is not recommended for those with a confirmed diagnosis, although exceptions can be considered for specific sports among those with an ICD and proper preparticipation counseling.[74] Although it is generally considered a right ventricular (RV) abnormality, with possible late involvement of the left ventricle in advanced cases, a left ventricle–dominant pattern has also been described.

ARVD/C is predominantly an inherited disorder in which the variants cause or predispose to the disease, interacting with high RV strain during exercise. In addition, there is some basis for considering that RV arrhythmogenic responses may be caused by very-high-intensity athletic activity as a result of repeated RV strain exposures.[75] The inheritance pattern is autosomal dominant, except in one geographically isolated cluster in which it is autosomal recessive (Naxos disease, plakoglobin locus on chromosome 17). Four loci encoding desmosome structure (plakoglobin, desmoplakin, plakophilin 2, and desmoglein 2) are collectively the most common known mutations associated with RV dysplasia.[76] Autosomal dominant mutations have also been identified in the ryanodine receptor locus on chromosome 1 (1q42) (**see Chapter 33**).

Valvular Heart Disease

Before the advent of surgery for valvular heart disease, severe aortic stenosis was associated with high risk for mortality. Approximately 70% of deaths were sudden and accounted for an absolute SCD mortality rate of 15% to 20% among all affected patients. A retrospective observational study of 133 asymptomatic patients with normal LV function and severe aortic stenosis, defined as a peak aortic gradient of greater than 60 mm Hg, observed without surgery, identified seven patients with SCDs (5%) during a mean follow-up of 3.3 years. Three of the deaths were preceded by a change in status: onset of dyspnea, decreasing LV function, and a coronary event.[77] The advent of aortic valve replacement has reduced the incidence, but patients with prosthetic or heterograft aortic valve replacements remain at some risk for SCD caused by arrhythmias, prosthetic valve dysfunction, or coexistent coronary heart disease. The incidence peaks 3 weeks after surgery and then levels off after 8 months. A high incidence of ventricular arrhythmia has been observed during the follow-up of patients with valve replacement, especially those who had aortic stenosis, multiple valve surgery, or cardiomegaly. Sudden death during follow-up was associated with ventricular arrhythmias and thromboembolism. An association between stenotic lesions of other valves and SCD has not been demonstrated. Regurgitant lesions, particularly chronic aortic regurgitation and acute mitral regurgitation, may cause SCD, but the risk is lower than with aortic stenosis. However, one study did detect greater ease of induction of VT/VF in patients with regurgitant lesions and clinical tachyarrhythmias.[78]

Mitral Valve Prolapse

Mitral valve prolapse is prevalent, but probably less so than previously thought, and is associated with a high incidence of annoying low-risk cardiac arrhythmias (**see Chapter 69**). However, the risk for SCD is apparent, although low. It correlates best with marked redundancy of mitral leaflets, in conjunction with nonspecific ST-T wave changes in inferior leads.

Endocarditis of the Aortic and Mitral Valves

Endocarditis of the aortic and mitral valves may be associated with rapid death resulting from acute disruption of the valvular apparatus (**see Chapter 73**), coronary embolism, or abscesses of valvular rings or the septum. However, such deaths are rarely true sudden deaths because conventionally defined tachyarrhythmic mechanisms are uncommon. Coronary embolism from valvular vegetations can trigger fatal ischemic arrhythmia on rare occasion.

Congenital Heart Disease

The congenital lesions most often associated with SCD are aortic stenosis (**see Chapter 75**) and communications between the left and right sides of the heart with the Eisenmenger physiology. In the latter, risk for SCD is a function of the severity of pulmonary vascular disease; also, pregnant patients with Eisenmenger syndrome have an extraordinarily high risk for maternal mortality during labor and delivery[79] (**see Chapter 90**). Potentially lethal arrhythmias and SCD have been described as late complications after surgical repair of complex congenital lesions, particularly tetralogy of Fallot, transposition of the great arteries, and atrioventricular canal defects. These patients should be observed closely and treated aggressively when cardiac arrhythmias are identified, although the late risk for SCD may not be as high as previously thought.

Electrophysiologic Abnormalities

Acquired disease of the atrioventricular (AV) node and His-Purkinje system and the presence of accessory pathways may be associated with SCD (**see Chapter 37**). Clinical surveillance and follow-up studies have suggested that intraventricular conduction disturbances in coronary heart disease are one of the few factors that can increase the proportion of SCD in these patients. Early studies demonstrated a very high risk for total mortality and SCD during the late in-hospital course and the first few months after hospital discharge in patients with anterior MIs and right bundle branch or bifascicular block. In a later study evaluating the impact of thrombolytic therapy versus the prethrombolytic era experience, the incidence of pure right bundle branch block was higher, but that of bifascicular block was lower, as were late complications and mortality.

Primary fibrosis (Lenègre disease) or injury secondary to other disorders (Lev disease) of the His-Purkinje system is frequently associated with intraventricular conduction abnormalities and symptomatic AV block and less often with SCD. Identification of those at risk and the efficacy of pacemakers for prevention of SCD, rather than only amelioration of symptoms, have been subjects of debate. However, survival appears to depend more on the nature and extent of the underlying disease than on the conduction disturbance itself.

Patients with congenital AV block (**see Chapter 40**) or nonprogressive congenital intraventricular block, in the absence of structural cardiac abnormalities and with a stable heart rate and rhythm, have been characterized as being at low risk for SCD in the past. Later data suggested that patients with the patterns of congenital AV block previously thought to be benign are at risk for dilated cardiomyopathy,[80] and routine pacemaker implantation in patients older than 15 years, if not indicated sooner based on symptoms, has been suggested by at least one group. Confirmation from clinical trial data is not available. Hereditary forms of AV block have also been reported in association with a familial propensity to SCD. Sodium channel gene mutations have been associated with progressive conduction system disturbances, along with aging, and some are variants of Brugada gene expression.[81] External ophthalmoplegia and

retinal pigmentation with progressive conduction system disease (Kearns-Sayre syndrome), which is associated with mitochondrial DNA variants, may lead to high-grade heart block and pacemaker dependence.

The anomalous pathways of conduction in Wolff-Parkinson-White (WPW) syndrome are frequently associated with nonlethal arrhythmias. However, when the anomalous pathways of conduction have short anterograde refractory periods, the occurrence of atrial fibrillation may allow the initiation of VF during very rapid conduction across the accessory pathway (**see Chapter 37**). Patients who have multiple pathways appear to be at higher risk for SCD, as do patients with a familial pattern of anomalous pathways and premature SCD. An infrequent genetic predisposition to WPW syndrome has been suggested.[82]

Long-QT Syndromes

Congenital long-QT syndrome is a functional abnormality usually caused by inherited mutations affecting the molecular structure of ion channel proteins and is associated with environmental or neurogenic triggers that can initiate symptomatic or lethal arrhythmias[83] (**see Chapters 33 to 39**). Less often, but not rarely, such mutations may occur de novo or may be transmitted from an apparently normal mosaic parent.[84] Syncope is the most common manifestation in symptomatic patients. SCD is less common, although data are limited by the absence of information on undiagnosed carriers in whom fatal cardiac arrest is the first clinical event. For example, the prevalence of LQT variants in the population is generally cited in the range of 1 per 2000 to 2500, but a study from Japan on routine ECG screening among first- and seventh-grade schoolchildren estimated a prevalence of 1 per 988, more than double the generally accepted figure from referral populations.[38] Some patients have prolonged QT intervals throughout life without any manifest arrhythmias, whereas others are highly susceptible to symptomatic and potentially fatal ventricular arrhythmias.[39,85] The concept of modifier genes interacting with the primary defect or physiologic contributors to expression is being explored.[86,87]

Higher levels of risk for LQTS are associated with female sex, greater degrees of QT prolongation or QT alternans, unexplained syncope, family history of premature SCD, and documented torsades de pointes (TdP) or previous VF. Patients with LQTS require avoidance of drugs that are associated with QT lengthening and careful medical management, which may include implantable defibrillators. Moreover, it is important to identify and to manage medically relatives who carry the mutation and may be at risk. Variants in *KCNQ1*, *KCNH2*, *SCN5A*, *KCNE1*, *KCNE2*, and *SCN4B* have been implicated in various patterns of the Romano-Ward and Jervell and Lange-Nielsen syndromes. LQT4 is associated with a mutation at a locus on chromosome 4 encoding the cytoskeletal element ankyrin-B.[88] A number of other loci have been linked with less common genetic variants associated with long QT (**see Chapters 33 and 39**).

There is epidemiologic interest in whether QT interval abnormalities or the propensity to these, interacting with acquired diseases, predisposes to SCD as a specific clinical expression.[2,44] In a prospective cohort study, a prolonged QTc emerged as a powerful risk factor for SCD in the presence of acquired cardiovascular disorders.[89] The hypothesis that common genetic variants may modulate QTc in unselected populations has stimulated interest in the relationship to selective risk for SCD in individuals with acquired diseases. However, a number of rare variants may be even more important.

The acquired form of prolonged–QT interval syndrome refers to excessive lengthening of the QT interval and the potential for the development of TdP in response to environmental influences. As with congenital LQTS, it is more common in women. The syndrome may be caused by drug effects or an individual patient's idiosyncrasies (particularly related to class IA or III antiarrhythmic drugs and

psychotropic drugs; **see Chapter 96**), electrolyte abnormalities, hypothermia, toxic substances, bradyarrhythmia-induced QT adjustments, and central nervous system injury (most often subarachnoid hemorrhage). It had also been reported in intensive weight reduction programs that involved the use of certain liquid-protein diets and in patients with anorexia nervosa. Lithium carbonate can prolong the QT interval and has been reported to be associated with an increased incidence of SCD in cancer patients with preexisting heart disease. Drug interactions have been recognized as a mechanism of prolongation of the QT interval and TdP. Inherited polymorphisms or mutations with low penetrance involving the same gene loci associated with phenotypically expressed LQTS may underlie the acquired form, in many cases.[18] In acquired prolonged-QT syndrome, as in the congenital form, TdP is frequently the specific arrhythmia that triggers or degenerates into VF.

Short-QT Syndrome

A familial pattern of risk for SCD has been associated with abnormally short QT intervals, defined as a QTc shorter than 300 milliseconds (QT <280 msec) (**see Chapter 33**).[18] Short-QT syndrome (SQTS) is much less common than LQTS, and there is little to guide risk profiling other than documented life-threatening arrhythmias and familial clustering of SCD.[72] Several ion channel gene loci variants have been suggested.[90]

Brugada Syndrome

Brugada syndrome (BrS), now considered part of the J wave syndromes (**see Chapter 39**), is characterized by an atypical right bundle branch block (RBBB) pattern and unusual forms of nonischemic ST-T wave elevations in the anterior precordial leads (**Fig. 42.10**). It is a familial disorder associated with risk for SCD and occurs most commonly in young and middle-aged men (**see Chapter 33**). Mutations involving the cardiac Na^+ channel gene (*SCN5A*) are the most commonly observed variants but are identified in only a minority of cases, and a number of other ion channel defects have been associated with BrS.[90,91] A variant in *SCN10A* has been observed in more than 16% of affected individuals.[92] The RBBB and ST-T wave changes may be intermittent and evoked or exaggerated by Na^+ channel blockers (e.g., flecainide, procainamide). Individual risk for SCD is difficult to predict. Persistent type I electrocardiographic patterns, syncope, gender, and life-threatening arrhythmias, in various combinations, are thought to be the best predictors.[93] The reliability and added value of inducibility of VTs during programmed electrical stimulation studies are controversial; it appears to be of no value in patients with type III electrocardiographic patterns, of limited if any value in those with type II patterns, but may be of some value in select patients with type I patterns or those who vary between type I and II, with or without provocation studies.[94]

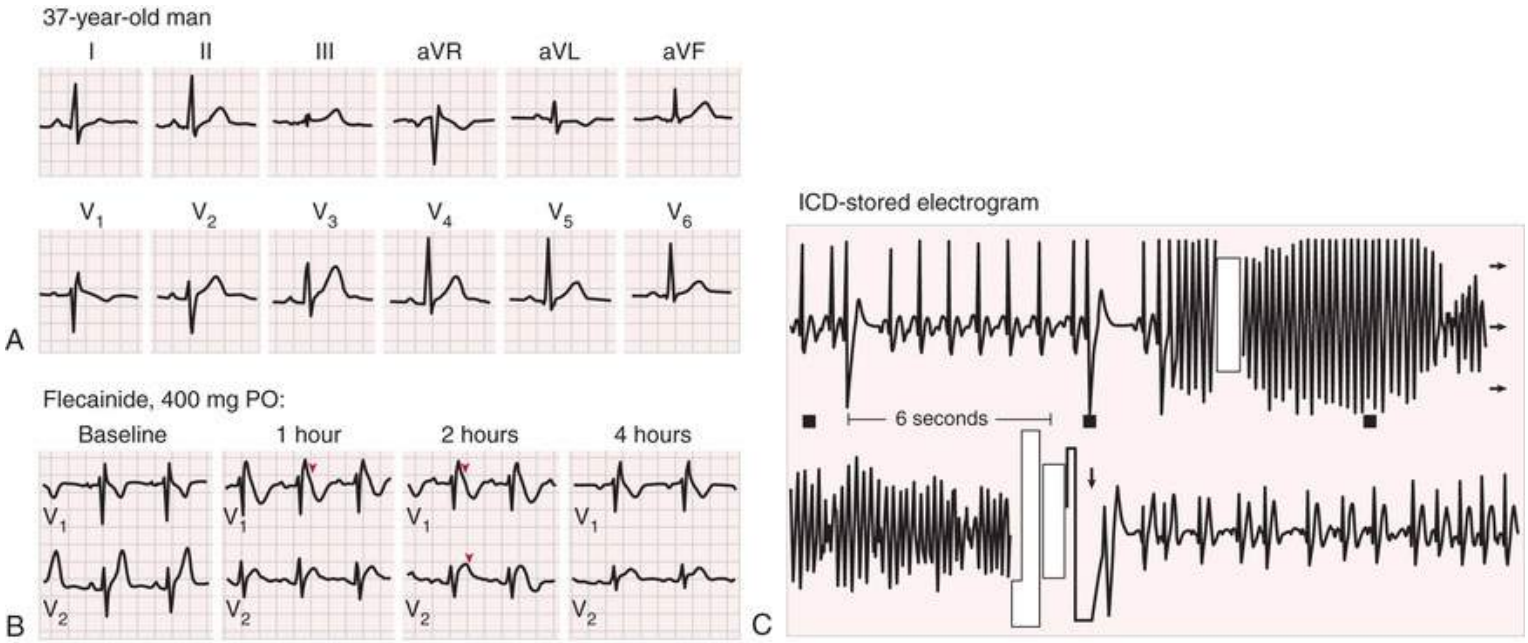

FIGURE 42.10 Electrocardiographic and clinical findings in a 37-year-old man with Brugada syndrome. The patient was resuscitated after out-of-hospital VF. No structural disease was identified. **A,** The 12-lead ECG shows an incomplete right bundle branch block pattern, which is not typical of Brugada syndrome. **B,** The typical repolarization changes associated with Brugada syndrome (*arrowheads*) were elicited by a single oral dose of flecainide, 400 mg. The patient received an ICD and 6 months later had an appropriate shock (*arrow*, **C**), as shown on the accompanying electrogram stored in the device.

In a prospective registry in Italy, Priori and colleagues[95] evaluated the predictive accuracy of sustained VT/VF inducibility to identify patients considered to be at high risk for sudden death and who might be candidates for a prophylactic ICD. A total of 308 individuals with a spontaneous or drug-induced type I ECG pattern but without a history of SCA underwent programmed electrical stimulation at enrollment, and patients were evaluated every 6 months. An induced arrhythmia was not a significant predictor of events at follow-up. A spontaneous type I ECG pattern plus a history of syncope was an independent predictor of arrhythmic outcomes, as was an effective ventricular refractory period of less than 200 milliseconds and QRS fragmentation.

Early Repolarization and Sudden Cardiac Death

An association between the ECG pattern of early repolarization (ER) and risk for idiopathic VF has been described[96] (J wave syndromes; **see Chapter 39**). ER was limited to the inferior and lateral leads, in contrast to the anterior leads, which were associated with the conventional definition of benign ER. The magnitude of J point elevation was significantly greater in cardiac arrest survivors than in controls with ER. Interestingly, a number of the clinical features were similar to the responses seen in patients with BrS, thus leading to speculation whether the reported cases of VF associated with ER might be another expression of the Brugada pathophysiologic process.[97]

An association between ER and risk for SCD was observed in a long-term surveillance study in Finland.[98] The observation that excess risk is expressed later in life suggests a possible interaction between the physiology of ER and acquired diseases, such as coronary heart disease. A subsequent study did demonstrate an association between ER and a higher incidence of SCA during acute coronary syndrome.[99] Risk was primarily associated with the presence of horizontal or downsloping ST segments with ER in the inferior leads.[100]

Catecholaminergic Polymorphic Ventricular Tachycardia.

CPVT is an inherited syndrome associated with catecholamine-dependent lethal arrhythmias in the absence of forewarning ECG abnormalities and with at least partial control by beta adrenoceptor–blocking agents (**see Chapters 33 and 39**). An autosomal dominant pattern involving the ryanodine receptor locus (RyR2) was initially described predominantly in younger patients, usually men, with bidirectional or polymorphic VT associated with risk for SCD. A pattern not associated with that genotype appeared to be more likely in older patients (young adults), usually women. More recent data suggest less dominance by male sex for RyR2 variants and another variant involving autosomal recessive inheritance of calsequestrin loci (*CASQ2*) in approximately 10% of genotyped cases and relatives.[101]

Electrical Instability Resulting from Neurohumoral and Central Nervous System Influences.

Several CNS-related interactions with cardiac electrical instability have been suggested (**see Chapters 34 and 99**). Epidemiologic data also suggest an association between behavioral abnormalities and risk for SCD. Psychological stress and emotional extremes have long been suggested as triggering mechanisms for advanced arrhythmias and SCD, but only limited, largely observational data support such associations (**see Chapter 96**). Takotsubo cardiomyopathy[102] is a catecholamine-mediated condition with a generally good long-term prognosis, but the short-term risk for SCD during the acute phase remains uncertain and can be associated with QT prolongation. The possibility that it contributed to unexplained SCD in the young and middle-aged population should be explored.[103]

Stress-induced arrhythmias are better supported than stress-induced risk for mortality, which requires further study. Data from the 1994 Los Angeles earthquake identified an increased rate of fatal cardiac events on that day, but the event rate was reduced during the ensuing 2 weeks, thus suggesting triggering of events about to happen rather than independent causation. Associations between auditory stimulation and auditory auras and SCD have been reported. Auditory abnormalities in some forms of congenital QT prolongation have also been observed.

A variant of torsades de pointes characterized by short coupling intervals between a normal impulse and the initiating impulse has been described (**eFig. 42.1**). It appears to have familial trends and to be related to alterations in autonomic nervous system activity. The 12-lead ECG demonstrates normal QT intervals, but VF and sudden death are common (**see Chapters 33 and 39**).

EFIGURE 42.1 Short-coupled runs of nonsustained polymorphic ventricular tachycardia. This variant has been observed in people without structural heart disease and with normal QT intervals. They are subject to spontaneous episodes of polymorphic ventricular tachycardia (torsades de pointes), which may degenerate into ventricular fibrillation. This uncommon syndrome is associated with a high risk for sudden death. Panels A, B, and C are not continuous but are three separate episodes of nonsustained polymporphic ventricular tachycardia.

The phenomenon of "voodoo death" has been studied in pockets of isolation in underdeveloped countries. Isolation from the tribe, a sense of hopelessness, severe bradyarrhythmias, and sudden death appear to be associated. Limited clinical observations and experimental data modeling voodoo death have suggested a mechanism related to parasympathetic overactivity, as opposed to the evidence of an adrenergic basis for syndromes related to acute emotional stress.

Sudden Infant Death Syndrome and Sudden Cardiac Death in Children

SIDS occurs between birth and 6 months of age, is more common in male infants, and had an incidence of 1.2 deaths per 1000 live births before widespread publication of appropriate sleep positions in at-risk infants.[104] Between 1992 and 2002, the incidence fell to 0.57 death per 1000 live births as attention to sleep position grew, thus supporting a major role for obstructive sleep apnea as a mechanism. Vulnerability as a result of various mechanisms of dysfunctional central respiratory control, both inherent and related to prematurity, is likely to interact with sleep position as a multicomponent mechanism.[105]

Because of its abrupt nature, a primary cardiac mechanism had been suspected in some cases, and a large study of ECGs of infants suggested prolonged QT intervals associated with risk for SIDS. A near-miss survivor with a de novo mutation of the cardiac Na^+ channel gene (*SCN5A*) provided proof of

concept that a long QT may be a mechanism of SIDS. Subsequent data have supported that as many as 15% of cases of SIDS may occur by this mechanism. Other, very rare potential cardiac associations, such as accessory pathways and dispersed or immature AV nodal or bundle branch cells in the annulus, have also been described.

Sudden death in children beyond the SIDS age-group and in adolescents and young adults is associated with identifiable heart disease in most cases. Approximately 25% of SCDs in children occur in those who have undergone previous surgery for congenital cardiac disease. Of the remaining 75%, more than half occur in children who have one of four lesions: congenital aortic stenosis, Eisenmenger syndrome, pulmonary stenosis or atresia, or obstructive HCM (**see Chapter 75**). Other common causes included myocarditis, hypertrophic and dilated cardiomyopathy, congenital heart disease, and aortic dissection.

Sudden Cardiac Death in Competitive and Recreational Athletes and During Intense Exercise

SCD can occur during or after extreme physical activity in competing athletes or under special circumstances in the general population (**see Chapter 53**). Examples of the latter include intense conditioning exercise and basic military training. Among adolescent and young adult competitive athletes, the estimated incidence was 1 per 75,000 annually in Italy, versus less than 1 per 125,000 for the general nonathlete population in the same age-group. In a survey of high school athletes in Minnesota, the frequency of sudden unexpected death related to cardiovascular disease during competitive sports was approximately 1 per 100,000 individual student athlete participants, a figure similar to that in the general population in that age-group.[106]

Exercise-related incidence figures are more difficult to ascertain in other populations, but one study reported an incidence of one SCD per 1.5 million exercise sessions in health clubs.[50] The incidence of exercise-related cardiac arrest appears to be lower in women. In a large study of both competitive and recreational athletes in France, the incidence of SCD was 0.5 per 1 million population in women, compared to 10.1 per million in men.[107] Most athletes and nonathletes have a previously known or unrecognized cardiac abnormality. In middle-aged and older adults, in whom coronary disease dominates as the cause of SCD, exercise-related deaths appear to be associated with acute plaque disruption. Whether exercise contributed to the initiation of plaque disruption or preexisting disruption simply set the stage for the fatal response during exercise remains unclear. Among adolescent and young adult athletes, HCM with or without obstruction (**see Chapter 78**) and occult congenital or acquired CAD (**Chapter 57**) are the most common causes identified after death,[108] with myocarditis contributing a significant minority (**Chapter 79**). In a report of a large cohort of U.S. Air Force recruits, a surprisingly large fraction of those who died suddenly during exertion had unsuspected myocarditis. Diseases attributed to molecular structural abnormalities, such as LQTS and RV dysplasia, are increasingly being recognized as causes of SCD in athletes and exercising nonathletes. Blunt chest wall trauma by sports objects, such as baseballs and hockey pucks, can initiate lethal arrhythmias, a syndrome known as *commotio cordis*.[109]

Attention to recreational athletics and high-level conditioning activities is emerging. A 5-year survey of sports-related SCD and resuscitated SCA among the general population in France was based on a prospective, comprehensive survey of individuals 10 to 75 years old.[110] The investigators detected an incidence of 4.6 cases per million population per year, with only 6% of cases occurring in young competitive athletes. The remainder occurred during recreational athletic activities, usually cycling, jogging, or soccer. Analysis of suspected underreporting suggested that the incidence of sports-related sudden death throughout France might be as high as 5 to 17 new cases per million population per year.

Case participants were predominantly male (95%) and had no previous history of heart disease. The mean age was 46 years. Just more than half (51.9%) of the sports-related SCDs occurred in public sports venues, and 99.8% of these were witnessed. However, bystander cardiopulmonary resuscitation (CPR) was performed in only 35.5%.

A study of SCA risk in marathon and half-marathon runners suggested that the overall incidence did not appear to be higher than that for the general population in the age-group of participants.[111] The most common identified causes were HCM, with or without other disorders, and CAD.

Sudden death from true cardiac causes in athletes should not be confused with precipitous death related to noncardiac causes, such as acute cerebrovascular accident (CVA, stroke),[7] heat stroke, or malignant hyperthermia. In the latter, the victim has usually exercised excessively in hot weather, often with athletic gear that impairs heat dissipation and sometimes with the use of substances such as ephedrine that may cause vasoconstriction, impairing heat exchange. This leads to collapse with greatly elevated core body temperatures and, ultimately, irreversible organ system damage. As a result, the U.S. Food and Drug Administration (FDA) has banned marketing of these substances for enhancement of athletic performance or weight loss.[112]

Other Causes and Circumstances Associated with Sudden Death

A small group of victims has neither previously determined functional abnormality nor identifiable structural abnormalities at postmortem examination. Such events or deaths, when associated with documented VF, are classified as “idiopathic.” Although long-term survival after an idiopathic, potentially fatal event is still unclear, some degree of risk appears to remain. The idiopathic category is decreasing as the subtle molecular causes become better defined, including recognition by postmortem genetic studies. Limited data suggest that higher risk persists primarily in patients with subtle cardiac structural abnormalities, in contrast to patients who are truly normal. In addition, these events tend to occur in young, otherwise healthy people.

A number of non–cardiac-related conditions can also cause or mimic SCD. Sleep apnea is associated with a risk for nocturnal death, including deaths attributable to cardiac causes (**see Chapter 87**). The risk for death peaks during the night rather than in the early-morning hours.[23] Another respiratory system–based cause of sudden death is the “café coronary,” in which food lodges in the oropharynx and causes an abrupt obstruction at the glottis. The “holiday heart” syndrome is characterized by cardiac arrhythmias, most often atrial, as well as other cardiac abnormalities associated with acute alcoholic states. It has not been determined whether potentially lethal arrhythmias occurring in such settings account for the reported sudden deaths associated with acute alcoholic states. Massive pulmonary embolism can cause acute cardiovascular collapse and sudden death (**see Chapter 84**); sudden death in severe acute asthmatic attacks, without prolonged deterioration of the patient's condition, is well recognized (**Chapter 86**). Air or amniotic fluid embolism at the time of labor and delivery may cause sudden death on rare occasion, with the clinical picture mimicking that of SCD. Peripartum air embolism caused by unusual sexual practices has been reported as a cause of such sudden deaths.

A number of abnormalities that do not directly involve the heart may cause sudden deaths that mimic SCD. Such abnormalities include aortic dissection (**see Chapter 63**), acute cardiac tamponade (**Chapter 83**), and rapid exsanguination. The electrical mechanism associated with these deaths is usually severe bradyarrhythmias, pulseless electrical activity, or asystole rather than VT/VF.

Pathology and Pathophysiology

Protocols and observations from postmortem studies of SCD victims have changed in recent years. It is now recommended that in SCD cases that do not have obvious causes identified on routine postmortem studies or available clinical information, specialized cardiac pathology centers should perform postmortem examination. This is particularly important for younger populations with unexplained SCA. A series of 200 cases in which information was available from both routine autopsies and referral evaluations yielded a 41% discrepancy in final diagnoses.[113] Notably, there was a tendency for the routine autopsy to overdiagnose cardiomyopathy as a cause of death, and CAD was less common than in other studies. However, the study was limited to some extent by an age discrepancy (median, 32 years), limiting extrapolation to the overall population. Additional data from unselected sources also suggest that the proportion of CAD-associated SCDs has decreased,[77] and that hypertensive heart disease, idiopathic "fibrosis," and other, less common causes are significant contributors. In addition, a number of studies now support the notion that postmortem genetic studies are useful for increasing the probability identifying a probable cause that is unexplained based on anatomic changes.[28,114,115] Earlier pathologic studies in SCD victims across a broader age spectrum reflected the epidemiologic and clinical observations that coronary atherosclerosis is the major predisposing cause. In one report, 81% of 220 victims of SCD had significant coronary heart disease at autopsy. At least one vessel with more than 75% stenosis was found in 94% of the victims, acute coronary occlusion in 58%, healed MI in 44%, and acute MI in 27%. These observations were consistent with studies of the frequency of CAD in SCD victims, but the focus has evolved from the simple anatomic presence of coronary lesions to specific associations with unstable plaque. All other causes of SCD collectively account for no more than 20% of cases, but they have provided a large base of enlightening pathologic data (**see Table 42.5**).

Pathology of Sudden Death Caused by Coronary Artery Abnormalities

Coronary Arteries.

Extensive atherosclerosis has long been recognized as the most common pathologic finding in the coronary arteries of victims of SCD. Combined study results have suggested a general pattern of at least two coronary arteries with 75% or greater narrowing in more than 75% of the victims. Several studies have demonstrated no specific pattern of distribution of coronary artery lesions that preselect for SCD, but the extent of coronary artery narrowing at postmortem examination was greater in SCD victims than in controls.

The role of active coronary artery lesions, characterized by plaque fissuring, plaque erosion or rupture, platelet aggregation, and thrombosis, as a major pathophysiologic mechanism of the onset of cardiac arrest has been further clarified (**see Chapter 58**). In an early study of 100 consecutive victims of sudden coronary death, 44% had major (>50% luminal occlusion) recent coronary thrombi, 30% had minor occlusive thrombi, and 21% had plaque fissuring. Only 5% had no acute coronary artery changes; 65% of the thrombi occurred at sites of preexisting high-grade stenoses, and an additional 19% were found at sites with greater than 50% stenosis. In a subsequent study, 50 (30%) of 168 victims had occlusive intraluminal coronary thrombi, and 73 (44%) had mural intraluminal thrombi. Disruption, platelet aggregation, and thrombosis are associated with markers of inflammation and various conventional risk factors for coronary atherosclerosis, such as cigarette smoking and hyperlipidemia.

Some of the less common, nonatherosclerotic coronary artery abnormalities have specific pathologic features as well. Coronary artery spasm, an established cause of acute ischemia and SCD, is commonly associated with nonobstructive plaque (**Fig. 42.11**), and the consequences of spasm/reperfusion have been recognized at postmortem examination. When deep myocardial bridges are identified in association with SCD, patchy fibrosis in areas subserved by the affected vessel is often seen at postmortem

examination. Coronary vasculitis in association with various autoimmune disorders may cause diffuse myocardial abnormalities, but asymptomatic cardiac involvement or global myocardial dysfunction is more common than SCD.

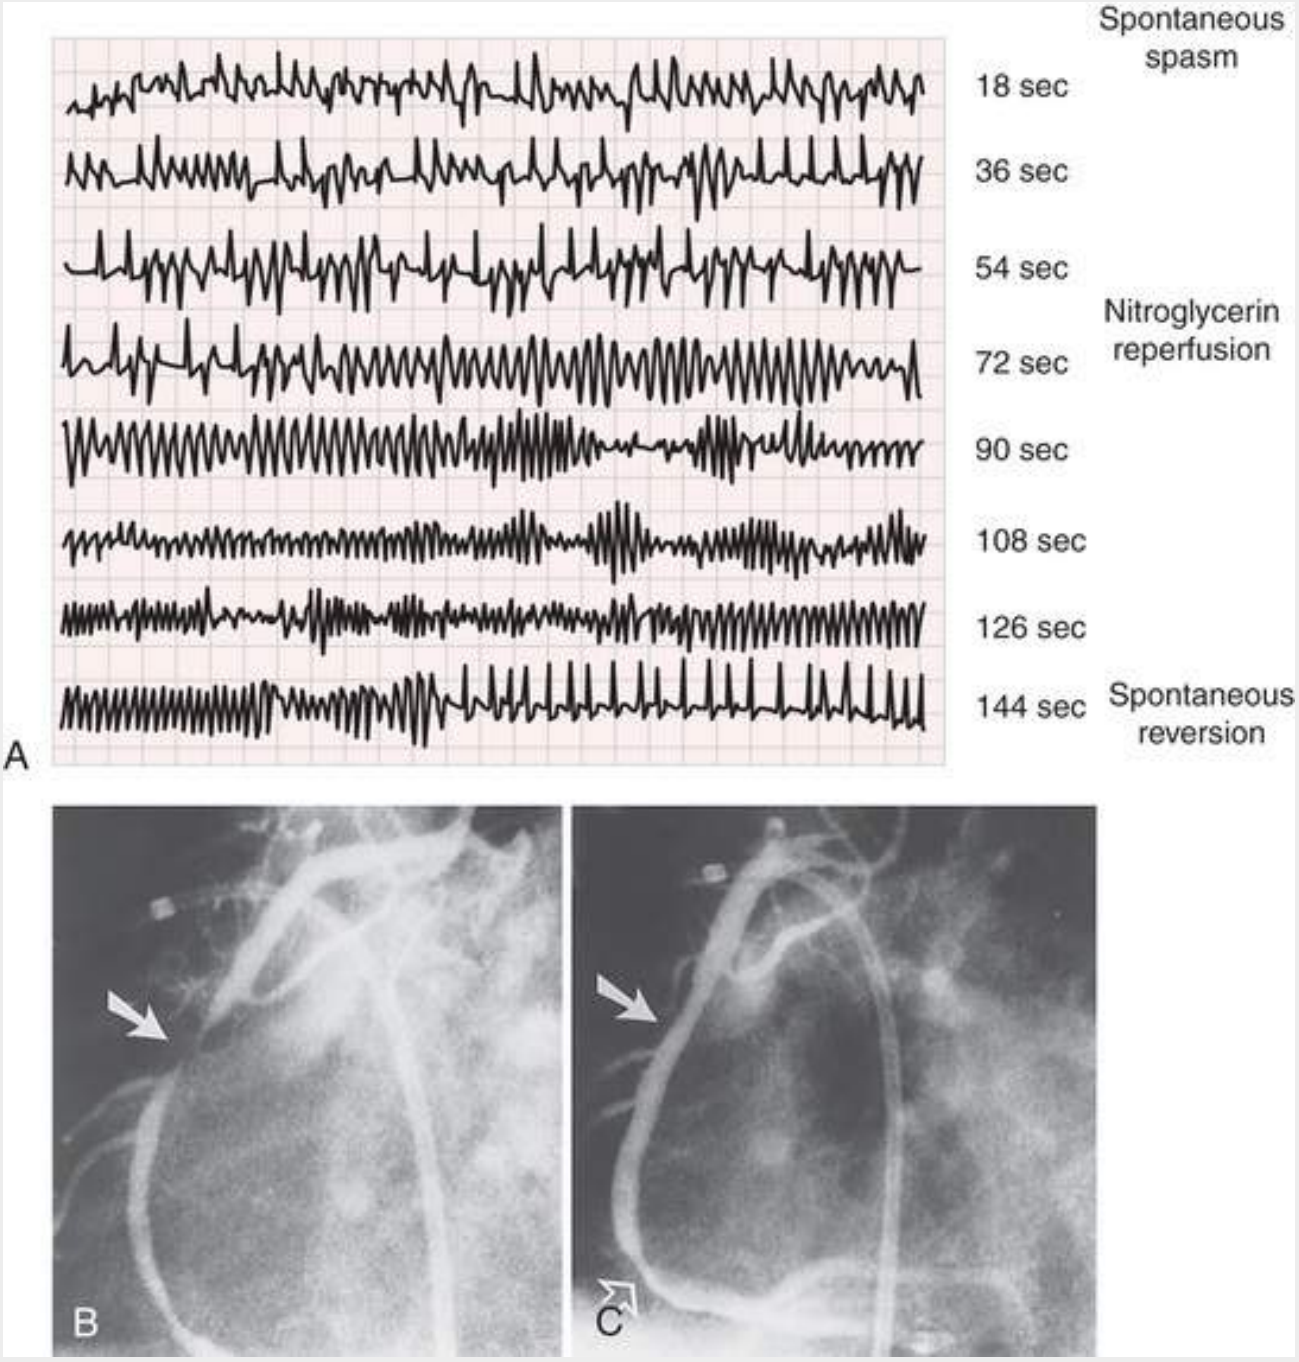

FIGURE 42.11 Life-threatening ventricular arrhythmias associated with acute myocardial ischemia related to coronary artery spasm and with reperfusion. **A,** Continuous lead II electrocardiographic monitor recording during ischemia (time, 0 to 55 seconds) caused by spasm of the right coronary artery **(B).** Following the administration of nitroglycerin at approximately 55 seconds, an abrupt transition from repetitive ventricular ectopy to a rapid polymorphic, prefibrillatory tachyarrhythmia occurs (time, 80 to 130 seconds) in association with reversal of the spasm **(C).** *Closed arrows* indicate the site of spasm before and after nitroglycerin; the *open arrow* indicates a lower-grade distal lesion. (Modified from Myerburg RJ, Kessler KM, Mallon SM, et al. Life-threatening ventricular arrhythmias in patients with silent myocardial ischemia due to coronary artery spasm. N Engl J Med 1992;326:1451.)

Myocardium.

Myocardial injury in SCD caused by coronary heart disease reflects the extensive atherosclerosis usually

present. Studies of victims of out-of-hospital SCD and from epidemiologic sources have indicated that healed MI is a common finding in SCD victims, with most investigators reporting frequencies ranging from 40% to more than 70%. In one study, 72% of men in the 25- to 44-year age-group who died suddenly (≤24 hours) with no previous clinical history of coronary heart disease had scars from large (63%) or small (<1-cm cross-sectional area, 9%) areas of healed myocardial necrosis. The incidence of acute MI is considerably lower, with cytopathologic evidence of recent MI found in approximately 20% of individuals. This estimate corresponds well with the results of studies of OHCA survivors, who were found to have an incidence of new MI of 20% to 30%, but with a wide range of numbers reported in various studies, especially among survivors. These pathologic observations do not provide insight into the likely possibility that many SCDs result from acute coronary syndrome mechanisms and progress from ischemia to fatal arrhythmias without time for structural markers to become visible. Since elevations in troponin levels occur during chest pain syndromes and also in a substantial proportion of cardiac arrest survivors, the determination whether myocardial injury preceded or resulted from the cardiac arrest is difficult to resolve in individual cases. In the absence of ST-segment elevation MI, it is difficult to distinguish primary from secondary troponin elevations. How troponin levels are handled (e.g., repeated measures over the first 48 hours after arrest) can impact on conclusions whether troponin release is primary or secondary.

Ventricular Hypertrophy.

Myocardial hypertrophy can coexist and interact with acute or chronic ischemia but appears to confer an independent risk for mortality. No close correlation has been found between increased heart weight and the severity of coronary heart disease in SCD victims; however, heart weight is higher in SCD victims than in those whose death is not sudden despite a similar prevalence of a history of hypertension before death. Risk for hypertrophy-associated mortality is also independent of LV function and the extent of CAD, and LV hypertrophy itself may predispose to SCD. Experimental data have also suggested increased susceptibility to potentially lethal ventricular arrhythmias in patients with LV hypertrophy and ischemia and reperfusion.

Specialized Conducting System.

Fibrosis of the specialized conducting system may be observed in SCD victims. Although this process is associated with AV block or intraventricular conduction abnormalities, its role in SCD is uncertain. Lev disease, Lenègre disease, ischemic injury caused by small-vessel disease, and numerous infiltrative or inflammatory processes can result in such changes. In addition, active inflammatory processes (e.g., myocarditis) and infiltrative processes (e.g., amyloidosis, scleroderma, hemochromatosis, morbid obesity) may damage or destroy the AV node, bundle of His, or both and result in AV block.[116]

Focal diseases, such as sarcoidosis, rheumatoid arthritis, fibrotic or fatty infiltration of the AV node or His-Purkinje system with apparent discontinuities, and very rarely Whipple disease, can also involve the conducting system (**see Chapter 40**). These various categories of conducting system disease have been considered possible pathologic substrates for SCD that might be overlooked because of the difficulty of performing careful postmortem examinations of the conducting system routinely, and careful studies of the conducting system has been suggested to identify up to 22% of otherwise unexplained SCDs in persons younger than 40.[117] Focal involvement of conducting tissue by tumors (especially mesothelioma of the AV node, but also lymphoma, carcinoma, rhabdomyoma, and fibroma) has also been reported, and rare cases of SCD have been associated with these lesions. Abnormal postnatal morphogenesis of the specialized conducting system may be a significant factor in some cases of SCD in infants and children.

Cardiac Nerves.

Diseases of cardiac nerves have been postulated to have a role in SCD (**see Chapter 99**). Neural involvement may result from random damage to neural elements within the myocardium (i.e., secondary cardioneuropathy) or may be primary, as in diabetic cardiac autonomic neuropathy, which is associated with a 3.5-fold increased risk of SCD, or rarely a selective cardiac viral neuropathy. Secondary involvement can be a consequence of ischemic neural injury in coronary heart disease and has been proposed to result in autonomic destabilization, thereby enhancing the propensity to arrhythmias, possibly by a mechanism of denervation supersensitivity to catecholamines causing increased dispersion of refractoriness. Nerve sprouting may be important.[118] Some experimental data have supported this hypothesis, and a clinical technique for imaging of cardiac neural fibers suggests a changing pattern over time after MI. Viral, neurotoxic, and hereditary causes (e.g., progressive muscular dystrophy, Friedreich ataxia) have been emphasized.

Mechanisms and Pathophysiology

Electrical mechanisms of cardiac arrest are divided into tachyarrhythmic and bradyarrhythmic-asystolic events, or conversely, shockable versus nonshockable. The tachyarrhythmias include VF and pulseless sustained VT, in which a perceptible pulse may not be present (<60 mm Hg), and adequate blood flow is not maintained. Bradyarrhythmic-asystolic events include severe bradyarrhythmias, pulseless electrical activity (PEA; formerly electromechanical dissociation, or EMD), and inability to generate a mechanical event because of complete absence of electrical activity (asystole). To qualify as a mechanism of cardiac arrest, severe bradyarrhythmias must be slow enough to result in an inability to perfuse adequately and maintain consciousness, which usually requires a heart rate of less than 20 beats/min. In PEA the electrical rate can be considerably faster, but in general much slower than true pulseless ventricular tachycardia (pVT). The important distinction between PEA and pVT is that pVT is a shockable rhythm. The classification of this group of rhythms includes the very slow agonal rhythm heralding death (random irregular depolarizations that do not generate a pulse), PEA at rates from 40 to more than 100 beats/min without a pulse, and pVT, which is a true VT, very rapid and equivalent to VF (**see Fig. 42.11**). In PEA, there is no perfusion because of absent mechanical activity or mechanical obstruction to blood flow, as in massive pulmonary embolism. However, echocardiographic imaging during PEA has suggested that residual LV wall motion may persist but is not adequate for generating a pulse, as in pVT. This phenomenon has implications for exploring new therapeutic approaches for PEA.[119] Many victims found to be asystolic at contact likely were initially in VF or VT. After a variable time, fibrillation may cease and asystole or less often PEA emerges. In contrast to earlier data, the most common initial recording documented in recent years is asystole or PEA, which can continue as such or very rarely transform into VF.

The occurrence of potentially lethal tachyarrhythmias or severe bradyarrhythmia or asystole is the end of a cascade of pathophysiologic abnormalities that result from complex interactions between coronary vascular events, myocardial injury, variations in autonomic tone, and the metabolic and electrolyte state of the myocardium[17] (**see Fig. 42.5**). There is no uniform hypothesis of mechanisms by which these elements interact to lead to the final pathway of lethal arrhythmias. However, **Fig. 42.7** shows models of the pathophysiologic process of SCD that include vascular, myocardial, and functional components. The risk for cardiac arrest is conditioned by the presence of structural abnormalities and modulated by functional variations.

Pathophysiologic Mechanisms of Lethal Tachyarrhythmias

Coronary Artery Structure and Function

Among the large fraction of SCDs associated with coronary atherosclerosis, an extensive distribution of chronic arterial narrowing has been well defined by pathologic studies. However, the specific mechanisms by which these lesions lead to potentially lethal disturbances in electrical stability are not simply the consequence of steady-state reductions in regional myocardial blood flow in association with variable demands[16,17] (**see Chapter 44**). A simple increase in myocardial oxygen demand, in the presence of a fixed supply, may be a mechanism of exercise-induced arrhythmias and sudden death during intense physical activity or in others whose heart disease had not previously become clinically manifested. However, the dynamic nature of the pathophysiologic mechanism of coronary events has led to the recognition that superimposed acute lesions create a setting where alterations in the metabolic or electrolyte state of the myocardium are the common circumstance leading to disturbed electrical stability. Active vascular events resulting in an acute or transient reduction in regional myocardial blood flow in the presence of a normal or previously compromised circulation constitute a common mechanism of ischemia, angina pectoris, arrhythmias, and SCD. Coronary artery spasm or modulation of coronary collateral flow, predisposed to by local endothelial dysfunction, exposes the myocardium to the double hazard of transient ischemia and reperfusion (**see Fig. 42.11**). Neurogenic influences may play a role but do not appear to be a sine qua non for the production of spasm. Vessel susceptibility and humoral factors, particularly those related to platelet activation and aggregation, also appear to be important mechanisms.

Transition of stable atherosclerotic plaque to an “active” state because of endocardial damage, with plaque fissuring leading to platelet activation and aggregation followed by thrombosis, is a mechanism that appears to be present in many SCDs related to coronary heart disease (**see Chapter 61**). Inflammatory responses in atherosclerotic plaque are now viewed as the condition leading to lesion progression, including erosion, disruption, platelet activation, and thrombosis. In addition to causing a subacute or acute critical reduction in regional blood flow, these mechanisms produce a series of biochemical alterations that may enhance or retard susceptibility to VF by means of vasomotor modulation.

The step in the cascade of coronary artery pathophysiology leading to ischemia-induced arrhythmias that follows conversion to an active plaque involves the thrombotic module of platelet aggregation and thrombosis (**see Figs. 42.5 and 42.7** and **Chapter 44**). However, there is a discrepancy between the relatively high incidence of platelet aggregation or acute thrombi in postmortem studies and the low incidence of evolution of new MI in survivors of out-of-hospital VF. The rapid initiation of lethal arrhythmias, the spontaneous thrombolysis, a dominant role of spasm induced by platelet products, or a combination of these factors may explain this observation.

Acute Ischemia and Initiation of Lethal Arrhythmias

The onset of acute ischemia produces immediate electrical, mechanical, and biochemical dysfunction of cardiac muscle. The specialized conducting tissue is more resistant to acute ischemia than working myocardium, and therefore the electrophysiologic consequences are less intense and are delayed in onset in specialized conduction tissue. In addition to the direct effect of ischemia on normal or previously abnormal tissue, reperfusion after transient ischemia can cause lethal arrhythmias (**see Fig. 42.11**). Reperfusion of ischemic areas can occur by three mechanisms: (1) spontaneous thrombolysis, (2) recruitment of collateral vessels from other vascular beds in response to local ischemia, and (3) reversal of vasospasm. Some mechanisms of reperfusion-induced arrhythmogenesis appear to be related to the

duration of ischemia before reperfusion. Experimentally, there is a window of vulnerability beginning 5 to 10 minutes after the onset of ischemia and lasting up to 20 to 30 minutes.

Electrophysiologic Effects of Acute Ischemia.

Within the first minutes after experimental coronary ligation, there is a propensity to ventricular arrhythmias that abates after 30 minutes and reappears after several hours (**see Chapter 34**). The initial 30 minutes of arrhythmias is divided into two periods, the first of which lasts for approximately 10 minutes and is presumably directly related to the initial ischemic injury. The second period (20 to 30 minutes) may be related either to reperfusion of ischemic areas or to the evolution of different injury patterns in epicardial and endocardial muscle. Multiple mechanisms of reperfusion arrhythmias have been observed experimentally, including slow conduction and reentry and afterdepolarizations and triggered activity.

At the level of the myocyte, the immediate consequences of ischemia, which include alterations in cell membrane physiology, with efflux of ionized potassium (K^+), influx of ionized calcium (Ca^{2+}), acidosis, reduction of transmembrane resting potentials, and enhanced automaticity in some tissues, are followed by a separate series of changes during reperfusion. Those of particular interest are the possible continued influx of Ca^{2+}, which may produce electrical instability; responses to alpha or beta adrenoceptor stimulation, or both; and afterdepolarizations as triggering responses for Ca^{2+}-dependent arrhythmias. Other possible mechanisms studied experimentally include the formation of superoxide radicals in reperfusion arrhythmias and differential responses of endocardial and epicardial muscle activation times and refractory periods during ischemia or reperfusion. The adenosine triphosphate–dependent K^+ current ($I_{K.ATP}$), which is inactive during normal conditions, is activated during ischemia. Its activation results in a strong efflux of K^+ from myocytes and marked shortening of the time course of repolarization, which leads to slow conduction and ultimately to inexcitability. This response is more marked in epicardium than in endocardium, which leads to a prominent dispersion of repolarization across the myocardium during transmural ischemia. At an intercellular level, ischemia alters the distribution of connexin 43, the primary gap junction protein between myocytes. This alteration results in uncoupling of myocytes, a factor that is arrhythmogenic because of altered patterns of excitation and regional changes in conduction velocity.[18]

The state of the myocardium at the onset of ischemia is important. Tissue healed after previous injury appears to be more susceptible to the electrical destabilizing effects of acute ischemia, as is chronically hypertrophied muscle. Remodeling-induced local stretch, regional hypertrophy, or intrinsic cellular alteration may contribute to this vulnerability. Of more direct clinical relevance is the suggestion that potassium depletion by diuretics and clinical hypokalemia may make ventricular myocardium more susceptible to potentially lethal arrhythmias, in part by its effect on repolarization (QT) duration.

The association of metabolic and electrolyte abnormalities and neurophysiologic and neurohumoral changes with lethal arrhythmias emphasizes the importance of integrating changes in the myocardial substrate with systemic influences. Most direct among myocardial metabolic changes in response to ischemia are local acute increase in interstitial K^+ levels to values exceeding 15 mM, decrease in tissue pH to below 6.0, changes in adrenoceptor activity, and alterations in autonomic nerve traffic, all of which tend to create and maintain electrical instability, especially if it is regional in distribution. Other metabolic changes, such as elevation of cyclic adenosine monophosphate levels, accumulation of free fatty acids and their metabolites, formation of lysophosphoglycerides, and impaired myocardial

glycolysis, have also been suggested as myocardial-destabilizing influences.[18] These local myocardial changes integrate with systemic patterns of autonomic fluctuation that can be observed as patterns of altered heart rate variability and fractal dynamics,[120] thus potentially identifying subsets of patients predetermined to be at higher risk for SCD during an ischemic event.

Transition from Myocardial Instability to Lethal Arrhythmias

The combination of a triggering event and a susceptible myocardium is a fundamental electrophysiologic concept for the mechanism of initiation of potentially lethal arrhythmias (**see Figs. 42.5 and 42.7**). The triggering event for VT or VF can be electrophysiologic, ischemic, metabolic, or hemodynamic. For VF, the endpoint of their interaction is disorganization of patterns of myocardial activation into multiple uncoordinated reentrant pathways. Clinical, experimental, and pharmacologic data have suggested that triggering events in the absence of myocardial instability are unlikely to initiate lethal arrhythmias.

Bradyarrhythmias and Asystolic Arrest

The basic electrophysiologic mechanism in asystolic arrest is failure of normal subordinate automatic activity to assume the pacing function of the heart in the absence of normal function of the sinus node, AV junction, or both. Asystolic arrest is more common in severely diseased hearts and in patients with a number of end-stage disorders, both cardiac and noncardiac. These mechanisms may result in part from diffuse involvement of subendocardial Purkinje fibers in advanced heart disease.

Pulseless Electrical Activity

PEA is separated into primary and secondary forms. No one unifying definition for PEA, mechanistically or clinically, is recognized. The common denominator in both forms is the presence of organized cardiac electrical activity in the absence of effective mechanical function.[119] The absence of rapid return of spontaneous circulation (ROSC) is important in that it excludes transient losses of cerebral blood flow, such as the various patterns of vasovagal reflex syncope, which have different clinical implications than the meaning attributed to true PEA. The secondary form of PEA results from an abrupt cessation of cardiac venous return, such as massive pulmonary embolism, acute malfunction of prosthetic valves, exsanguination, and cardiac tamponade from hemopericardium. Primary PEA is the more familiar form, in which none of these obvious mechanical factors is present, but ventricular muscle fails to produce an effective contraction despite continued electrical activity. It usually occurs as an end-stage event in advanced heart disease, but can occur in patients with acute ischemic events or, more often, after electrical resuscitation from prolonged cardiac arrest. Although primary PEA is not thoroughly understood, it appears that diffuse disease, metabolic abnormality, or global ischemia provides the pathophysiologic substrate. The proximate mechanism for failure of electromechanical coupling may be abnormal intracellular Ca^{2+} metabolism, intracellular acidosis, or perhaps depletion of ATP.

Clinical Features of Patients With Cardiac Arrest

Although the pathologic anatomy associated with SCD caused by CAD often reflects the changes associated with acute myocardial injury, less than 20% of survivors of OHCA have clinical evidence of a new transmural MI. Nonetheless, many have elevated enzyme levels along with nonspecific electrocardiographic changes suggesting myocardial damage, which may be caused by transient ischemia as a triggering event or by the loss of myocardial perfusion during the cardiac arrest. The recurrence rate is low in survivors of OHCA caused by transmural MI. In contrast, early studies demonstrated a 30% recurrence rate at 1 year and 45% at 2 years in the survivors who did not have a new transmural MI. Recurrence rates decreased subsequently, probably in part the result of long-term interventions.

Prodromal Symptoms

Patients at risk for SCD can have prodromes such as chest pain, dyspnea, weakness or fatigue, palpitations, syncope, and a number of nonspecific complaints. Several epidemiologic and clinical studies have demonstrated that such symptoms can presage coronary events, particularly MI and SCD, and result in contact with the medical system weeks to months before SCD.

Attempts to identify early prodromal symptoms specific for SCD risk have not been successful. Although several studies have reported that 12% to 46% of fatalities occur in patients who had seen a physician 1 to 6 months before death, such visits are more likely to presage MI or nonsudden death, and most complaints responsible for these visits are not heart related. However, patients who have chest pain as a prodrome to SCD appear to have a higher probability of intraluminal coronary thrombosis at postmortem examination. Fatigue has been a particularly common symptom in the days or weeks before SCD in a number of studies, but this symptom is nonspecific. The symptoms that occur within the last hours or minutes before cardiac arrest are more specific for heart disease and may include symptoms of arrhythmias, ischemia, and heart failure.

Onset of the Terminal Event

Ambulatory recordings fortuitously obtained during the onset of an unexpected cardiac arrest have indicated dynamic changes in cardiac electrical activity during the minutes or hours before the event. Increasing heart rate and advancing grades of ventricular ectopy are common antecedents of VF. Alterations in autonomic nervous system activity may also contribute to onset of the event. Studies of short-term variations in heart rate variability or related measures have identified changes that correlate with the occurrence of ventricular arrhythmias. Although these physiologic properties may be associated with transient electrophysiologic destabilization of the myocardium, the extent to which they are paralleled by clinical symptoms or events has been less well documented.[120] SCDs caused by arrhythmias or acute circulatory failure mechanisms correlate with a high incidence of acute myocardial disorders at the onset of the terminal event. Such disorders are more likely to be ischemic when the death is caused by arrhythmias and to be associated with low-output states or myocardial anoxia when the deaths are caused by circulatory failure.

Cardiac Arrest

Cardiac arrest is characterized by abrupt loss of consciousness caused by lack of adequate cerebral blood flow as a result of failure of cardiac pump function. In contrast to previous data, the most common electrical mechanism of OHCA currently identified by EMS is asystole (50%), with VF/pVT and PEA each estimated in the range of 25%. The extent to which these proportions of first-recorded rhythms reflect the rhythms that trigger the onset of SCA remains unknown because of the lag between onset, 911 contact, and EMS arrival. Mechanical mechanisms include rupture of the ventricle, cardiac tamponade, acute mechanical obstruction to flow, and acute disruption of a major blood vessel, each of which is more likely to present with PEA or asystole.

The potential for successful resuscitation is a function of the setting in which the cardiac arrest occurs, the mechanism of the arrest, and the underlying clinical status of the victim. The decision whether to attempt to resuscitate is closely related to the potential for success.[121]

At present, fewer low-risk patients with otherwise uncomplicated MI are weighting in-hospital cardiac arrest (IHCA) statistics than in the past. In one report, only 14% of patients receiving in-hospital cardiopulmonary resuscitation (CPR) were discharged from the hospital alive, and 20% of these patients died within the ensuing 6 months. Although 41% of the patients had an acute MI, 73% had a history of congestive heart failure, and 20% had experienced previous cardiac arrests. The mean age of 70 years may have influenced the outcome statistics, but patients with high-risk complicated MI and those with other high-risk markers heavily influenced the population of patients at risk for IHCA. Non–cardiac-related clinical diagnoses were dominated by renal failure, pneumonia, sepsis, diabetes, and a history of cancer. The strong male preponderance consistently reported in OHCA studies is not present with in-hospital patients, but the better prognosis of VT or VF mechanisms than PEA or asystolic mechanisms persists (27% versus 8% survival rate). However, the proportion of arrests caused by in-hospital VT or VF is considerably less (33%), with the combination of respiratory arrest, asystole, and PEA dominating the statistics (61%). In another report, a 22% survival rate to hospital discharge was observed. Adverse risks were age older than 70 years, previous stroke or renal failure, and heart failure on admission. Better outcomes were predicted by previous angina pectoris or admission because of ventricular arrhythmias. Strategic factors affecting survival after IHCA include the location in the hospital, the type of hospital, daytime and evening events versus night and weekend events, and a rapid time to performance of defibrillation.[122]

A multihospital study of outcomes after IHCA in pediatric patients demonstrated a major improvement in survival to hospital discharge between 2000 and 2009, with a risk-adjusted improvement from 14.3% in 2000 to 43.4% in 2009.[123] There was neither improvement nor worsening of the proportion with residual neurologic deficits. The proportion with VF or pVT decreased from 22% in 2000 to 2003 to 9.7% in 2007 to 2009, and those with asystole decreased from 51.4% to 20%. In contrast, PEA increased from 26.6% to 70.3%. The reason for the dramatic increase in the proportion of PEA events is not clear because respiratory insufficiency as an initial condition increased only from 68.8% to 75.5%. However, the proportion maintained on mechanical ventilators at the time of arrest did increase from 67.4% (2000 to 2003) to 81.6% (2007 to 2009).

Important risk factors for death after in-hospital CPR are listed in **eTable 42.1**. Survival after IHCA is lower for events that occur during weeknights and weekends than during the daytime and evening hours during the week,[121] and more rapid times to defibrillation are advantageous.[124] Such data suggest the need for additional strategies for uniformly rapid in-hospital responses, as well as for the limitations reported for in-hospital early-warning systems.[125]

ETABLE 42.1

Predictors of Mortality after in-Hospital Cardiopulmonary Resuscitation

Before Arrest
Hypotension (systolic BP <100 mm Hg)
Pneumonia
Renal failure (BUN >50 mg/dL)
Cancer
Homebound lifestyle
During Arrest
Arrest duration >15 min
Intubation
Hypotension (systolic BP <100 mm Hg)
Pneumonia
Homebound lifestyle
After Resuscitation
Coma
Need for pressors
Arrest duration >15 min

BP, Blood pressure; *BUN,* blood urea nitrogen.

Modified from Bedell SE, Delbanco TL, Cook EF, Epstein FH. Survival after cardiopulmonary resuscitation in the hospital. N Engl J Med 1983;309:569.

Among elderly persons, outcomes after community-based responses to OHCA are not as good as for younger victims. In one study comparing persons younger than 80 (mean age, 64) with those in their 80s and 90s, the survival rate to hospital discharge in the younger group was 19.4%, compared to 9.4% for octogenarians and 4.4% for nonagenarians. However, when the groups were analyzed according to markers favoring survival (e.g., VF, pVT), the incremental benefit was even better for the elderly than for the younger patients (36%, 24%, and 17%, respectively), but the frequency of ventricular tachyarrhythmias versus nonshockable rhythms was lower in elderly persons. Overall, advanced age is only a weak predictor of an adverse outcome and should not be used in isolation as a reason not to resuscitate. Long-term neurologic status and length of hospitalization were similar in older and younger surviving patients.

Progression to Biologic Death

The time course for progression from cardiac arrest to biologic death is related to the mechanism of the cardiac arrest, the nature of the underlying disease process, and the delay between onset and resuscitative efforts. The onset of irreversible brain damage usually begins within 4 to 6 minutes after loss of cerebral circulation, and biologic death follows quickly in unattended cardiac arrest. In large series, however, it has been demonstrated that a limited number of victims can remain biologically alive for longer periods and may be resuscitated after delays in excess of 8 minutes before beginning basic life support and in excess of 16 minutes before advanced life support. Despite these exceptions, it is clear that the probability of a favorable outcome—survival neurologically intact—deteriorates rapidly as a function of time after cardiac arrest. Younger patients with less severe cardiac disease and the absence of coexistent multisystem disease have a higher probability of a favorable outcome after such delays.

Irreversible injury to the central nervous system usually occurs before biologic death, and the interval may extend days to weeks and occasionally result in very prolonged persistent vegetative states in patients who are resuscitated during the temporal gap between brain damage and biologic death. IHCA caused by VF is less likely to have a protracted course between the arrest and biologic death, with patients surviving after a prompt intervention or succumbing rapidly because of inability to stabilize their cardiac rhythm or hemodynamics. Overall, patients who have ROSC with persistent neurologic status of

CPC 3 or 4 have a very low survival rate, both in-hospital and at 6 months after arrest.

Patients whose cardiac arrest is caused by sustained VT with cardiac output inadequate to maintain consciousness can remain in VT for considerably longer periods with blood flow that is marginally sufficient to maintain viability. Thus there is a longer interval between the onset of cardiac arrest and the end of the period that allows successful resuscitation. The lives of such patients usually end in VF or an asystolic event (PEA or asystole) if the VT is not reverted.

The progression in patients with asystole or PEA as the initiating event is more rapid. Such patients, whether in or out of hospital, have a poor prognosis because of advanced heart disease or coexistent multisystem disease. They tend to respond poorly to interventions, even if the heart is successfully paced. Although survival from PEA has increased in recent years, it is generally limited to the small subgroup of patients with reversible conditions (e.g., respiratory, electrolyte imbalances) that respond well to interventions, and most progress rapidly to biologic death. Cardiac arrests caused by mechanical factors such as tamponade, structural disruption, and impedance to flow by major thromboembolic obstructions to right or left ventricular outflow are reversible only in patients in whom the mechanism is recognized and an intervention is feasible.

Survivors of Cardiac Arrest

Hospital Course

Cardiac arrests during the acute phase of MI may be primarily related to an electrical event, or secondarily to LV dysfunction or cardiogenic shock. Patients who are resuscitated immediately from primary VF associated with ST-segment elevation myocardial infarction (STEMI) usually stabilize promptly, and they require no long-term arrhythmia management based on the early arrhythmia (**see Chapter 62**). Management after secondary cardiac arrest in MI patients is dominated by the patient's hemodynamic status.

Survivors of OHCA may have repetitive ventricular arrhythmias during the initial 24 to 48 hours of hospitalization. These arrhythmias have variable responses to antiarrhythmic therapy, depending on hemodynamic status. The overall rate of recurrent cardiac arrest is low, 10% to 20%, but the mortality rate in patients who have recurrent cardiac arrests is approximately 50%. Only 5% to 10% of in-hospital deaths after out-of-hospital resuscitation are caused by recurrent cardiac arrhythmias. Patients with recurrent cardiac arrest have a high incidence of new or preexisting AV or intraventricular conduction abnormalities.

The most common causes of death in hospitalized OHCA survivors are noncardiac events related to CNS injury, including anoxic encephalopathy and sepsis related to prolonged intubation and hemodynamic monitoring lines. During the index hospitalization after out-of-hospital resuscitation, 59% of deaths have been reported from these causes. Approximately 40% of those who arrive at the hospital in coma never awaken after admission to the hospital and die after a median survival of 3.5 days. Two thirds of those who regain consciousness have no gross deficits, and an additional 20% have persisting cognitive deficits only. Of the patients who do awaken, 25% do so by admission, 71% by the first hospital day, and 92% by the third day. A small number of patients have awakened after prolonged hospitalization. Among those who die in the hospital, 80% do not awaken before death. Therapeutic hypothermia in patients with post–cardiac arrest coma is beneficial[126,127] (see next section).

Cardiac causes of delayed death during hospitalization after OHCA are most often related to hemodynamic deterioration, which accounts for about one third of deaths in hospitals. Among all deaths, those that occurred within the first 48 hours of hospitalization were usually caused by hemodynamic

deterioration or arrhythmias regardless of neurologic status; later deaths were dominated by neurologic complications. Admission characteristics most predictive of subsequent awakening included motor response, pupillary light response, spontaneous eye movement, and blood glucose level below 300 mg/dL.

Clinical Profile of Survivors of Out-of-Hospital Cardiac Arrest

The clinical features of OHCA survivors are heavily influenced by the type and extent of the underlying disease associated with the event. Causation is dominated by coronary heart disease and cardiomyopathies. All other structural heart diseases plus functional abnormalities and toxic or environmental causes are responsible for the remainder.

In a study of 63 survivors of OHCA with normal EF and no obvious heart disease, no cause was identified after intensive studies in 44% of the patients.[128] The remainder were found to have LQTS (23%), catecholaminergic polymorphic VT (23%), RV dysplasia (17%), ER (14%), coronary spasm (11%), BrS (9%), and myocarditis (3%). The mean age of this group was 43 years, and 46% had had no previous history of presyncope or syncope.

Postresuscitation Electrocardiographic Changes

Among survivors of OHCA, the 12-lead ECG has proved to be of value only for discriminating risk for recurrence in those whose cardiac arrest was associated with new transmural MI (**see Chapter 12**). Patients in whom documented new Q waves develop in association with a clinical picture that supports acute STEMI as the mechanism of cardiac arrest itself are at lower risk for recurrence, unless they develop criteria for post-MI primary prevention, such as EF less than 30%. In contrast, nonspecific electrocardiographic markers of ischemia, associated with elevation of troponin or creatine kinase MB levels, indicate higher risk for recurrence. Nonspecific repolarization abnormalities (e.g., ST-segment depression, flat T waves) are frequently present, often transiently, after a cardiac arrest. Transient prolongation of the QT interval, often associated with postresuscitation hypokalemia, can follow CPR and is associated with risk of recurrent arrhythmias. A prolonged QRS duration in association with a greatly reduced EF portends increased risk for mortality.

Left Ventricular Function

LV function is abnormal in most survivors of OHCA, often severely abnormal, but ranging from severe dysfunction to normal or near-normal measurements.[129] The severity of MI estimated shortly after cardiac arrest results from a combination of myocardial stunning caused by the cardiac arrest itself and the extent of preexisting dysfunction. Stunning usually improves within the first 24 to 48 hours,[130] and the residual is assumed to be a result of preexisting disease or the acute injury leading to the cardiac arrest. Reliance on postarrest troponin elevations alone to determine whether MI caused a cardiac arrest can be treacherous, because cardiac arrest and even non–life-threatening sustained arrhythmias, as well as ICD shocks, can be associated with transient elevations.[131] If the EF is severely reduced initially, failure to begin improvement within the first 48 hours is an adverse short-term prognostic sign. In a study of resuscitated OHCA victims admitted to the hospital and subsequently discharged neurologically intact, 47% had acute coronary syndromes identified during evaluation and had a mean EF of 42%, compared to 32% in nonsurvivors.[132] Among survivors to hospital discharge, a reduced EF is an adverse long-term prognostic sign.

Exercise Testing

Exercise testing is no longer commonly used to evaluate the need for and response to anti-ischemic therapy in OHCA survivors, except when transient ischemia is in question as a mechanism for onset (**see Chapter 13**). The probability of a positive test result related to ischemia is relatively low, although termination of testing because of fatigue is common. Mortality during follow-up is higher in patients who fail to achieve a normal rise in systolic blood pressure during exercise.

Coronary Angiography

Coronary angiography is performed with increasing frequency during initial hospitalization after OHCA. In a recent report based on data from the National Inpatient Sample, 143,607 of 407,974 OHCA survivors (35.2%) underwent coronary angiography, increasing from 27.2% in 2000 to 43.9% 2012, and percutaneous coronary intervention (PCI) increased from 9.5% in 2000 to 24.1% in 2012.[133] OHCA survivors tend to have extensive coronary disease but no specific pattern of abnormalities. Acute coronary lesions, often multifocal, are present in many survivors. Significant lesions in two or more vessels are present in at least 70% of patients who have any coronary lesion. Patients with recurrent cardiac arrests have a higher incidence of triple-vessel disease than those without recurring arrest.. However, the frequency of moderate to severe stenosis of the left main coronary artery does not differ between cardiac arrest survivors and the overall population of patients with symptomatic coronary heart disease.

Blood Chemistry

Serum potassium levels are lower in survivors of cardiac arrest than in patients with acute MI or stable coronary heart disease. This finding is often a consequence of resuscitation interventions rather than a preexisting hypokalemic state because of chronic diuretic use or other causes. Among survivors who are hypokalemic during the first 12 to 24 hours after SCA, serum K^+ levels following stabilization should be checked to exclude a chronic potassium-wasting state. Low Ca^{2+} levels with normal total calcium levels were also observed during OHCA resuscitation. Higher resting lactate levels have been reported in OHCA survivors than in normal individuals. Lactate levels are correlated inversely with EF and directly with PVC frequency and complexity.

Long-Term Prognosis

Studies from Miami, Florida, and Seattle, Washington, in the early 1970s had indicated that the risk for recurrent cardiac arrest in the first year after survival of an initial VT/VF event was approximately 30% and at 2 years was 45%. Total mortality at 2 years was approximately 60% in both studies. More recent mortality data, including those from the control groups of secondary prevention ICD trials,[72] have demonstrated 2-year mortality rates between 15% and 25%. The apparent improved outcomes, independent of the benefit provided by ICD therapy, are probably attributable to the current interventions used in survivors, such as beta adrenoceptor blockers, statins and angiotensin-converting enzyme (ACE) inhibitors/angiotensin receptor blockers (ARBs), anti-ischemic procedures, and heart failure therapies that were not previously available or in general use. The risk for recurrent cardiac arrest and all-cause mortality is higher during the first 12 to 24 months after the index event and relates best to the EF during the first 6 months.

Management of Cardiac Arrest

The response to cardiac arrest is driven by two principles: (1) maintaining continuous cardiopulmonary support until ROSC has been achieved and (2) achieving ROSC as quickly as possible. To meet these goals, the management strategy is divided into five elements: (1) initial assessment by a witness/bystander and summoning of an emergency response team, (2) basic life support (BLS), (3) early defibrillation by a first responder (if available), (4) advanced life support, and (5) post–cardiac arrest care. If successful, the algorithm is followed by a sixth element, long-term management. The initial elements can be applied by physicians and nurses, emergency medical technicians (EMTs) or paramedics, laypeople trained in bystander interventions, and untrained bystanders prompted in CPR by 911 telecommunicators trained to prompt callers in BLS technique. Emerging data suggest that telephone prompts by 911 operators can improve survival with preserved neurologic status.[134] Requirements for specialized knowledge and skills increase progressively as the patient is moved through post–cardiac arrest management into long-term follow-up care. These emergency response principles are intended for both in-hospital and community-based responses.

In-Hospital Interventions

Development of the coronary care unit (CCU) resulted in an immediate reduction of in-hospital mortality risk during acute MI from 30% to 15% based almost entirely on the reduction of cardiac arrests. Other specialized monitoring and intensive care units demonstrated various levels of benefit as well, but the impact has been less in general care hospital units and for cardiac arrests associated with complex comorbid states.[135] A registry study from 2000 to 2009 provided trends for risk-adjusted rates of survival to discharge after cardiac arrest in monitored units and general hospital units.[136] Among 84,625 patients, 20.7% had VF or pulseless VT (pVT) as the initial rhythm, and 79.3% had asystole or PEA, with the proportion of cardiac arrests attributable to asystole/PEA increasing over time ($P < 0.001$). The overall survival rate to discharge increased from 13.7% in 2000 to 22.3% in 2009 ($P < 0.001$), with improvement in both the VT/VF and the PEA/asystole subsets (**Fig. 42.12A**). Absolute rates of survival to discharge remained higher for the VT/VF group, whereas improvement in survival occurred in the two rhythm groups. The improvement in survival appeared to be a result of both improved acute resuscitation actions and postresuscitation care. A small decrease in rates of clinically significant neurologic disability in survivors occurred over time (32.9% in 2000 and 28.1% in 2009 ([$P = 0.02$]).

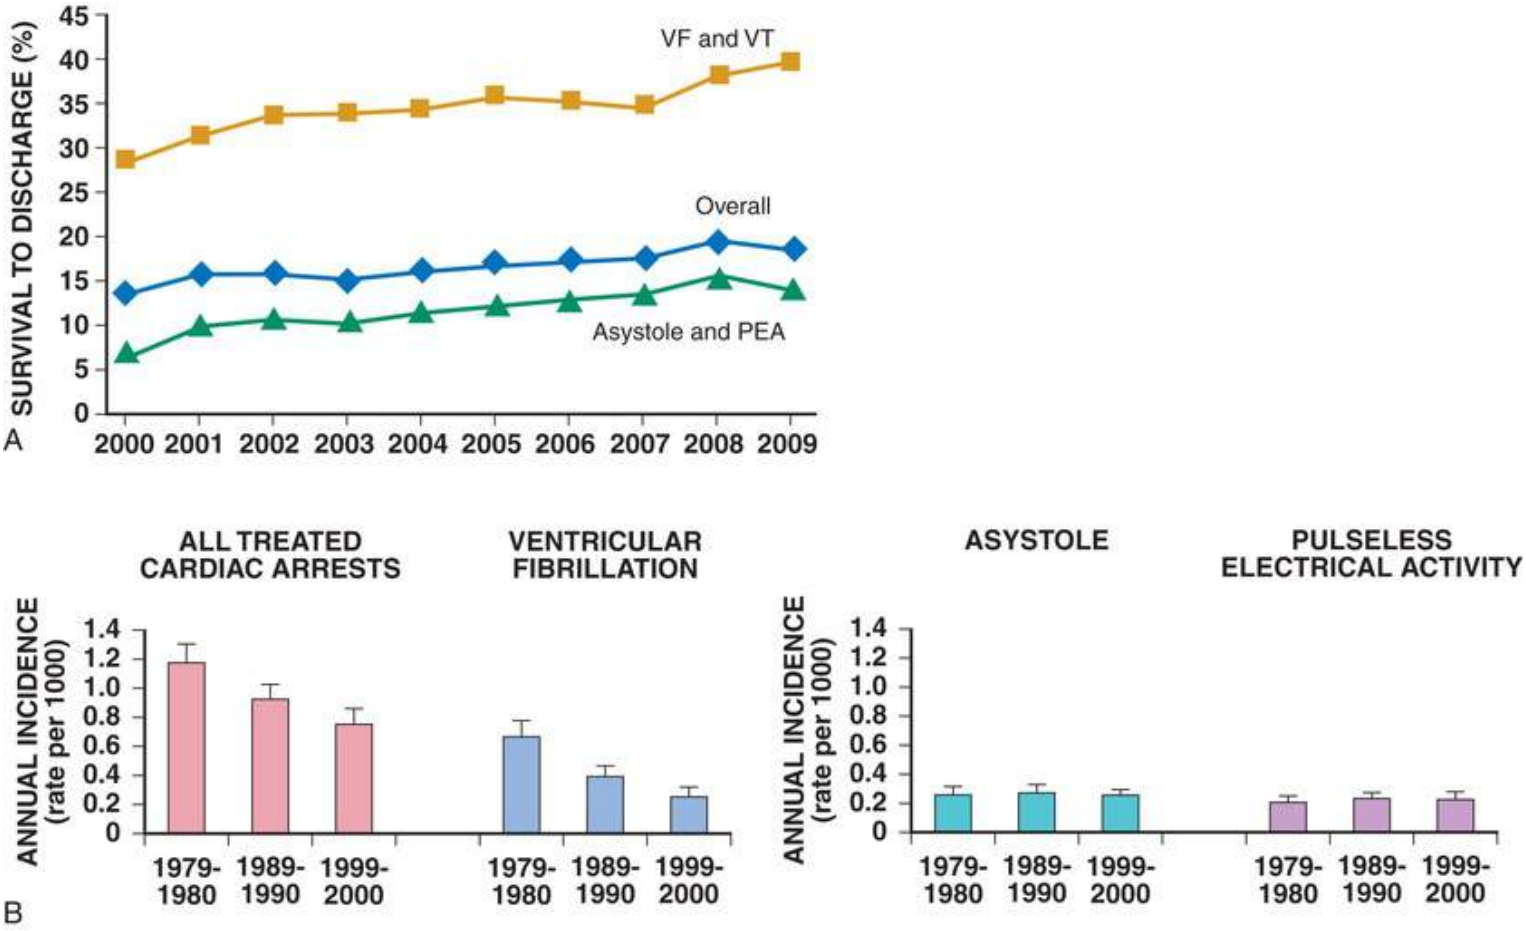

FIGURE 42.12 Changing incidence of shockable and nonshockable rhythms. **A,** Survival to discharge for VF and pulseless VT versus asystole and PEA between 2000 and 2009 ($P < 0.001$ for trend in each survival curve). **B,** Between 1980 and 2000 a progressive decrease in the VF event rate occurred in the Seattle, Washington, community for unexplained reasons. Of note, no concomitant increase in nonshockable rhythms took place. The proportion of events with VF at initial contact is decreasing, as observed in several other studies. (**A,** From Girotra S, Nallamothu BK, Spertus JA, et al. Trends in survival after in-hospital cardiac arrest. N Engl J Med 2012;367:1912; **B,** modified from Cobb LA, Fahrenbruch CE, Olsufka M, Copass MK. Changing incidence of out-of-hospital ventricular fibrillation, 1980-2000. JAMA2002;288:3008.)

Community-Based Interventions

The initial out-of-hospital intervention experience in Miami and Seattle yielded only 14% and 11% rates of survival to discharge, respectively (**eFig. 42.2**). Subsequent improvements correlated with the addition of EMTs as another tier of responders to provide CPR and earlier defibrillation. In general, rural areas have lower success rates, and the U.S. national success rate is probably 5% or less. Regional variability is highlighted by a 10-community analysis in the United States and Canada demonstrating a range of VF survival rates from 0% to 39.5%.[15]

HISTORY OF COMMUNITY-BASED EMERGENCY RESPONSE SYSTEMS

1971-1974	Initial Miami/Seattle outcomes	14%, 11%
1978-1985	Peak Miami/Seattle outcomes	25%-35%
1984	Rural outcomes:	
	• Standard basic life support	3%
	• Ambulance-based expanded access	19%
1991	Estimated cumulative U.S. survival	1%-3%
1992-1994	Major metropolitan population centers	2%
1996	Dade County, Florida, current outcomes	9%
1996-1998	Updated U.S. EMS outcomes, cumulative	<5%
1999	"Optimized" EMS systems [OPALS]	5%
2000-2004	Nonconventional responders:	17% to >50%
	Public access sites [police, security guards, airline personnel, laypersons; airports and airliners, malls, casinos, stadiums]	

EFIGURE 42.2 The history of out-of-hospital cardiac arrest survival statistics demonstrates that standard emergency rescue systems are not sufficient to have a meaningful impact on sudden cardiac death in the community. *EMS,* Emergency medical services. (From Myerburg RJ. Sudden cardiac death: exploring the limits of our knowledge. J Cardiovasc Electrophysiol 2001;12:369.)

Reports from different areas in the United States show marked variations in outcomes.[137] Some very densely populated areas (i.e., Chicago and New York City) have provided disturbing outcome data. A study from Chicago reported that only 9% of OHCA victims survive to be hospitalized, and only 2% are discharged alive. Moreover, outcomes in blacks are much worse than in whites (0.8% versus 2.6%). A large majority had bradyarrhythmias, asystole, or PEA on initial contact with EMS, which suggests prolonged times between collapse and EMS arrival, absent or ineffective bystander interventions, or both. The New York City report indicated a survival to hospital discharge rate of only 1.4%. Among those who undergo bystander CPR, the rate increases to 2.9%, and bystander CPR plus VF as the initial rhythm yields a further increase to 5.3%. For those whose arrest occurred after EMS arrival, the success rate increases further to 8.5%. These trends support the concept that delays and breaks in the "chain of survival"[121] have a major negative impact on EMS results in densely populated areas.[137]

In some circumstances, resuscitative effort in the out-of-hospital setting is deemed futile. A victim found unconscious after an unwitnessed collapse, reasonably assumed to be found after a prolonged interval (e.g., cool skin, rigor mortis), obviously fulfills this classification. However, studies have provided markers of futility under less stark circumstances. In a study involving trained responders with automated external defibrillators (AEDs), only 0.5% of victims survived if (1) the arrest was not witnessed by EMS personnel, (2) there was no ROSC, and (3) no shocks were delivered per protocol. Adding a response time longer than 8 minutes reduced the survival rate to 0.3%, and events unwitnessed by a bystander yielded no survivors.

Impact of Tiered Response Systems

Improvements in both out-of-hospital care and in-hospital technology and practices can contribute to better outcomes, as described in the chain-of-survival concept.[121] Of these two general factors, the influence of out-of-hospital care has been studied in more detail.[138] Many studies support the importance of early defibrillation for improving outcome (**eFig. 42.3**). These observations have motivated a search for strategies that shorten response times, largely by the development of two-tiered systems, in which nonconventional first responders, such as police, firemen, security guards, and lay bystanders, deploy AEDs now commonly available in public places (**Fig. 42.13**). Available data suggest that this strategy may improve outcome, primarily in public locations.[13,139]

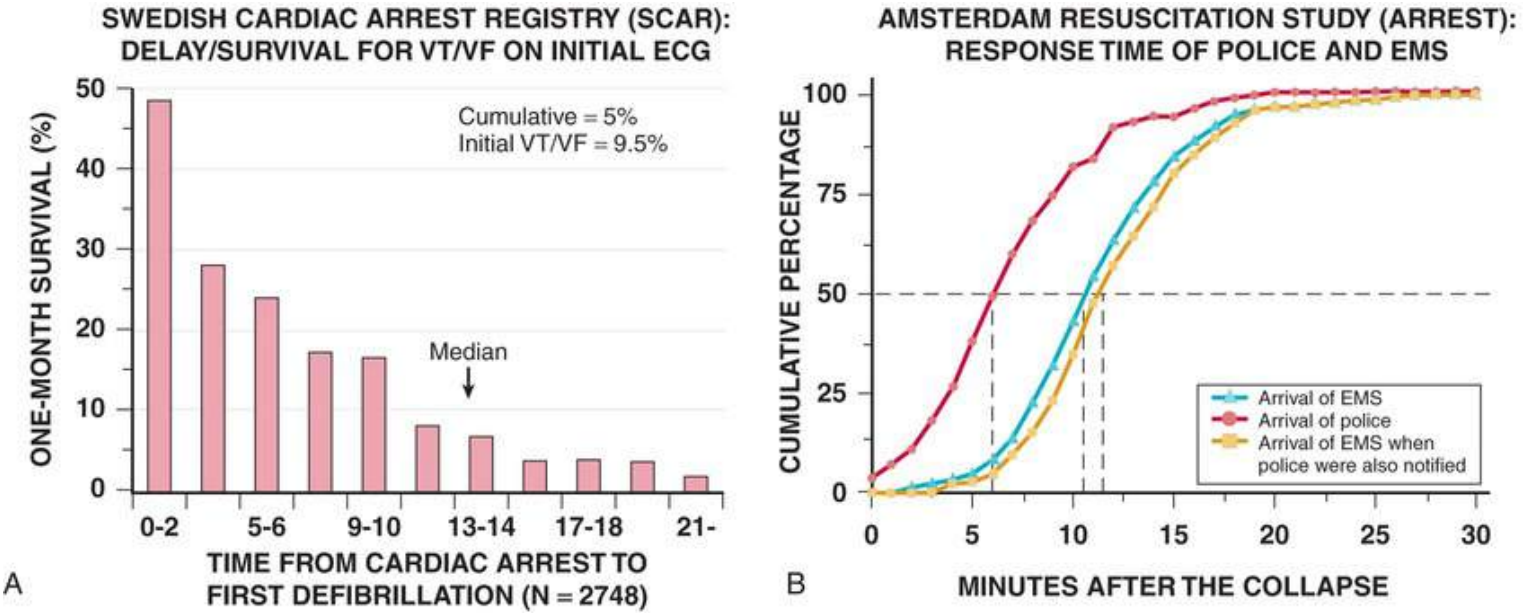

FIGURE 42.13 Influence of response time on survival from out-of-hospital cardiac arrest. **A,** The time from the onset of cardiac arrest to the initial defibrillation attempt is related to 1-month survival on the basis of data from the Swedish Cardiac Arrest Registry. The cumulative survival rate was 5%, and the survival rate for victims whose initial rhythm was VT or VF was 9.5%. The median response time was almost 13 minutes. Thirty-day survival rates ranged from a maximum of 48% with responses shorter than 2 minutes to less than 5% with response time longer than 15 minutes. **B,** Potential for faster response systems based on the Amsterdam Resuscitation Study. The response times of police vehicles are compared with those of conventional emergency medical services (EMS). At the 50th percentile of response times, police vehicles provided an almost 5-minute improvement in arrival time (approximately 6 minutes). (**A,** Modified from Holmberg M, Holmberg S, Herlitz J. The problem of out-of-hospital cardiac arrest: prevalence of sudden death in Europe today. Am J Cardiol 1999;83:88D; **B,** modified from Waalewijn RA, de Vos R, Koster RW. Out-of-hospital cardiac arrests in Amsterdam and its surrounding areas: results from the Amsterdam Resuscitation Study [ARREST] in "Utstein" style. Resuscitation 1998;28:157.)

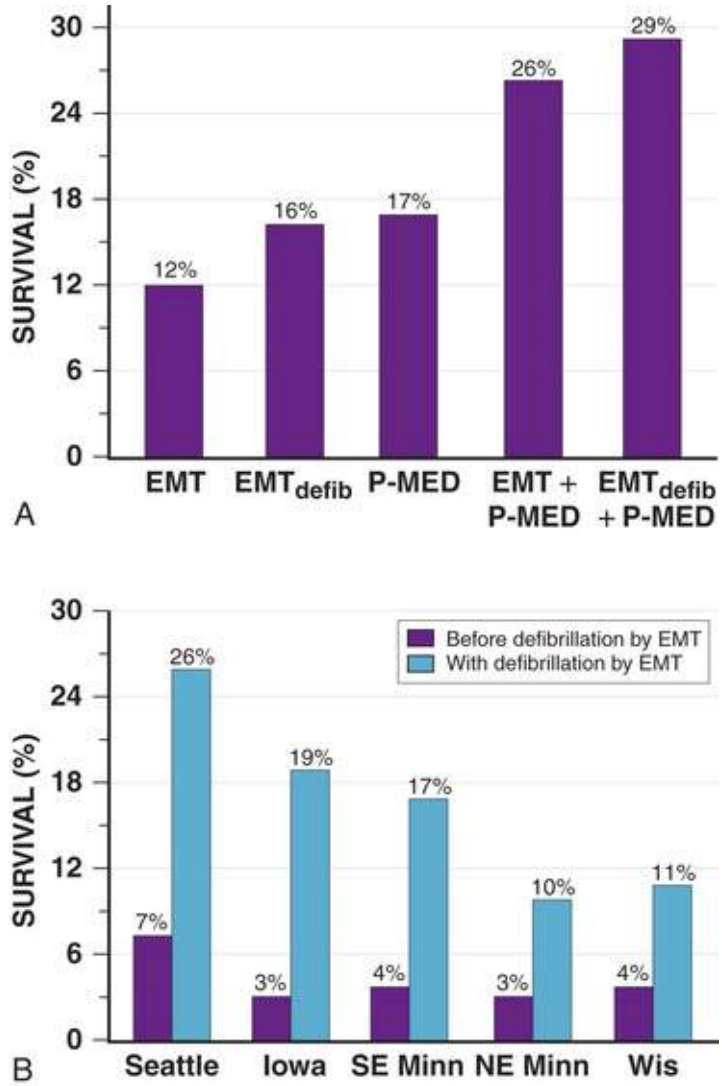


EFIGURE 42.3 Impact of emergency rescue system design and immediate defibrillation on out-of-hospital cardiac arrest survival. **A,** Percent survival to hospital discharge with rescue activities by standard emergency medical technicians (EMTs) trained in cardiopulmonary resuscitation (CPR), EMTs allowed to defibrillate immediately (EMT_{defib}), initial response by paramedics (P-MED), two-tiered system with EMT and P-MED, and two-tiered system with EMTs allowed to defibrillate if they are the first responders plus P-MED. Training of first-responders (EMT_{defib}) and a two-tiered system have the best outcome. **B,** Comparison of outcomes observed in five geographic areas, with EMTs providing only CPR (*purple*) versus EMTs trained to defibrillate as first responders (*blue*). Each group had a marked improvement in outcome when EMTs were trained and permitted to defibrillate. (Modified from Ornato JP, Om A. Community experience in treating out-of-hospital cardiac arrest. In Akhtar M, Myerburg RJ, Ruskin JN, editors: Sudden Cardiac Death: Prevalence, Mechanisms and Approach to Diagnosis and Management. Baltimore: Williams & Wilkins; 1994, p 450.)

In rural communities, earlier defibrillation by ambulance technicians yielded a 19% survival rate, versus only 3% for standard CPR. In another report, analysis of the relationship between response delay and survival to hospital discharge revealed a 48% survival rate for response times of 2 minutes or less and less than 10% survival when response was longer than 10 minutes (**Fig. 42.13**). The mean response time was approximately 13 minutes, and the overall survival rate was 5%. Survival was 9.5% for those in VT or VF on first contact. A second element in out-of-hospital care that contributes to outcome is the role of bystander CPR by laypeople awaiting EMS arrival.[140] Although there was no significant difference in the percentage of patients successfully resuscitated and admitted to the hospital alive with (67%) or without (61%) bystander intervention, almost twice as many OHCA victims were ultimately discharged alive when they had undergone bystander CPR (43%) than when such support was not provided (22%). CNS protection, expressed as early regaining of consciousness, is the major protective element of bystander CPR. The rationale for bystander intervention is further highlighted by the relationship between

time to defibrillation and survival when analyzed as a function of time to initiation of basic CPR. It has been reported that more than 40% of victims whose defibrillation and other advanced life support activities were instituted more than 8 minutes after collapse survived if basic CPR had been initiated less than 2 minutes after onset of the arrest. A period of CPR before defibrillation may also be helpful, particularly if the time to defibrillation exceeds 4 minutes from the onset of arrest.[141]

Importance of Electrical Mechanisms

Several sources have identified a changing distribution of initial rhythms recorded by EMS personnel. Compared with data from the 1970s and 1980s, there has been a decrease in the number of events in which ventricular tachyarrhythmias are the initial rhythm recorded, with a consequent reduction in the proportion of victims who have rhythms amenable to cardioversion-defibrillation (**see Fig. 42.12B**). Similar observations have been reported for in-hospital settings.[136,142] Some studies now suggest that less than 50% of victims have shockable rhythms at initial contact. This fact is paralleled by a reduction in cumulative survival probability with community-based interventions,[11,119] even with a smaller percentage of shockable rhythms.[143] It is likely that pre-911 delays in recognition of and reaction to an event may be playing a role, in conjunction with longer response times based on geographic considerations. This suggests a need for more extensive public education programs. Thus response times may not accurately reflect true downtimes, and consequently the potential for success is impaired. The 4- to 6-minute time for a desirable response is not optimal. By 4 minutes, significant circulatory and ischemic changes have taken place, and conditions worsen rapidly beyond that time.

The electrical mechanism of OHCA, as defined by the initial rhythm recorded by EMS personnel, has a powerful impact on outcome. They are generally categorized as shockable (VF, pVT) and nonshockable (PEA, asystole) rhythms[119] (**Table 42.6**). The distinction between pVT and PEA is sometimes confused and has relevance because it impacts response strategies. The subgroup of patients who are in pVT at the time of first contact, although small, has the best outcome. Of patients in cardiac arrest related to VT, 88% were successfully resuscitated and admitted to the hospital alive, and 67% were ultimately discharged alive. However, this relatively low-risk group represents only 7% to 10% of all cardiac arrests. Because of the inherent time lag between collapse and initial recordings, it is likely that many more cardiac arrests begin as rapid, sustained VT and degenerate into VF before the arrival of rescue personnel.

TABLE 42.6

Tachyarrhythmic and Nontachyarrhythmic Cardiac Arrest

PRIMARY ARRHYTHMIAS	ELECTRICAL MECHANISMS	MECHANICAL MECHANISMS
Tachyarrhythmic Cardiac Arrest		
Ventricular fibrillation (VF)	Absence of organized ventricular depolarization	Absence of LVWM
Pulseless ventricular tachycardia	Organized ventricular pattern; rapid rate	Absent LVWM or LVWM insufficient for organ perfusion
Secondary Arrhythmias		
Sinus tachycardia; other	Sinus or other supraventricular rhythm; narrow QRS complex	Obstruction to cardiac blood flow; hypovolemia
Nontachyarrhythmic Cardiac Arrest		
PEA, Primary (Initial Rhythm)		
With residual LV contraction	Organized QRS complexes, usually wide	LVWM insufficient for organ perfusion
Without LV contraction	Organized QRS complexes, usually wide	Absence of LVWM
PEA, Secondary		
Postshock	Regular or irregular QRS complexes, usually wide	Absent LVWM or LVWM insufficient for organ perfusion
Primary noncardiac	Regular or irregular QRS complexes, usually wide	Usually LVWM insufficient for organ perfusion; LVWM may be absent
Agonal PEA	Slow, usually irregular, wide QRS	Absence of LVWM
Ventricular asystole	Absent ventricular electrical activity; exclude fine VF	Absence of LVWM

LV, Left ventricular; *LVWM,* left ventricular wall motion; *PEA,* pulseless electrical activity.

Modified from Myerburg RJ, Halperin H, Egan D, et al. Pulseless electrical activity: definition, causes, mechanisms, management, and research priorities for the next decade. Report from a National Heart, Lung, and Blood Institute Workshop. Circulation 2013;128:2532.

Patients with a bradyarrhythmia or with asystole or PEA at initial contact have the worst prognosis; only 9% of such patients in the Miami study were admitted to the hospital alive, with none discharged. In a later experience, some improvement in outcome was noted, although this was limited to patients in whom the initial bradyarrhythmia recorded was an idioventricular rhythm that responded promptly to chronotropic agents in the field. In a large, prospective, observational in-hospital study of cardiac arrests in children and adults, children had a higher probability of asystole or PEA as the initial documented rhythm, but had a better overall survival rate because they had better outcomes of interventions for these rhythms than adults.[142] Overall survival after PEA appears to be better in recent years,[143] but it is not clear whether this applies to asystole.

Bradyarrhythmias also have adverse prognostic implications after defibrillation from VF in the field. Patients with a heart rate lower than 60 beats/min after defibrillation, regardless of the specific bradyarrhythmic mechanism, had a poor prognosis, with 95% of such patients dying before hospitalization or in the hospital. The outcome in the group of patients in whom VF is the initial rhythm recorded is intermediate between the outcomes associated with sustained VT and with bradyarrhythmia and asystole. Of such patients, 40% were resuscitated successfully and admitted to the hospital alive, and 23% were ultimately discharged alive. Later data indicate improvement in outcome. The proportion of each of the electrophysiologic mechanisms responsible for cardiac arrest varied among the earlier reports, with VF ranging from 65% to more than 90% of the study populations, and bradyarrhythmia and asystole ranging from 10% to 30%. In reports from densely populated metropolitan areas, however, the ratios of tachyarrhythmic to bradyarrhythmic or pulseless activity events were reversed, and outcomes were much worse.[137]

Initial Assessment and Basic Life Support

Activities at initial contact with the unconscious victim include diagnostic maneuvers and basic cardiopulmonary support interventions. The first action must be confirmation that collapse is or is suspected of being a cardiac arrest. A few seconds of evaluation for response to voice, observation for respiratory movements and skin color, and simultaneous palpation of major arteries for the presence or

absence of a pulse yields sufficient information to determine whether a life-threatening incident is in progress. Once a life-threatening event has been suspected or confirmed, contact with an available emergency medical rescue system (911) for out-of-hospital settings or a “code” team in the hospital should be an immediate priority.

The absence of a carotid or femoral pulse detected by a medical professional, particularly if it is confirmed by the absence of an audible heartbeat, is a primary diagnostic criterion. For lay responders, the pulse check is no longer recommended.[121] Skin color may be pale or intensely cyanotic. Absence of respiratory effort or the presence of only agonal respiratory effort in conjunction with an absent pulse is diagnostic of cardiac arrest; however, respiratory effort can persist for 1 minute or longer after onset of the arrest. In contrast, absence of respiratory effort or the presence of severe stridor with persistence of a pulse suggests a primary respiratory arrest that will lead to cardiac arrest in a short time. In the latter circumstance, initial efforts should include exploration of the oropharynx in search for a foreign body and performance of the Heimlich maneuver, particularly if the incident occurs in a setting in which aspiration is likely (e.g., restaurant death or café coronary).

Chest Thump

A blow to the chest (precordial thump, “thumpversion”) may be attempted by a properly trained rescuer. It has been recommended that it be reserved as an advanced life support activity.[139] Its use has been supported on the basis of a prospective study involving 5000 patients. Precordial thumps successfully reverted apparent VF in 5 events, VT in 11, asystole in 2, and undefined cardiovascular collapse in 2 others in which the electrical mechanism was unknown. In no case was conversion of VT to VF observed. Because the latter is the only major concern and electrical activity can be initiated by mechanical stimulation in an asystolic heart, the technique is considered optional for responding to a pulseless cardiac arrest in the absence of monitoring when a defibrillator is not immediately available. It should not be used unmonitored in a patient with a rapid tachycardia without complete loss of consciousness. The thumpversion technique involves one or two blows delivered firmly to the junction of the middle and lower thirds of the sternum from a height of 8 to 10 inches (20 to 25 cm). The effort should be abandoned if a spontaneous pulse does not develop immediately. Another mechanical method, which requires that the patient still be conscious, is so-called cough-induced cardiac compression. It is a conscious act of forceful coughing by the patient that may support forward flow by cyclic increases in intrathoracic pressure during VF or may cause conversion of sustained VT. Available data supporting its successful use are limited; it is not an alternative to conventional techniques.

Basic Life Support—Initial Steps in Cardiopulmonary Resuscitation

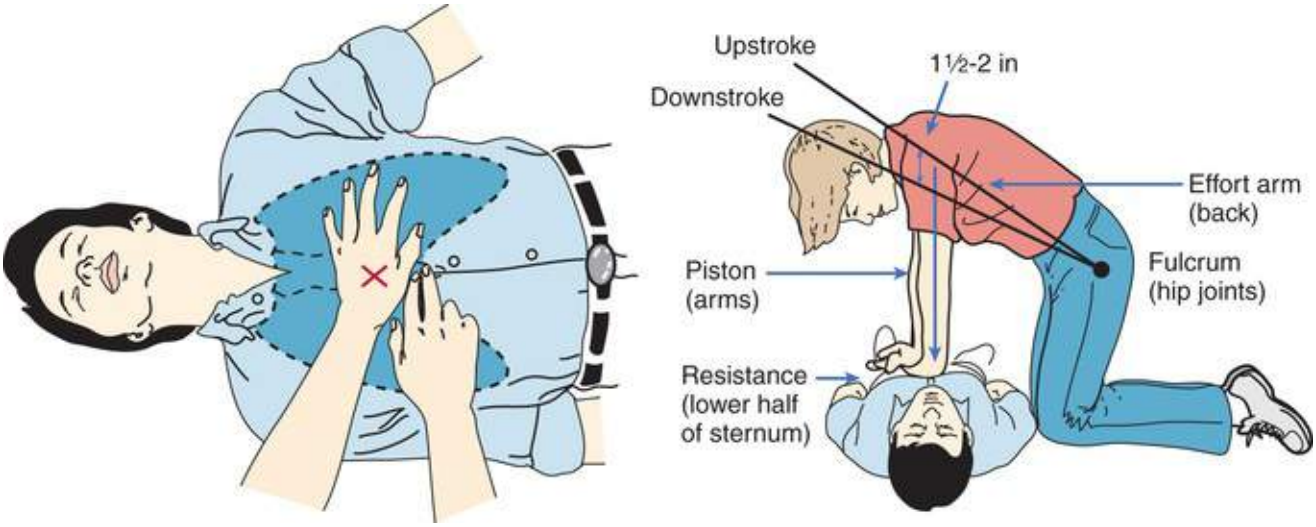
The goal of BLS is to maintain viability of the central nervous system, heart, and other vital organs until definitive return of spontaneous circulation can be achieved. BLS encompasses both the initial responses outlined earlier and their natural flow into establishing perfusion and ventilation. This range of activities can be carried out not only by professional and paraprofessional personnel but also by trained EMTs and laypeople. There should be minimal delay between diagnosis and preparatory effort in the initial response and institution of BLS. The first steps are to verify the environmental safety of the site and confirm that the victim is unresponsive.[144] The responder should call for nearby help, activate an emergency response system (via mobile device, if appropriate), and send for an AED.

These principles have measurable impact for both OHCA and IHCA. The survival rate to discharge for IHCA, considering all causes and mechanisms, was reported to be 33% when CPR was initiated within

the first minute, versus 14% when the time was longer than 1 minute (odds ratio [OR], 3.06).[124] When VF was the initial rhythm, the corresponding figures were 50% and 32%, respectively. In OHCA, if only one witness is present, notification of emergency personnel (calling 911) is the only activity that should precede BLS. The previous sequence of the "ABC" of basic life support—airway, breathing, compression—has been changed to "CAB"—compression, airway, breathing—based on the recognition that compression alone is the better strategy[145] because it minimizes interruptions in perfusion and avoids excessive ventilation.[121]

Circulation

This element of BLS is intended to maintain blood flow (i.e., circulation) until definitive steps can be taken. The rationale is based on the hypothesis that chest compression allows the heart to maintain an externally driven pump function by sequential emptying and filling of its chambers, with competent valves favoring forward direction of flow. In fact, application of this technique has proved successful when it is used as recommended.[121] The palm of one hand is placed over the lower half of the sternum and the heel of the other rests on the dorsum of the lower part of the hand. The sternum is then depressed, with the resuscitator's arms straight at the elbows to provide a less tiring and more forceful fulcrum at the junction of the shoulders and back (**eFig. 42.4**). By use of this technique, sufficient force is applied to depress the sternum at least 2 inches (5 cm). Compressions should be followed by abrupt relaxation, and the cycle is carried out at a rate of about 100 compressions/min.[121]



EFIGURE 42.4 External chest compression. **Left,** Locating the correct hand position on the lower half of the sternum. **Right,** Proper position of the rescuer, with the shoulders directly over the victim's sternum and the elbows locked. (From National Academy of Sciences, National Research Council. Standards and guidelines for cardiopulmonary resuscitation [CPR] and emergency cardiac care [ECC]. JAMA 1986;255:2906.)

Techniques of CPR based on the hypothesis that increased intrathoracic pressure is the prime mover of blood, rather than cardiac compression itself, have been evaluated, and the guidelines for conventional CPR ventilatory techniques were modified in 2005. For single responders to victims from infants (excluding newborns) to adults, and for two-rescuer response to adults, a compression/ventilation ratio of 30 : 2 is now recommended.[121] For two-rescuer CPR in infants and children, the former compression/ventilation ratio of 15 : 2 is retained. A more recent modification intended to encourage more bystander participation in CPR and to allay concerns about mouth-to-mouth ventilation of unknown victims is the "hands-only" (compression-only) technique.[146] This technique is particularly important for

untrained or remotely trained bystanders who are not confident in their ability to perform compression-ventilation sequences. The 2005 changes in CPR recommendations, in which the number of successive shocks and pulse checks during initial responses is reduced (see later, Defibrillation-Cardioversion, and **Chapter 36**), are retained in the 2010 recommendations. This is intended in part to increase the cumulative time of circulatory support during CPR before restoration of a spontaneous pulse.

Concept of Cardiocerebral Resuscitation

Cardiocerebral resuscitation, also referred to as "minimally interrupted cardiac resuscitation," is based on the hypothesis that the primary benefit of CPR is its pumping action rather than the combination of compression and ventilation. It challenges the general guidelines, which assume a benefit of interrupting compression to provide ventilation, and that an initial phase of ventilation before initial defibrillation improves outcomes when response times are longer than 4 or 5 minutes. Cardiocerebral resuscitation emphasizes continuous chest compressions, interrupted primarily for single shocks and evaluation of responses to shocks, and deferring and limiting ventilatory and certain pharmacologic actions. Data from studies in Japan[147] and the United States[148] suggest a neurologically intact survival advantage of the cardiocerebral protocol over conventional CPR based on the 2000 guidelines and 2005 update. For witnessed arrests with documented VF, the study from Japan demonstrated a neurologically intact survival rate advantage of 22% versus 10%. The two recent reports from the United States demonstrated comparable advantages of 39% versus 15% for neurologically intact survival and 28.4% versus 11.9% for survival, respectively. Despite these interesting data, it remains generally agreed that a randomized trial is needed before the minimal interruption concept can replace the current guidelines.

Even though conventional techniques produce measurable carotid artery flow with a record of successful resuscitations, the absence of a pressure gradient across the heart in the presence of an extrathoracic arteriovenous pressure gradient has led to the concept that it is not cardiac compression per se but rather a *pumping action* produced by changes in pressure in the entire thoracic cavity that optimizes systemic blood flow during resuscitation. Experimental work in which the chest is compressed during ventilations rather than between them (simultaneous compression-ventilation) has demonstrated better extrathoracic arterial flow. However, increased carotid artery flow does not necessarily equate with improved cerebral perfusion, and the reduction in coronary blood flow caused by elevated intrathoracic pressure with the use of certain techniques may be too high a price for the improved peripheral flow. In addition, a high thoracoabdominal gradient has been demonstrated during experimental simultaneous compression-ventilation, which could divert flow from the brain in the absence of concomitant abdominal binding. On the basis of these observations, new mechanically assisted techniques, including an active decompression phase (i.e., active compression-decompression), have been evaluated for improved circulation during CPR.[149] More clinical studies are needed before their general clinical application can be established.

Airway

Clearing of the airway is a critical step in preparing for successful resuscitation. This process includes tilting the head backward and lifting the chin, in addition to exploring the airway for foreign bodies, including dentures, and removing them. The Heimlich maneuver should be performed if there is reason to suspect that a foreign body is lodged in the oropharynx. This maneuver entails wrapping the arms around the victim from the back and delivering a sharp thrust to the upper part of the abdomen with a closed fist. If it is not possible for the person in attendance to carry out the maneuver because of insufficient physical

strength, mechanical dislodgment of the foreign body can sometimes be achieved by abdominal thrusts with the unconscious patient in a supine position. The Heimlich maneuver is not entirely benign; ruptured abdominal viscera in the victim have been reported, as has a case in which the rescuer disrupted his own aortic root and died. If there is strong suspicion that respiratory arrest precipitated cardiac arrest, particularly in the presence of a mechanical airway obstruction, a second precordial thump should be delivered after the airway has been cleared.

Breathing

With the head placed properly and the oropharynx clear, mouth-to-mouth resuscitation can be initiated if no specific rescue equipment is available. To a large extent the procedure used to establish ventilation depends on the site at which the cardiac arrest occurs. Various devices are available, including plastic oropharyngeal airways, esophageal obturators, masked Ambu bags, and endotracheal tubes. Intubation is the preferred procedure, but time should not be sacrificed, even in the in-hospital setting, while awaiting an endotracheal tube or a person trained to insert it quickly and properly. Thus, in the in-hospital setting, temporary support with Ambu bag ventilation is the usual method until endotracheal intubation can be carried out, and in the out-of-hospital setting, mouth-to-mouth resuscitation is used while awaiting EMS. The effect of acquired immunodeficiency syndrome and hepatitis B transmission on attitudes about mouth-to-mouth resuscitation by bystanders and even professional personnel in hospitals is an area of concern, but currently available data assessing risk for infection suggest that it is minimal.[121] The impact of this concern on attitudes toward and outcomes of resuscitative efforts has not been evaluated.

Early Defibrillation by First Responders

The time from the onset of cardiac arrest to advanced cardiac life support (ACLS) influences outcome statistics. Both early neurologic status and survival are better in patients defibrillated by first responders than if one awaits the assistance of more highly trained paramedics. The term *first responder* refers to the person on scene providing initial CPR and has emerged from minimally trained EMTs allowed to carry out defibrillation in conjunction with BLS to nonconventional responders, such as trained security guards and police, and subsequently to lay bystanders knowledgeable in CPR with access to AEDs. Because the time to defibrillation plays a central role in determining outcome in cardiac arrest caused by VF, the development and deployment of AEDs in public locations has had impact on outcomes (**see Chapter 41**). This technology is potentially applicable to a number of different strategic models, each with its own benefits and limitations (**Fig. 42.14**; **see eFig. 42.2**). A study from France demonstrated a considerable increase in sports-related deaths when recreational athletes of a wider age range are considered.[110] Because CPR (OR, 3.73; $P < 0.0001$) and cardiac defibrillation (OR, 3.71; $P < 0.0001$) were the strongest independent predictors of survival to hospital discharge (15.7%), survival from SCA in recreational sports settings could be improved significantly by increased public education in CPR responses and availability of public AEDs.

AED DEPLOYMENT STRATEGIES

Deployment	Examples	Rescuers	Advantages	Limitations
Emergency vehicles	• Police cars • Fire engines • Ambulances	• Trained emergency personnel	• Experienced users • Broad deployment • Objectivity	• Deployment time • Arrival delays • Community variations
Public access sites	• Public buildings • Stadiums, malls • Airports • Airliners	• Security personnel • Designated rescuers • Random laypersons	• Population density • Shorter delays • Lay and emergency personnel access	• Low event rates • Inexperienced users • Panic and confusion
Multifamily dwellings	• Apartments • Condominiums • Hotels	• Security personnel • Designated rescuers • Family members	• Familiar locations • Defined personnel • Shorter delays	• Infrequent use • Low event rates • Geographic factors
Single-family dwellings	• Private homes • Apartments • Neighborhood "Heart watch"	• Family members	• Immediate access • Familiar setting	• Acceptance • Victim may be alone • One-time user; panic

FIGURE 42.14 Various deployment strategies for nonconventional responders with access to automated external defibrillators (AEDs). For each example, the type of rescuer and the advantages and limitations of each strategy are provided. It is unlikely that any single strategy will dominate; rather, there will be a cumulative benefit from the additive effect of multiple approaches. (From Myerburg RJ. Sudden cardiac death: exploring the limits of our knowledge. J Cardiovasc Electrophysiol 2001;12:369.)

Among the strategies that have yielded various levels of identifiable survival benefit to date are deployment in police vehicles, airliners and airports, casinos, and more general community-based sites.[150,151] Police AED deployment data have been inconsistent in various studies, possibly because of appropriateness for various types of communities and the specific deployment strategies used, but data suggest that it is beneficial in large metropolitan areas (**eFig. 42.5**). Initial airline data were similarly uncertain, but a more recent report on data from a large airline with a well-organized system has suggested benefit (**eFig. 42.6**). Similar encouraging results have been reported with the deployment of AEDs in the Chicago airport system. The special circumstance of casinos, in which continuous television monitoring alerts security officers to medical problems immediately, has yielded impressive survival rates (**Fig. 42.15**). For more general community sites, defined as true public access, a large study has suggested a twofold benefit.[150] However, there appears to be great variability in efficiency on the basis of expected event rates at different types of community sites, and deployment strategies have been suggested on the basis of projected event rates at various locations.[150,151] Deployment in schools, accompanied by comprehensive response planning, is associated with good outcomes, even with relatively low event rates.[152] A study of the deployment of AEDs in the homes of patients with recent MI who were not candidates for implantable defibrillators did not demonstrate benefit.[153] Because the home is the most common site of cardiac arrest, and survival rates are lower than in public sites, additional strategies for both AEDs and other technologies should be tested. Additional data have also demonstrated limited efficacy of home-based AEDs[13]; further research on effective strategies is needed because most community-based cardiac arrests occur in the home.

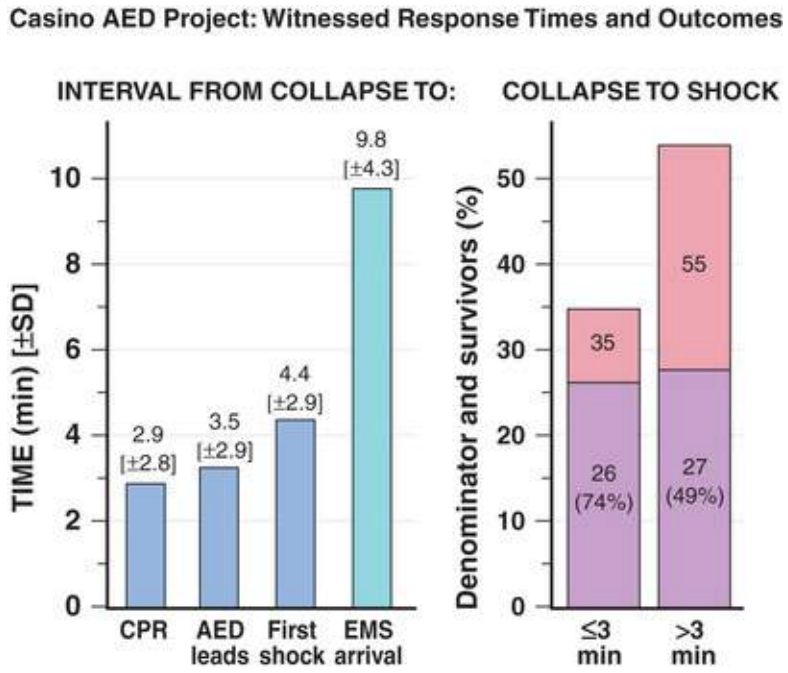


FIGURE 42.15 Results of AED deployment in the controlled environment of casinos. Because the onset of cardiac arrest can frequently be witnessed, short intervals from the onset of collapse to CPR and AED shocks were achieved. Response times were reduced by more than 50% in comparison to the standard EMS. For those found in VT/VF, the survival rate was better than expected from other community-based systems and approached 60% for VT/VF with a witnessed onset. When response time was less than 3 minutes, the survival rate after VT/VF was higher than 70%. (Modified from Valenzuela TD, Roe DJ, Nichol G, et al. Outcomes of rapid defibrillation by security officers after cardiac arrest in casinos. N Engl J Med 2000;343:1206.)

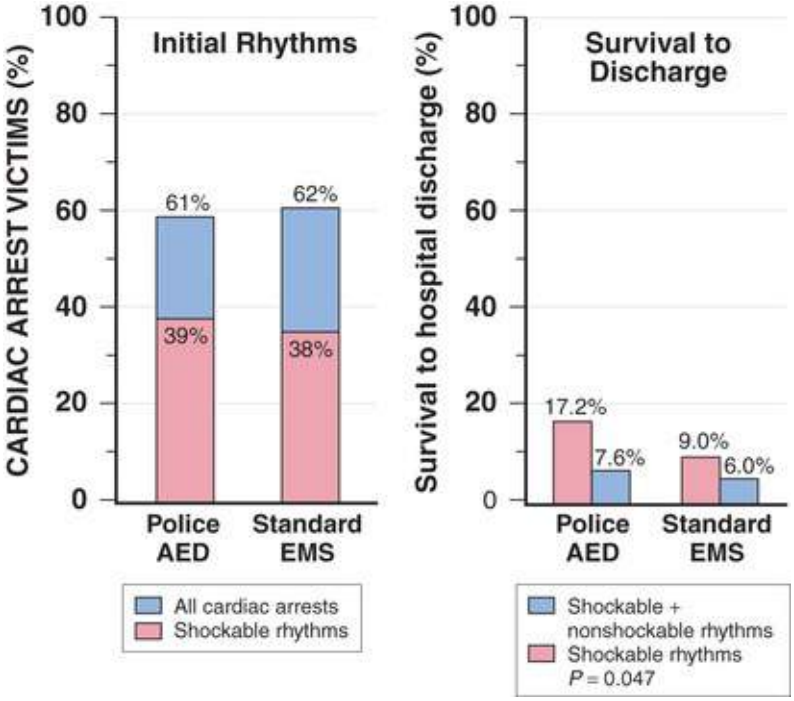
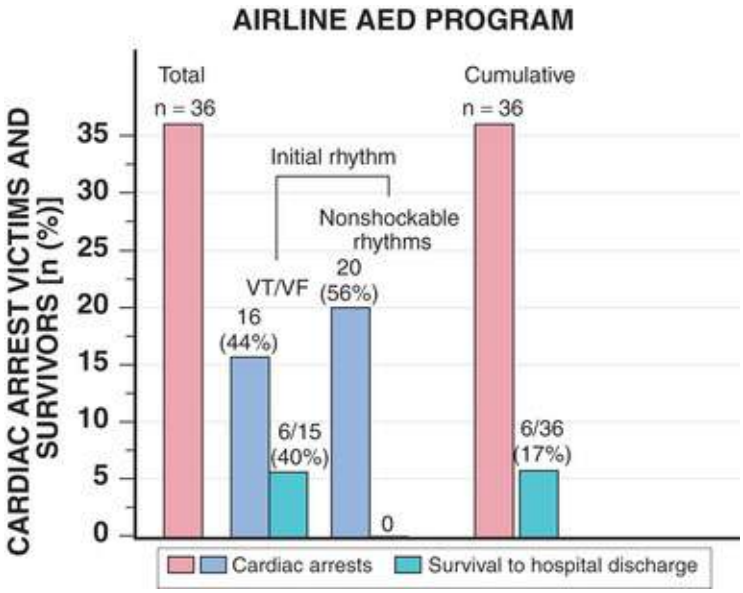


EFIGURE 42.5 Rhythms at initial contact and survival statistics from the Miami–Dade County, Florida, police automated external defibrillator (AED) project. Shockable rhythms were observed in just less than 40% of cardiac arrest victims in both the police AED program and the standard emergency medical services (EMS) historical control data. Those with shockable rhythms had improved survival to hospital discharge, but the improvement was small when both shockable and nonshockable rhythms were included in the data analyzed. (Modified from Myerburg RJ, Fenster J, Velez M, et al. Impact of community-wide police car deployment of automated external defibrillators on out-of-hospital cardiac arrest. Circulation 2002;106:1058.)



EFIGURE 42.6 Data on outcomes after deployment of AEDs by a major airline demonstrated that approximately 44% of the cardiac arrests were associated with a documented ventricular tachycardia/fibrillation (VT/VF) mechanism, and 40% of these victims survived. There were no survivors among the 56% of victims who had nonshockable rhythms. The cumulative survival rate for the program was 17%. (**A,** Modified from Page RL, Joglar JA, Kowal RC, et al. Use of automated external defibrillators by a U.S. airline. N Engl J Med 2000;343:1210.)

As with any medical device,[154] malfunctions of AEDs may occur infrequently because of design or manufacturing defects[155] or failure to adhere to manufacturers' recommendations for replacement of batteries and leads. It is an obligation of those responsible for maintaining AEDs to remain cognizant of FDA safety alerts and recalls and the shelf-life of batteries and leads.

Advanced Cardiac Life Support

This next step in the resuscitative sequence is designed to achieve stable ROSC and hemodynamic stabilization.[121] Implementation of ACLS is not intended to suggest an abrupt cessation of BLS activities, but rather a transition from one level of activity to the next. In the past, ACLS required judgments and technical skills that removed it from the realm of activity of lay bystanders and even EMTs, instead limiting these activities to specifically trained paramedical personnel, nurses, and physicians. With further education of EMTs, most community-based CPR programs now permit them to carry out ACLS activities. However, some studies suggest that the addition of ACLS to an otherwise optimized out-of-hospital response system (i.e., bystander CPR and early defibrillation) does not improve statistics for neurologically intact survival.[156] In this regard, the development and testing of AEDs that have the ability to sense and analyze cardiac electrical activity and to prompt the user to deliver definitive electrical intervention provide a role for rapid defibrillation by less highly trained rescue personnel (i.e., police, ambulance drivers) and even minimally trained lay bystanders.

The general goals of ACLS are to restore cardiac rhythm to hemodynamic effectiveness, to optimize ventilation, and to maintain and support the restored circulation. Thus, during ACLS, the patient's cardiac rhythm is promptly cardioverted or defibrillated as the first priority if appropriate equipment is immediately available. A short period of closed-chest cardiac compression immediately before defibrillation enhances the probability of survival, especially if circulation has been absent for 4 to 5 or more minutes.[137,141] After the initial attempt to restore a hemodynamically effective rhythm, the patient is intubated and oxygenated, if needed, and the heart is paced if bradyarrhythmia or asystole occurs. An intravenous (IV) line is established to deliver medications. After intubation, the goal of ventilation is to

reverse the hypoxemia and not merely to achieve high alveolar oxygen pressure (P_{O_2}). Thus, oxygen rather than room air should be used to ventilate the patient; if possible, arterial P_{O_2} should be monitored. Respiratory support in the hospital by means of an endotracheal tube and Ambu bag—or facemasks in the out-of-hospital setting—is generally used.

Successful ROSC after IHCA is associated with a shorter median duration of resuscitation than in nonsurvivors (12 minutes, interquartile range [IQR] of 6 to 21, versus 20 minutes, IQR of 14 to 30). Nonetheless, hospitals that habitually ran the longest maximum code runs (the median value in the longest quartile was 25 versus 16 minutes) generated a higher likelihood of ROSC and survival to discharge.[157] This observation supports longer attempts at resuscitation in patients without "do-not-resuscitate" instructions and/or futile medical status.

Defibrillation-Cardioversion

Rapid conversion to an effective cardiac electrical mechanism is a key step in successful resuscitation (**Fig. 42.16**). Delay should be minimal, even when conditions for CPR are optimal. When VF or VT that is pulseless and/or accompanied by loss of consciousness is recognized on a monitor or by telemetry, defibrillation should be carried out immediately. An initial shock of 360 J should be delivered by monophasic devices and 120 to 200 J by biphasic devices, with the energy depending on the recommendations for the individual biphasic devices. Energies delivered through AEDs are generally preprogrammed and vary among the devices available. Failure of the initial shock to provide an effective rhythm is a poor prognostic sign. The 2010 updated guidelines[121] recommend that failure of a single adequate shock to restore a pulse should be followed by continued CPR and a second shock delivered after five cycles of CPR. This supersedes the previous strategy of three successive shocks before resuming CPR. The intent is to maximize circulatory time by chest compressions until a pulse has been restored. If cardiac arrest persists, the patient is intubated and IV access achieved. Epinephrine is administered and followed by repeated defibrillation attempts at 360 J (monophasic) or 200 J or higher (biphasic). Epinephrine may be repeated at 3- to 5-minute intervals with a defibrillator shock in between,[121] but studies of the value of high-dose versus standard-dose epinephrine have been inconsistent with regard to short-term added benefit (i.e., ROSC); there is no apparent long-term benefit (i.e., survival to hospital discharge) with higher doses.[158] Vasopressin is an effective alternative to epinephrine.

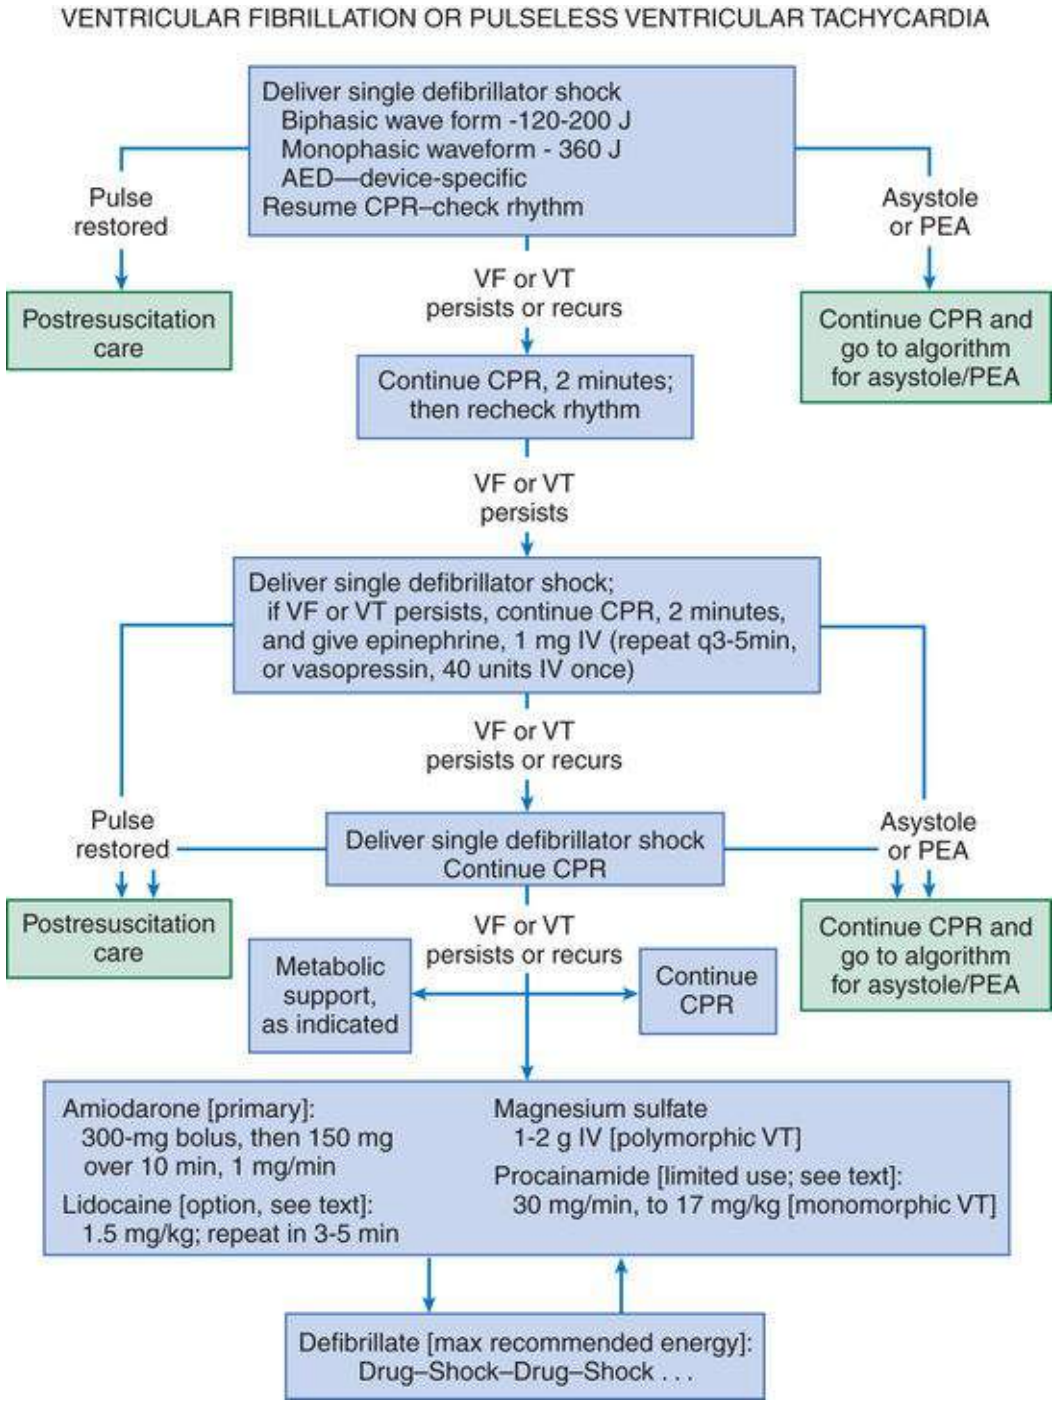


FIGURE 42.16 Advanced cardiac life support for VF and pulseless VT. If initial defibrillation fails, the patient should be intubated and IV access established immediately while CPR is continued. Epinephrine, 1 mg intravenously, should be administered and may be repeated several times with additional defibrillation attempts at 360 J. If conversion is still unsuccessful, epinephrine may be administered again, although it is unlikely that higher doses will provide any further benefit. Sodium bicarbonate should be administered at this time only if the patient is known to be hyperkalemic, and IV antiarrhythmic drugs should be tried (see text). Additional attempts to defibrillate should follow the administration of each drug attempted. Concomitant with all steps, continuation of CPR is paramount. (Modified from 2010 American Heart Association Guidelines for Cardiopulmonary Resuscitation and Emergency Cardiovascular Care Science. Circulation 2010;122[Suppl 3]:S640.)

Simultaneously, the rescuer should focus on ventilation to correct the chemistry of the blood and render the heart more likely to reestablish a stable rhythm, such as improved oxygenation, reversal of acidosis, and improvement of the underlying electrophysiologic condition. Although adequate oxygenation of the blood is crucial in immediate management of the metabolic acidosis of cardiac arrest, additional correction can be achieved, if necessary, by the IV administration of sodium bicarbonate. Sodium bicarbonate is recommended for circumstances of known or suspected preexisting bicarbonate-responsive

causes of acidosis, certain drug overdoses, and prolonged resuscitation runs.[121] A more general role for bicarbonate during cardiac arrest has been questioned, but in any circumstance, much less sodium bicarbonate than previously recommended is adequate for treatment of acidosis in this setting. Excessive quantities can be deleterious. Although some investigators have questioned the use of sodium bicarbonate because the risk for alkalosis, hypernatremia, and hyperosmolality may outweigh its benefits, patients in the circumstances cited may benefit from the administration of sodium bicarbonate while CPR is performed. Up to 50% of the dose may be repeated every 10 to 15 minutes during the course of CPR. When possible, arterial pH, P_{O_2}, and P_{CO_2} should be monitored during the resuscitation.

Pharmacotherapy

For patients who continue to have persistent or recurrent VT or VF despite direct-current cardioversion after epinephrine, IV administration of antiarrhythmic agents has been recommended to achieve electrical stability of the heart during continued resuscitative efforts (**see Fig. 42.16 and Chapter 36**). Based on a single controlled trial with a survival to hospital admission endpoint, IV amiodarone emerged as the initial treatment of choice.[121] Bolus therapy (150 mg), followed by a maintenance dose during the next 18 hours and for several days if necessary, was recommended, depending on response. A bolus of lidocaine (60 to 100 mg) may be given intravenously and the dose repeated in 2 minutes for patients in whom amiodarone is unsuccessful and possibly for those who have an acute transmural MI as the triggering mechanism for the cardiac arrest. IV procainamide is rarely used in this setting now, but it may be tried for persisting, hemodynamically stable arrhythmias. A recent study, randomizing IV amiodarone (150 mg, followed by a second bolus if necessary) or lidocaine (60 mg) against placebo, showed no difference between either drug or placebo for survival to discharge outcomes or survival with favorable neurologic status.[159] However, survival to hospital admission was significantly better with both active drugs compared to placebo. In addition, survival to discharge was improved with both drugs among the subgroup with bystander-witnessed arrest, although neither active drug was superior to the other.

For patients in whom acute hyperkalemia is the triggering event for resistant VF or for those who have hypocalcemia or are toxic from Ca^{2+} entry–blocking drugs, 10% calcium gluconate may be helpful.[121] Calcium should not be used routinely during resuscitation, even though ionized calcium levels may be low during resuscitation from cardiac arrest. Some resistant forms of polymorphic VT or torsades de pointes, rapid monomorphic VT or ventricular flutter (rate ≥260/min), or resistant VF may respond to IV beta-blocker therapy or IV magnesium sulfate. For patients with acute ventricular arrhythmias or VT storm associated with LQTS, IV magnesium sulfate is often an effective antiarrhythmic, even if it has no effect on QT duration.

Bradyarrhythmic and Asystolic Arrest; Pulseless Electrical Activity

The approach to patients with bradyarrhythmic or asystolic arrest or with PEA differs from the approach to those with a tachyarrhythmic event[121] (**Fig. 42.17**). When this form of cardiac arrest is recognized, effort should focus first on establishing control of cardiorespiratory status (i.e., continue CPR, intubate, and establish IV access), reconfirming the rhythm (in two leads if possible), and then taking action that favors the emergence of a stable spontaneous rhythm or an attempt to pace the heart. Possible reversible causes, particularly for bradyarrhythmia and asystole, should be considered and excluded (or treated) promptly. Such causes include hypovolemia, hypoxia, cardiac tamponade, tension pneumothorax, preexisting acidosis, drug overdose, hypothermia, and hyperkalemia. Epinephrine is commonly used in an attempt to elicit spontaneous electrical activity or to increase the rate of a bradycardia. It has had only

limited success, as has IV isoproterenol infusions in doses of up to 15 to 20 µg/min. In the absence of an IV line, epinephrine, 1 mg (10 mL of a 1 : 10,000 solution) may be given by the intracardiac or intraosseous (IO) route, but there is danger of coronary or myocardial laceration with the former. Endotracheal delivery can be used if neither IV nor IO administration can be achieved. The added value of high-dose epinephrine is unclear,[158] as in the case of resistant VF. Atropine is no longer considered of value for PEA or asystole,[121] although it may be of benefit for other bradyarrhythmic mechanisms. Sodium bicarbonate, 1 mEq/kg, may be tried for known or strongly suspected preexisting hyperkalemia or bicarbonate-responsive acidosis.

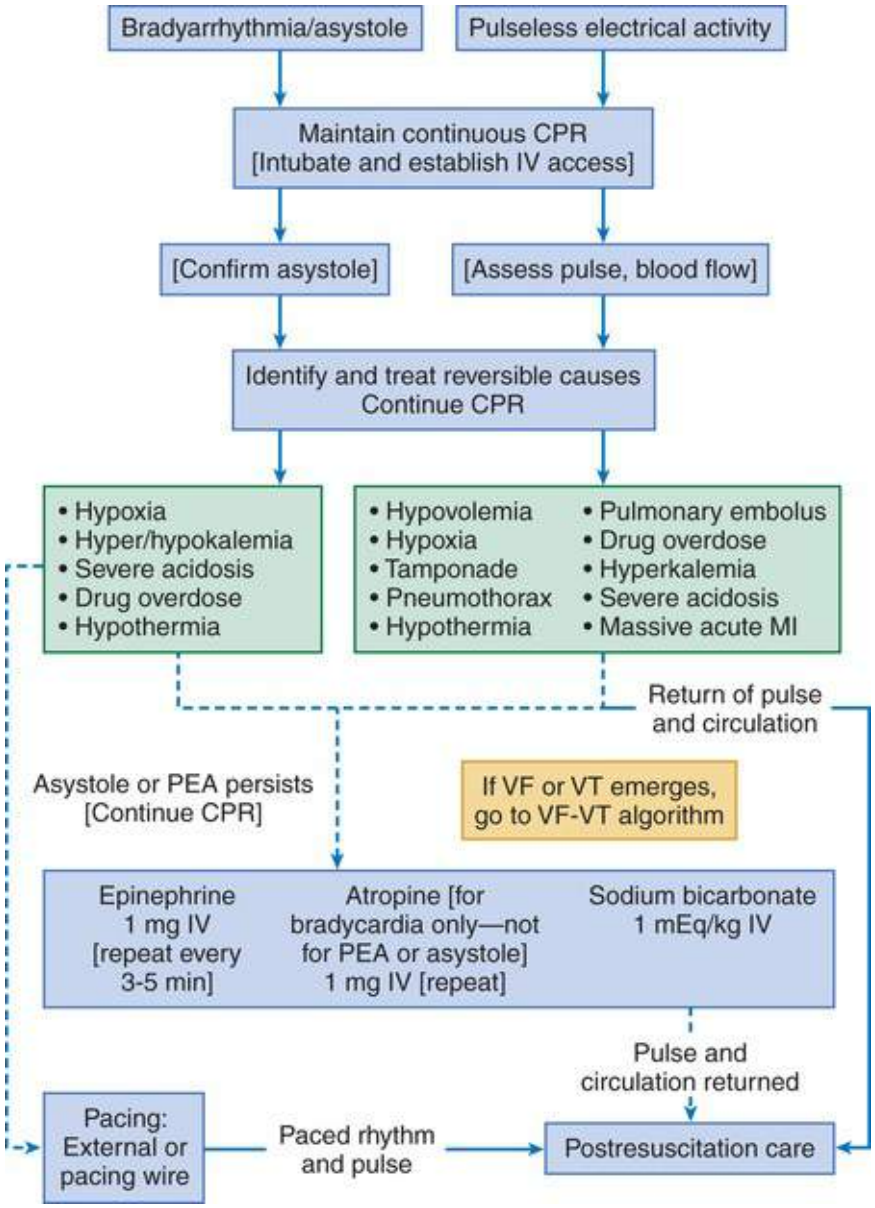

FIGURE 42.17 Advanced cardiac life support for patients with bradyarrhythmic-asystolic arrest and PEA. A patient in any of these states should have CPR continued and be intubated, with IV access established, before pharmacologic treatment. The initial activity is to confirm persisting asystole or attempt to assess blood flow in patients thought to have PEA. An immediate attempt should be made to identify and treat reversible or treatable causes of these forms of cardiac arrest. Epinephrine is generally administered first, and atropine or bicarbonate, or both, may be administered subsequently. An attempt to pace the heart with an external device or an intracardiac pacing catheter is advisable although not usually successful, except for certain reversible bradyarrhythmias. (From 2010 American Heart Association Guidelines for Cardiopulmonary Resuscitation and Emergency Cardiovascular Care Science. Circulation 2010;122[Suppl 3]:S640.)

Pacing of a bradyarrhythmic or asystolic heart has been limited in the past by the unavailability of

personnel capable of carrying out such procedures at the scene of cardiac arrest. With the development of more effective external pacing systems, the role of pacing and its influence on outcome must now be reevaluated. Unfortunately, all data to date have suggested that asystolic patients continue to have a very poor prognosis despite new techniques.

The published standards for CPR and emergency cardiac care[121] include a series of teaching algorithms to be used as guides to appropriate care. **Figs. 42.16 and 42.17** provide the algorithms for VF and pulseless VT, asystole (or cardiac standstill), and PEA. These general guides are not to be interpreted as inclusive of all possible approaches or contingencies. CPR in pregnant women requires attention to the influence of the gravid uterus on the mechanics of CPR. The pregnant patient should be placed in a left lateral decubitus position with left uterine displacement during CPR to relieve aortocaval compression,[160] and standard defibrillation has no risk for the fetus. Acute antiarrhythmic drug (AAD) therapy during ACLS is generally safe, although long-term amiodarone therapy raises concern for potential fetal organ toxicity.

Stabilization of Cardiac Rhythm after Initial Return of Spontaneous Circulation

If frequent PVCs and runs of nonsustained VT persist after restoration of a sinus mechanism, continuous infusion of an effective AAD is used. IV amiodarone is the preferred agent, but lidocaine is an option for arrhythmias caused by acute ischemic events, and IV procainamide may be considered if the others fail. On occasion, continuous infusion of propranolol or esmolol is used, sometimes in conjunction with magnesium sulfate, especially for recurrent episodes of polymorphic VT or VT storm unresponsive to amiodarone.

Catecholamines are used for cardiac arrest not only in an attempt to achieve better electrical stability (e.g., conversion from fine to coarse VF or increasing the rate of spontaneous contraction during bradyarrhythmias) but also for their inotropic and peripheral vascular effects. Epinephrine is the first choice among the catecholamines for use in cardiac arrest because it increases myocardial contractility, elevates perfusion pressure, may convert electromechanical dissociation to electromechanical coupling, and improves the chances for successful defibrillation. Because of its adverse effects on renal and mesenteric flow, norepinephrine is a less desirable agent despite its inotropic effects. When the chronotropic effect of epinephrine is undesirable, dopamine or dobutamine is preferable to norepinephrine for inotropic effect. Isoproterenol may be used for the treatment of primary or postdefibrillation bradycardia when heart rate control is the primary goal of therapy intended to improve cardiac output. Calcium chloride is sometimes used in patients with PEA that persists after the administration of catecholamines. The efficacy of this intervention is uncertain. Stimulation of alpha adrenoceptors may be important during definitive resuscitative efforts. For example, the alpha adrenoceptor–stimulating effects of epinephrine and higher dosages of dopamine, which elevate aortic diastolic pressure by peripheral vasoconstriction with increased cerebral and myocardial flow, have been reemphasized.

Post–Cardiac Arrest Care and Post–Cardiac Arrest Syndrome

After return of spontaneous or stable assisted circulation, focus shifts to the diagnostic and therapeutic elements of post–cardiac arrest syndrome,[161] a field of pathophysiology and clinical intervention that emerged from the recognition that the various elements of injury following cardiac arrest should be organized into a multidisciplinary continuum. The four elements of post–cardiac arrest syndrome include

brain injury, myocardial dysfunction, systemic ischemia and reperfusion responses, and control of persistent precipitating factors. The therapeutic goal is to achieve and maintain stable electrical, hemodynamic, and CNS status, based on complex algorithms.[161] The specialized and multidisciplinary nature of post–cardiac arrest care have led to the proposal and preliminary data supporting the concept of specialized cardiac centers for post–cardiac arrest patients,[162] analogous to trauma or stroke centers. When transporting the hemodynamically unstable or comatose patient, EMS responders would selectively bypass the nearest hospital in favor of the closest facility having facilities and staff sufficient to manage post–cardiac arrest complexities, assuming an added transport time of no more than 15 minutes. The profile of the patient ready for transport is matched to the capabilities of the institution to which the victim is transported (**Fig. 42.18**).

Level	Patient Status	Hospital Resource Minimums
Level 1 	Failure to restore circulation; ROSC without regaining consciousness ± hemodynamic instability ± acute coronary syndrome; ± recurrent arrhythmias	Local or regional facility capable of providing highest level of neurological, cardiovascular, and intensive care support 24/7 (ICU/CCU/NICU)
Level 2 	ROSC with restoration of consciousness; Persistent hemodynamic instability ± acute coronary syndrome; ± recurrent arrhythmias	Nearest facility capable of providing high level cardiovascular and intensive care support 24/7; cardiac catheterization laboratory capable of providing PCI within 90 minutes
Level 3 	ROSC with restoration of consciousness; hemodynamically stable Evidence of acute coronary syndrome; ± recurrent arrhythmias	Nearest facility with cardiac catheterization laboratory capable of providing PCI within 90 minutes - 24/7
Level 4 	ROSC with restoration of consciousness; hemodynamically stable; no evidence of acute coronary syndrome ± recurrent arrhythmias	Nearest facility capable of providing standard ED, ICU/CCU; cardiac catheterization desirable with PCI capability within 24 hours

FIGURE 42.18 A four-tiered EMS bypass model aligning immediate post–cardiac arrest status and level of required care is illustrated to reflect a priority-based hospital bypass system. The Copenhagen model provides a foundation for this additional level of coordination. Patients can be transported to the closest facility appropriate to the optimal or minimal care requirements. Color-coded symbols link level of patient urgency to recommended hospital resources on community grid maps. *CCU,* Coronary care unit; *ED,* emergency department; *ICU,* intensive care unit; *NICU,* neurologic ICU; *PCI,* percutaneous coronary intervention; *ROSC,* return of spontaneous circulation. (From Myerburg RJ: Initiatives for improving out-of-hospital cardiac arrest outcomes. Circulation 2014; 30:1840. Reproduced with permission of the publisher.)

For successfully resuscitated cardiac arrest victims, whether the event occurred in or out of the hospital, post–cardiac arrest care includes admission to an intensive care unit (ICU) and continuous monitoring for a minimum of 48 to 72 hours. Some elements of post–cardiac arrest syndrome are common to all resuscitated patients, but the prognosis and certain details of management are specific for the clinical setting in which the cardiac arrest occurred. The major management categories include (1) primary cardiac arrest in patients with acute myocardial infarction (AMI); (2) secondary cardiac arrest in patients with AMI; (3) cardiac arrest associated with non–cardiac-related diseases, drug effects, or

electrolyte disorders; and (4) survival after out-of-hospital cardiac arrest.

Cardiac Arrest in Patients with Hemodynamically Stable Acute Myocardial Infarction

Ventricular fibrillation in patients with AMI free of concomitant hemodynamic complications (i.e., primary VF; **see Chapter 59**) is now less common in hospitalized patients compared to the 15% to 20% incidence noted before the availability of cardiac care units (CCUs). The events that do occur are almost always reverted successfully by prompt interventions in properly equipped emergency departments or CCUs. If ventricular arrhythmias persist after successful resuscitation, a lidocaine infusion is used. AAD support is generally discontinued after 24 hours if sustained arrhythmias do not recur (**see Chapter 36**). The occurrence of VF during the early phase of AMI (i.e., first 24 to 48 hours) does not identify long-term risk and is not an indication for long-term AAD or device therapy. Pulseless VT producing the clinical picture of cardiac arrest in AMI is treated similarly; its intermediate- and long-term implications are the same as those of VF, as with polymorphic VT. The implications for sustained hemodynamically stable monomorphic VT in this situation are less clear in the early setting and warrant reevaluation of the patient during the convalescent phase. Cardiac arrest caused by bradyarrhythmias or asystole in acute *inferior* wall MI, in the absence of primary hemodynamic deterioration, is uncommon, and the patient may respond to atropine or pacing. The prognosis is good, with no special long-term care required in most cases. Persistent symptomatic bradyarrhythmias requiring permanent pacemakers rarely occur in such patients. In contrast, bradyarrhythmic cardiac arrest associated with large *anterior* wall MI (and AV or intraventricular block) has a poor prognosis.

Cardiac Arrest in Patients with Hemodynamically Unstable Acute Myocardial Infarction

Cardiac arrest occurring in association with, or as a result of hemodynamic or mechanical dysfunction, during the acute phase of MI has an immediate mortality rate ranging from 59% to 89%, depending on the severity of the hemodynamic abnormalities and size of the MI. Resuscitative efforts usually fail in such patients, and when successful, post–cardiac arrest management is often difficult. When secondary cardiac arrest occurs by the mechanisms of VT or VF in this setting, aggressive postresuscitation hemodynamic or anti-ischemic measures may help achieve rhythm stability. IV amiodarone has emerged as the antiarrhythmic therapy of choice. Lidocaine may also be tried if the mechanism appears to be ischemic but is less likely to be successful in this setting than in primary VF. The success of interventions and prevention of recurrent cardiac arrest are closely related to the success in managing the patient's hemodynamic status. The proportion of cardiac arrests caused by bradyarrhythmias or asystole or by PEA is higher in hemodynamically-unstable patients with AMI. Such patients usually have large MI and major hemodynamic abnormalities and may be acidotic and hypoxemic. Even with aggressive therapy, the prognosis after asystolic arrest in such patients is poor, and they are resuscitated only rarely from PEA. All patients in circulatory failure at the onset of arrest are in a high-risk category, with only a 2% survival rate in hypotensive patients noted in one study.

Cardiac Arrest among in-Hospital Patients with Noncardiac Abnormalities.
These patients fall into two major categories: (1) those with life-limiting diseases, such as malignant

neoplasms, sepsis, organ failure, end-stage pulmonary disease, and advanced CNS disease, and (2) those with acute toxic or proarrhythmic states that are potentially reversible. In the former category, the ratio of tachyarrhythmic to bradyarrhythmic cardiac arrest is low, and the prognosis for survival of cardiac arrest is poor. Although the data may be somewhat skewed by the practice of assigning “do-not-resuscitate” orders to patients with end-stage disease, the data available for attempted resuscitations show a poor outcome. Only 7% of cancer patients, 3% of renal failure patients, and no patients with sepsis or acute CNS disease were successfully resuscitated and discharged from the hospital. For the few successfully resuscitated patients in these categories, postarrest management is dictated by the underlying precipitating factors.

Most antiarrhythmic drugs (**see Chapter 36**), a number of drugs used for noncardiac purposes, and electrolyte disturbances can precipitate potentially lethal arrhythmias and cardiac arrest. Class IA and class III AADs can cause proarrhythmic responses by lengthening the QT interval and generating torsades de pointes (TdP). Class IC drugs rarely cause TdP but result in excess risk for SCD in patients with recent MI, possibly by interacting with transient ischemia. Among other categories of drugs, the phenothiazines, tricyclic antidepressants, lithium, terfenadine interacting with ketoconazole (or other blockers of enzymes in the hepatic cytochrome P-450 system), pentamidine, cocaine, erythromycin, and cardiovascular drugs that are not AADs (e.g., lidoflazine) are recognized causes (see https://www.crediblemeds.org). Beyond these, a broad array of pharmacologic and pathophysiologic-metabolic causes have been reported. Hypokalemia, hypomagnesemia, and perhaps hypocalcemia are the electrolyte disturbances most closely associated with cardiac arrest. Acidosis and hypoxia can potentiate the vulnerability associated with electrolyte disturbances. Proarrhythmic effects are often forewarned by prolongation of the QT interval, although this electrocardiographic change is not always present.

Impending or manifest cardiac arrest caused by TdP is managed by IV magnesium, pacing, or treatment with isoproterenol and removal of the offending agent. When QT prolongation is the basis, magnesium may effectively control the arrhythmia without shortening the QT interval. Class IC drugs may cause a rapid, sinusoidal VT pattern, especially in patients with poor LV function. This VT tends to recur repetitively after cardioversion until the drug has begun to clear, and it has been controlled by propranolol in some patients. When the patient's condition can be stabilized until the offending factor is removed (e.g., proarrhythmic drugs) or corrected (e.g., electrolyte imbalances, hypothermia), the prognosis is excellent. Recognition of TdP and identification of its risk by prolongation of the QT interval in association with the offending agent are helpful in managing these patients (**see Chapter 39**).

Risk Identification by QT Interval Prolongation after Cardiac Arrest

The initial management of survivors of OHCA centers on stabilizing cardiac electrical status, supporting hemodynamics, and providing supportive care for reversal of any organ damage resulting from the cardiac arrest. The in-hospital risk for recurrent cardiac arrest is relatively low, and arrhythmias account for only 10% of in-hospital deaths after successful out-of-hospital resuscitation. However, the mortality rate during the index hospitalization is 50%, indicating that nonarrhythmic mortality dominates the mechanisms of early postresuscitation deaths (30% hemodynamic, 60% CNS related). Antiarrhythmic therapy, usually IV amiodarone, is used in an attempt to prevent recurrent cardiac arrest in patients who demonstrate recurrent arrhythmia during the first 48 hours of postarrest hospitalization. Patients who have preexisting or new AV or intraventricular conduction disturbances are at particularly high risk for recurrent cardiac arrest. The routine use of temporary pacemakers has been evaluated in such patients but has not been found to be helpful for prevention of early recurrent cardiac arrest. Invasive techniques for hemodynamic

monitoring are used in patients whose condition is unstable but are not used routinely in those whose condition is stable on admission.

Anoxic encephalopathy is a strong predictor of in-hospital death or death within 6 months after discharge. The induction of therapeutic hypothermia to reduce metabolic demands and cerebral edema[126,127] should be applied promptly to a postarrest survivor who remains unconscious on hospital admission, providing a measurable survival benefit. A randomized study of prehospital infusion (IV cold saline) hypothermia demonstrated a small reduction in ROSC and no benefit for survival to hospital discharge.[163] The initial temperature target was 32°C to 34°C (89.6°F to 93.2°F), but subsequent data suggest that a target of 36°C (96.8°F) is equally effective and easier to achieve.[164] The benefit may derive from prevention of hyperthermia.

During the later convalescent period, continued attention to CNS status, including physical rehabilitation, is of primary importance for an optimal outcome. Respiratory support by conventional methods is used as necessary. Management of other organ system injury (e.g., renal, hepatic), as well as early recognition and treatment of infectious complications, also contributes to ultimate survival.

Long-Term Management of Survivors of Out-of-Hospital Cardiac Arrest

When a survivor of OHCA has awakened and achieved electrical and hemodynamic stability, usually within a few days if it is to occur at all, decisions must be made about the nature and extent of the workup required to establish a long-term management strategy. The goals of the workup are to identify the specific causative and triggering factors of the cardiac arrest, to clarify the functional status of the patient's cardiovascular system, and to establish long-term therapeutic strategies. Patients who have limited return of CNS function usually do not undergo extensive workups, and patients whose cardiac arrest was triggered by an transmural AMI have workups similar to those for other AMI patients (**see Chapter 59**).

Survivors of OHCA not associated with AMI who have good return of neurologic function appear to have a long-term survival probability commensurate with their age, sex, and extent of disease when they are treated according to existing guidelines.[165-167] These patients should undergo diagnostic workups to define the cause of the cardiac arrest and to tailor long-term therapy, the latter targeted to the underlying disease and strategies for prevention of recurrent cardiac arrest or SCD. The workup includes cardiac catheterization with coronary angiography if coronary atherosclerosis is known or considered to be the possible cause of the event, evaluation of the functional significance of coronary lesions by stress imaging techniques if indicated, determination of functional and hemodynamic status, and assessment of whether the life-threatening arrhythmic event was caused by a transient risk associated with AMI or there is persisting risk based on clinical characteristics.

General Care

The general management of survivors of cardiac arrest is determined by the specific cause and the underlying pathophysiologic process. For patients with ischemic heart disease (**see Chapters 60 and 61**), interventions to prevent myocardial ischemia, optimization of therapy for LV function, and attention to general medical status are all addressed. Although limited data suggest that revascularization procedures may improve the recurrence rate and total mortality rates after survival from OHCA, no properly controlled prospective studies have validated this impression for bypass surgery or percutaneous interventions. The indications for revascularization after cardiac arrest are limited to those who have a

generally accepted indication for angioplasty or surgery, including a documented ischemic mechanism of the cardiac arrest.

Although no data from placebo-controlled trials are available to define a benefit of various anti-ischemic strategies (including beta blockers or other medical therapy) for long-term management after OHCA, medical, catheter interventional, or surgical anti-ischemic therapy, rather than AAD therapy, is generally considered the primary approach to long-term management of the subgroup of prehospital cardiac arrest survivors in whom transient myocardial ischemia was the inciting factor. Moreover, in an uncontrolled observation comparing cardiac arrest survivors who had ever received beta blockers after the index event with those who had not, a significant improvement in long-term outcome with beta-blocker therapy was noted. Further evaluation of the specific role of revascularization procedures and anti-ischemic medical therapy after OHCA is needed.

Whether the various pharmacologic strategies (e.g., ACE inhibitors, carvedilol and other beta-adrenergic blocking agents, spironolactone) that have been shown to provide a clinical and mortality benefit in patients with LV dysfunction provide a specific SCD benefit separate from a total mortality benefit remains uncertain.

Prevention of Cardiac Arrest and Sudden Cardiac Death

Prevention of SCA can be classified into five clinical subgroup categories: (1) prevention of recurrent events in survivors of cardiac arrest (secondary prevention) (**Table 42.7**); (2) prevention of an initial event in patients at high risk because of advanced heart disease with low ejection fraction and other markers of risk (primary prevention) (**Table 42.8**); (3) primary prevention in patients with less advanced common or uncommon structural heart diseases; (4) primary prevention in patients with structurally normal hearts, subtle or minor structural abnormalities, or genetically based molecular disorders (**Table 42.9**); and (5) primary prevention in the general population. The last category includes the substantial proportion of SCDs that occur as a first cardiac event in victims previously free of known disease (see earlier).

TABLE 42.9

Indications for Implantable Cardioverter-Defibrillators in Genetic Disorders Associated with Risk for Sudden Cardiac Death

DIAGNOSIS	ICD INDICATION	PRIMARY SOURCE OF DATA	RISK INDICATORS	GUIDELINES	
				Classification	Evidence
HCM	Secondary SCA protection	Registries, cohorts	Previous SCA, pulseless VT	Class I	Level B
			Sustained VT, unexplained syncope	Class IIa	Level C
	Primary SCA protection	Registries, cohorts	LV thickness >30 mm, high LV outflow gradient, family history of SCD, N-S VT, blunted blood pressure response to exercise	Class IIa	Level C
ARVD/RVCM	Secondary SCA protection	Registry, case series	Previous SCA, sustained VT	Class I	Level B, C
			Unexplained syncope	Class IIa	Level C
	Primary SCA protection	Registry, case series	Induced VT, ambient N-S VT, extensive disease	Class IIa	Level C
Congenital LQT	Secondary SCA protection	Registry, cohorts	Previous SCA, symptomatic VT	Class I	Level B
	Primary SCA protection	Registry, cohorts	VT or syncope while taking a beta blocker, QTc >500 msec, family history of premature SCA (?)	Class IIa, IIb	Level B
Familial SQT	Secondary SCA protection	Small case series	Previous SCA, "idiopathic" VF	Class I	Level C
	Primary SCA protection	Small case series	Unknown; family history of SCD (?)	Class IIb, III	Level C
Brugada syndrome	Secondary SCA protection	Case cohorts	Previous SCA, pulseless VT	Class I	Level B
	Primary SCA protection	Case cohorts	Symptomatic VT, unexplained syncope, family history of premature SCA with type I electrocardiographic pattern	Class IIa	Level C
CPVT/F	Secondary SCA protection	Small case series	Previous SCA, pulseless VT	Class I	Level C
	Primary SCA protection	Small case series	Syncope or VT while taking beta blockers, family history of premature SCA (?)	Class IIa	Level C

ARVD/RVCM, Arrhythmogenic right ventricular dysplasia/cardiomyopathy; *CPVT/F,* catecholaminergic polymorphic ventricular tachycardia/"idiopathic" ventricular fibrillation; *HCM,* hypertrophic cardiomyopathy; *LQT,* long-QT syndrome; *LV,* left ventricular; *N-S,* nonsustained; *PVT,* polymorphic ventricular tachycardia; *SCA,* sudden cardiac arrest; *SQT,* short-QT syndrome; *VA,* ventricular arrhythmia; *VF,* ventricular fibrillation; *VT,* ventricular tachycardia; (?), uncertain.

Guideline classifications and levels of evidence are derived from an amalgamation of narrative and tabular statements in two recent guidelines documents,[165,166] with variations in the documents adjudicated by the authors. Definitions are the standard usages provided in guideline documents.

From Myerburg RJ, Reddy V, Castellanos A. Indications for implantable cardioverter-defibrillators based on evidence and judgment. J Am Coll Cardiol 2009;54:747-63.

Four antiarrhythmic strategies, which are not mutually exclusive, can be considered for patients at high risk for cardiac arrest: implantable defibrillators, antiarrhythmic drugs, catheter ablation, and antiarrhythmic surgery. The mainstay of therapy for the highest-risk patients is the implantable defibrillator. The role of the other options for secondary prevention of subsequent SCD, as opposed to adjunctive therapy, has not been established. In addition to these specific antiarrhythmic strategies, therapies for other medical and cardiovascular conditions are integral to managing patients at risk for SCD.

The choice of a therapy, or combinations of therapies, is based on estimation of risk determined by evaluation of the individual patient by various risk-profiling techniques, coupled with available efficacy and safety data.

Methods to Estimate Risk for Sudden Cardiac Death

General Medical and Cardiovascular Risk Markers

The presence and severity of acquired medical disorders (e.g., coronary atherosclerosis and associated myocardial ischemia or MRI-defined scar patterns, LV dysfunction and ventricular volume, heart failure) and general medical conditions (e.g., hypertension, diabetes, dyslipidemias, chronic renal failure,

cigarette smoking) are integral to estimation of risk for SCD. Although lacking the specificity of individual SCD risk prediction, they provide general indicators of risk and data supporting the benefit of therapies (e.g., beta blockers, ACE inhibitors and ARBs, statins) in appropriate subgroups of patients. In a recent report a series of easily identified markers was used to generate a risk score for SCD among participants in two long-term population studies without a history of cardiovascular disease.[168] The model demonstrated large, nonlinear gradients of risk, with the major impact in the highest one or two deciles. This type of model moves in the right direction for individual risk prediction but is limited by its effect sizes: a 5% SCD risk over 10 years in the highest decile in a population with a mean age of 54 years and 11% risk in those with a mean age of 72 years. This magnitude of risk is not sufficient to justify certain interventions, and further risk stratification is needed to identify even higher-risk subgroups at sufficient risk to merit advanced therapies.

In patients with known or suspected coronary heart disease or nonischemic cardiomyopathy, other noninvasive markers of risk are being explored, including measures reflecting autonomic function, QT interval stability, and genetic influences on risk for SCD (see earlier, Risk Factors for Sudden Cardiac Death). The potential importance of proper timing and combining of risk markers has been explored.[2] One study suggested greater risk predictive power for post-MI adverse events when markers were evaluated after 8 weeks, versus closer to the index event.[169] Another study of a cohort of 231 patients with acute MI and an initial EF less than 35% reported that the distribution of EFs on echocardiograms at 90 days of follow-up remained at 35% or less in 43%, increased to 36% to 49% in 31%, and increased to 50% or more in 26% of patients.[170] How this impacts future SCD risk remains to be determined. In another study, optimized medical therapy at the time of an AMI was associated with a dramatically reduced risk for SCD during a 2.9-year mean follow-up (optimized treatment, 1.2%, and annual incidence, 0.4%; compared with nonoptimized treatment, 3.6%, and annual incidence, 1.4%; $P < 0.01$), with the largest impact provided by PCI during the acute event.[171]

Ambulatory Monitoring

Ambulatory monitoring remains useful for profiling the risk for development of life-threatening sustained arrhythmias in individuals with certain forms of structural or electrophysiologic disease who are considered to be at high risk (**see Chapter 35**). Technological advances facilitate very-long-term monitoring and allow identification of episodic arrhythmias as causes of relevant symptoms, such as near-syncope and syncope. In addition to the common disorders associated with SCA, loop recorders are useful in disorders such as HCM, LQTS, and RV dysplasia and in patients with dilated cardiomyopathy or heart failure.

Programmed Electrical Stimulation for Risk Profiling

Despite a large but somewhat conflicting database on the role of electrophysiologic testing (EPT) for risk profiling, particularly in patients with advanced heart disease, its use is currently more limited than in the past. In primary prevention trials such as MADIT and MUSTT, programmed electrical stimulation studies were used to profile risk and suggested large benefits.[72] MADIT II, which enrolled patients with lower EF than in MADIT or MUSTT and did not use programmed stimulation or other arrhythmia markers, demonstrated a survival benefit of ICD therapy without the need for incorporating EPT results in the treatment decision. The question of whether EPT is generally useful has yet to be fully resolved, although it appears to have a role in select patients and clinical circumstances. Of interest, a follow-up study of patients in MADIT II suggested inducibility was associated with a higher incidence of VT and

noninducibility with a higher incidence of VF.[172]

The secondary prevention trials of cardiac arrest survivors did not seek to determine whether routine EPT offered predictive value.[72] EPT is not a necessary component of the evaluation unless there is no structural heart disease or unless a supraventricular tachycardia is suspected as the initiating rhythm for cardiac arrest. In the latter patients, treatment targeting the supraventricular tachycardia should be pursued rather than ICD therapy. For the evaluation of precipitating ventricular arrhythmias, most previous studies had demonstrated limitations because an average of less than 50% of cardiac arrest survivors had inducible ventricular arrhythmias. Under conditions in which a potentially reversible trigger for cardiac arrest can be identified, and perhaps in some cardiac arrest survivors in whom transient ischemia was the initiating mechanism and EF is normal or near-normal, there might be a continuing limited role for EPT as a guide to therapy.

For patients without prior cardiac arrest who have symptomatic arrhythmias or who are considered to be at potentially high risk, programmed stimulation is still used, although to a more limited extent. Inducibility of sustained or hemodynamically unstable monomorphic VT, initiated with an appropriate protocol, is considered positive and predictive. However, the implications of induced nonsustained or polymorphic forms of VT or VF are more controversial. Although it has been suggested that induction of nonsustained ventricular rhythms may indicate risk, it is generally considered nonspecific in the absence of structural heart disease or when an aggressive protocol is used. The reliability of noninducibility to predict absence of risk is also questioned.[172] A recent meta-analysis demonstrated that the inducibility of even polymorphic VT and VF indicates risk in patients with nonischemic dilated cardiomyopathies.[173]

Strategies to Reduce Risk for Sudden Cardiac Death

Antiarrhythmic Drugs

Historically, the earliest approach to management of risk for out-of-hospital cardiac arrest and VT with hemodynamic compromise was the use of membrane-active AADs. This approach was based initially on the assumption that a high frequency of ambient ventricular arrhythmias constituted a triggering mechanism for potentially lethal arrhythmias, and that their suppression by AADs was protective. It was also assumed that electrophysiologic instability of the myocardium, likely associated with regional disease changes in refractory periods and conduction velocities, predisposed to potentially lethal arrhythmias and could be modified by AADs. Suppression of inducibility of VT or VF during programmed electrical stimulation studies likely reflected this effect as well. Suppression of ambient arrhythmias was demonstrated by the empiric use of amiodarone, beta-adrenergic blocking agents, or membrane-active AADs, but scientifically valid demonstration of a survival benefit was lacking. The discrepancy between ambient arrhythmia suppression and survival benefit was clarified by the results of CAST, which showed that certain class I AADs increased mortality despite suppression of ambient ventricular ectopy. In contrast, beta-blocker therapy might have some benefit in such patients, and amiodarone might also be effective for some,[72] although it did not perform better than the control group in the heart failure patients studied in SCD-HeFT (Sudden Cardiac Death–Heart Failure Trial). A subgroup analysis of patients in AVID suggested that cardiac arrest survivors with EF greater than 35% had identical outcomes with ICD and amiodarone, but there was no untreated control group to determine if both were beneficial versus ineffective. In summary, ambient arrhythmia suppression and empiric AAD therapy enjoyed a short period of popularity as a strategy for reduction of risk in VT/VF survivors and in high-risk primary prevention candidates, but in time yielded to the benefit of AADs for arrhythmia symptom control, in the presence or absence of ICD.

Therapy Guided by Programmed Electrical Stimulation

The use of programmed electrical stimulation to identify benefit on the basis of suppression of inducibility by an AAD gained popularity for evaluation of long-term therapy in OHCA survivors. It had evolved as the preferred method of management despite concerns about the sensitivity and specificity of the various pacing protocols and the extent to which myocardial status at the time of the programmed electrical stimulation study reflects that present at the clinical cardiac arrest. Nonetheless, as mentioned, most studies have demonstrated limitations based on observations that a relatively small fraction of cardiac arrest survivors (an average of <50% on the basis of multiple studies) had inducible arrhythmias.

Drug suppression of inducibility of sustained ventricular arrhythmias during EPT as an endpoint for secondary prevention of SCD or primary prevention in high-risk post-MI patients has yielded to the benefits of ICD therapy in most subgroups, with a few exceptions in the primary prevention categories.[174]

Surgical Intervention Strategies

The previously popular antiarrhythmic surgical techniques now have limited applications. Intraoperative map-guided cryoablation may be used for patients who have inducible, hemodynamically stable, sustained monomorphic VT during EPT and ventricular and coronary artery anatomy amenable to catheter ablation. However, it has minimal applicability to OHCA survivors because the type of arrhythmia favoring this surgical approach is infrequently observed in cardiac arrest survivors. It can be used as adjunctive therapy for ICD recipients whose arrhythmia burden requires frequent shocks.

Catheter Ablation Therapy

The use of catheter ablation techniques to prevent ventricular tachyarrhythmias has been most successful for benign focal tachycardias that originate in the right ventricle or left side of the interventricular septum (**see Chapter 36**) and for some reentrant VTs. With rare exceptions, catheter ablation techniques are not used for the treatment of higher-risk ventricular tachyarrhythmias or for definitive therapy in patients at risk for progression of the arrhythmic substrate. For VT caused by bundle branch reentrant mechanisms, which occur in cardiomyopathies as well as in other structural cardiac disorders, ablation of the right bundle branch to interrupt the reentrant cycle has been successful. However, this has limited applicability to many patients with structural heart disease who are at risk for SCD or those who have survived a cardiac arrest. Nonetheless, catheter ablation is an appropriate adjunctive treatment strategy for patients with ICD who are having multiple tachyarrhythmic events. Catheter-based substrate modification or ablation has been demonstrated to be useful in ICD recipients receiving multiple therapies,[175] and it performed somewhat better than escalation of antiarrhythmic therapy in another study.[176] Presently, this benefit is limited to reducing the number of patients receiving ICD therapies; further studies are needed to determine whether it has an expanded role for survival.

Implantable Defibrillators

Development of the ICD added a new dimension to the management of patients at high risk for cardiac arrest (**see Chapter 41**). After the initial reports of small case series of very-high-risk patients in the early 1980s, a number of observational studies confirmed that ICDs can achieve rates of sudden death consistently less than 5% at 1 year and total death rates in the 10% to 20% range in populations at high risk for mortality, as predicted by mortality surrogates such as historical controls or time to the first delivered appropriate therapy.[72] However, determination of the mortality benefit of ICDs remained uncertain and was debated (**Fig. 42.18**). More than 16 years elapsed between the first clinical use of an

implanted defibrillator and publication of the first major randomized clinical trial comparing implantable defibrillator therapy with AAD therapy.[72] During that period, reports had documented the ability of ICDs to revert potentially fatal arrhythmias but could not identify a valid relative or absolute mortality benefit because of confounding factors, such as competing risks for sudden and nonsudden death and determination of whether appropriate shocks represented the interruption of an event that would have been fatal.

MADIT (Multicenter Automatic Defibrillator Implantation Trial) provided the first randomized trial data on the relative benefit of defibrillators over AAD therapy (largely amiodarone) for primary prevention of SCD in a high-risk population. The outcome demonstrated a 59% reduction in the relative risk for total mortality (54% cumulative) and a 19% reduction in the absolute risk of dying at 2 years of follow-up. It was followed over less than 10 years by a series of randomized trial reports evaluating ICD therapy for primary and secondary prevention of SCD in patients with previous MI, previous cardiac arrest, and heart failure.

Although these studies documented the ability of ICDs to revert potentially fatal arrhythmias and showed a relative benefit over amiodarone in some groups of patients, the absence of placebo-controlled trials still prevents quantitation of the true magnitude of any mortality benefit because of the inability of positive-controlled trials to identify the absolute benefit of an intervention. Despite these limitations, an ICD is now the preferred therapy for survivors of cardiac arrest at risk for recurrences and for primary prevention in patients in a number of high-risk categories. Major questions remain and include the relative benefit of amiodarone versus ICDs in lower-risk subgroups of survivors of OHCA and the role of beta blockers, catheter-based and surgical anti-ischemic therapy, and medical therapy as definitive approaches.

Application of Therapeutic Strategies to Specific Groups of Patients

Secondary Prevention of SCD after Survival from Cardiac Arrest

As populations of OHCA survivors began to accumulate from community-based emergency rescue activities, the development of therapeutic strategies intended to improve long-term survival emerged as a mandate for clinical investigators. The problem that affects all long-term strategies for cardiac arrest survivors, however, is the lack of a reliable concurrent natural history denominator against which to compare the effects of interventions, because of ethical concerns about withholding therapy in a placebo-controlled study model for patients at high risk of dying, in conjunction with the confounding influence of specific cardiovascular therapies that may also improve survival. Early approaches to long-term therapy centered on the use of AADs, largely guided by EPT results or the empiric use of AADs, particularly amiodarone. Various observational and positive-controlled studies had suggested that suppression of inducible ventricular arrhythmias yielded a better outcome than did failure of suppression, and that amiodarone was better than class I AADs. This approach is no longer widely used.

The first adequately powered secondary prevention trial of ICDs versus AADs was published in 1997. This study, the AVID Trial, demonstrated a 27% reduction in the relative risk for total mortality at 2 years of follow-up, with an absolute risk reduction of 7% (**Fig. 42.19**).[72] It was followed shortly thereafter by reports of two other studies, CIDS (Canadian Implantable Defibrillator Study) and CASH (Cardiac Arrest Study Hamburg), both limited by their enrollment numbers but suggesting trends toward similar benefits (**see Table 42.7**). A meta-analysis of these data confirmed the benefit of ICDs for secondary

prevention,[177] although only AVID demonstrated a statistically significant survival benefit of an ICD over AAD therapy, usually amiodarone. A subgroup analysis of AVID has also suggested that ICDs had no advantage over AADs for VT/VF survivors with EF greater than 35%. Because it is a retrospective analysis and underpowered, the observation calls for confirmation. Since a placebo-controlled trial cannot be done on ethical grounds, this would require a rigidly designed and executed postimplant surveillance study. Currently, despite these limitations, ICDs have emerged as the preferred therapy for survivors of OHCA or hemodynamically significant VT, regardless of EF, in the absence of identifiable and correctable transient causes of cardiac arrest.

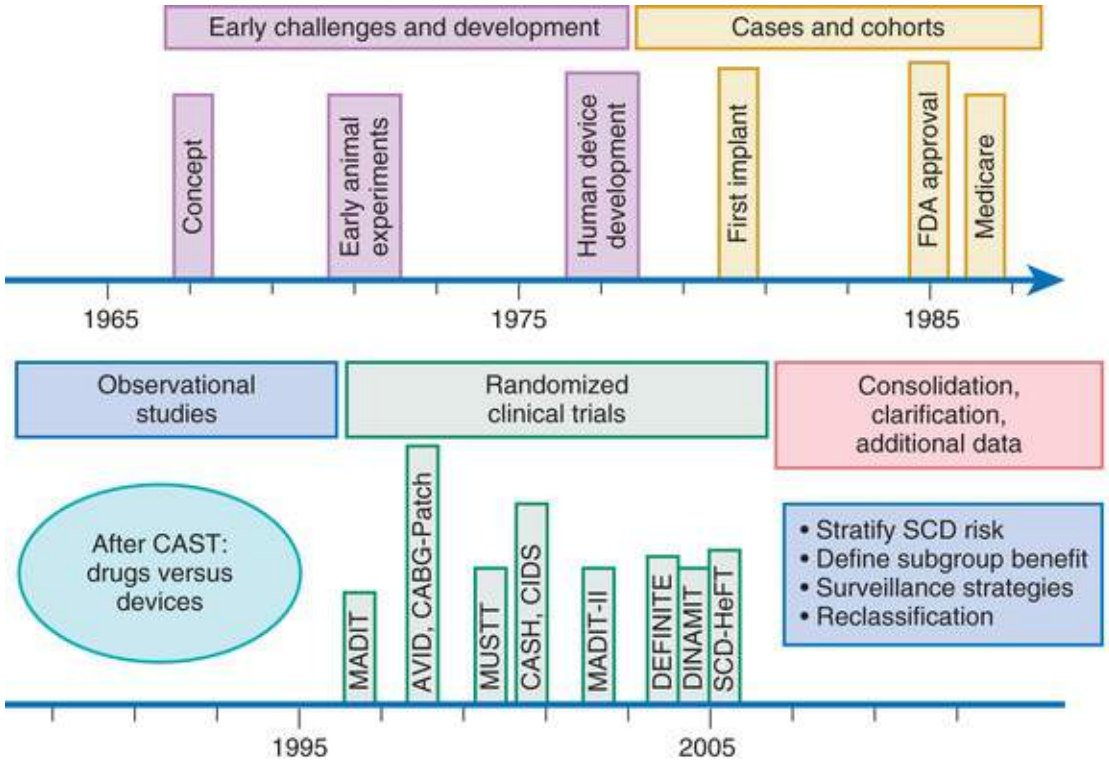

FIGURE 42.19 The concept of an implantable cardioverter-defibrillator (ICD) originated in the late 1960s, and development of the technology and proof of concept leading to the first clinical implant extended to 1980. From 1980 until late 1996, data supporting the benefit of ICDs were largely observational or based on small high-risk cohorts or case-control studies. All the major trials for both primary and secondary indications were published during an interval of 10 years between late 1996 and early 2005. Additional studies since then have aided in interpretation of the outcomes from the clinical trials, but there remains a need for consolidation and clarification and for additional data to better define the efficiency of therapy and targeted selection of individual candidates who have a high likelihood of benefit. (Modified from Myerburg RJ, Reddy V, Castellanos A. Indications for implantable cardioverter-defibrillators based on evidence and judgment. J Am Clin Cardiol 2009;54:747.).

Primary Prevention of SCD in Patients with Advanced Heart Disease

After the disturbing outcome of CAST and suggestions of a lack of efficacy or adverse effects of the class I AADs in general when used for primary or secondary prevention of SCD, interest shifted to the use of amiodarone and implantable defibrillators. Two major trials of amiodarone in post-MI patients, EMIAT and CAMIAT, one of which required EF lower than 40%, demonstrated no total mortality benefit, even though both trials demonstrated AAD benefit, expressed as a reduction in arrhythmic deaths or resuscitated VF. Subgroup analyses have suggested that the concomitant use of beta blockers does confer a mortality benefit.

In parallel with the amiodarone trials, the first randomized controlled trial comparing AAD therapy (primarily amiodarone) with ICD therapy (MADIT) was carried out (**see Table 42.8**). The randomly assigned patients had EF lower than 35%, nonsustained VT during ambulatory recording, and inducible VT that was not suppressible by procainamide. This very-high-risk group demonstrated a 54% reduction in total mortality with ICD therapy versus drug therapy, primarily amiodarone. At the same time, a trial comparing ICD implantation with no specific therapies for arrhythmias in patients with EF less than 36% who were undergoing coronary bypass surgery (CABG Patch Trial) demonstrated no benefit of defibrillators on total mortality. The only markers for arrhythmic risk required for entry into the study were a low EF and a positive signal-averaged ECG. A third trial, MUSTT,[72] was a complex study designed to determine whether electrophysiologically guided therapy would lead to an improved outcome in patients with ambient nonsustained VT, inducible VT, history of previous MI, and EF less than 40%. The results demonstrated that although a statistically significant beneficial effect on total mortality was achieved by EPT-guided therapy, compared to patients with inducible tachycardia who did not receive therapy, the subgroup of patients who received ICDs because they failed to respond to drug therapy accounted for all the benefit. Mortality was 24% in ICD-treated patients at 5 years of follow-up versus 55% in those receiving EPT-guided drug therapy and 48% in those randomly assigned to no therapy. MADIT II, the next post-MI primary prevention trial, demonstrated that ICD therapy provided a mortality benefit over conventional therapy in patients with previous MI and EF less than 30%, with a relative risk reduction of 28% and an absolute risk reduction of 6% (22% versus 16%) at 2 years (**see Fig. 42.19**). During long-term follow-up, a constant annualized risk of approximately 8.5% was estimated in survivors, with the most powerful risk predictors being age over 65 years, class III or IV heart failure, diabetes, non–sinus rhythm, and elevated blood urea nitrogen levels.[178]

MADIT and MADIT II had set entry requirements of more than 3 weeks and more than 1 month after the qualifying infarction, but the actual enrollment in these studies and MUSTT was considerably longer on average. Because both old and recent[25] data suggested higher risk for SCD early after MIs, DINAMIT (Defibrillator in Acute Myocardial Infarction Trial) was designed to evaluate any possible benefit of ICD implantation early after MI in patients with EF of 35% or lower[179] and other markers of risk. DINAMIT demonstrated no survival benefit attributable to early implantation of ICDs in patients randomly assigned at 6 to 40 days after MI (mean, 18 days) despite reduced arrhythmic mortality. There was also an unexplained increase in nonarrhythmic mortality over conventional therapy that needs to be explored in future studies. The IRIS (Immediate Risk Stratification Improves Survival) trial also evaluated ICD implantation early after MI (entry criteria for days from infarct to randomization, 5 to 31; mean to randomization, 13 ±7 days) in patients with either EF of 40% or lower and other markers of risk or nonsustained VT.[180] No survival benefit was noted with ICD therapy. These data suggest that either some SCDs in the early post-MI period are caused by a nonarrhythmic mechanism, or that different risk predictors are required in this setting. Indeed, limited data support both these possibilities. The VALIANT investigators evaluated autopsy findings in 105 patients considered to be SCD and identified that approximately half the SCDs in the early post-MI period were caused by mechanical complications, with a large proportion being recurrent MI and ruptured ventricular aneurysms.[181] Another ICD trial in the early post-MI period (BEST-ICD) was terminated prematurely because of low enrollment. In this trial, ICD implantation early after MI (days 5 to 30) in patients with EF less than 35% and other markers of risk was considered only in patients randomized to an electrophysiology study (EPS)–guided treatment approach in whom sustained ventricular arrhythmias were inducible.[182] The point estimates for mortality in the conventional versus EPS-guided treatment groups were 18% versus 14% at 1 year and 29.5% versus 20% at 2 years. This trend was not statistically significant, but the study was also underpowered

because of premature termination. Observational data from Australia support the potential for this approach to identify risk for SCD in the early post-MI period.[183] Further efforts to address SCD risk prediction properly in this critical period are necessary.

The promise of early ICD benefit came from intervention studies reported between 1996 and 2005 and designed and executed beginning in the early 1990s and extending to 2004. More recent data suggest that optimized therapy during and after MI, with "optimized" being defined as revascularization and the use of beta blockers, acetylsalicylic acid, statins, and ACE inhibitors, may beneficially influence risk for SCD during long-term follow-up after the event.[171] In this study, the greatest impact was achieved by revascularization. Even though EF was improved in association with these interventions, it was not determined whether risk is reduced with EFs equivalent to those in the early ICD trials. However, the population burden of SCD in post-MI patients was reduced by these MI-related interventions. Another study also suggested that both thrombolytic therapy and PCI during acute MI and other changes in therapy that have occurred between 1995 and 2010 have improved 30-day mortality.[47] A 2009 to 2011 randomized trial was designed to evaluate ICD therapy programming strategies on delivered shocks and mortality.[184] Higher detection rates and longer detection times were associated with fewer shocks and improved survival compared to conventional programming. Interestingly, cumulative mortality at 24 months in the conventional programming group was 10% versus 16% in the original MADIT II cohort (1997 to 2001), thus suggesting beneficial influences other than ICDs on outcomes.

The DEFINITE study, designed to determine whether patients with nonischemic cardiomyopathy and a history of heart failure, EF of 35% or lower, and PVCs or nonsustained VT could benefit from prophylactic ICD therapy, was underpowered to achieve statistical significance ($P = 0.08$). However, the reported results demonstrated a strong trend toward benefit, with a 35% reduction in relative risk and a 6% reduction in absolute risk during 2 years of follow-up.[185] Subgroups with prolonged QRS durations, EF higher than 20%, and class III heart failure performed better than did the overall cohort data. SCD-HeFT was designed to test the potential benefit of ICDs versus amiodarone and placebo in patients with functional class II or III congestive heart failure and EF lower than 35%. Nonischemic cardiomyopathy and ischemic cardiomyopathy were almost equally represented, with 85% of patients with ischemic cardiomyopathy having a history of MI. Results demonstrated a 23% reduction in relative risk and 7% reduction in absolute risk during 5 years[186] (**Fig. 42.20**). Amiodarone provided no added benefit over conventional therapy. In contrast to DEFINITE, the class II patients in SCD-HeFT had better outcomes than did the class III patients.

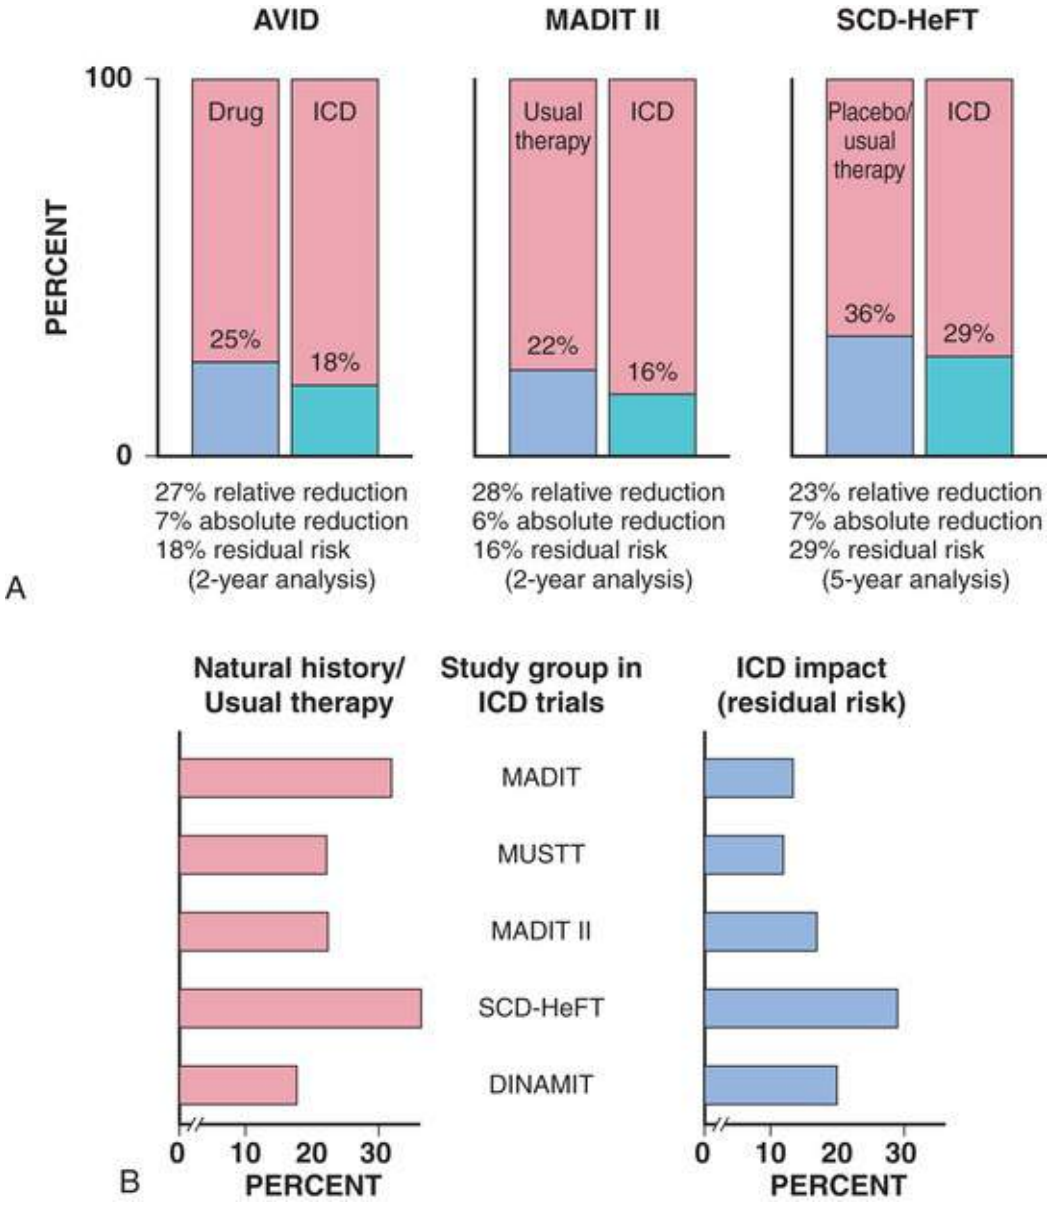

FIGURE 42.20 **A,** Relative and absolute benefits of ICDs in three ICD trials: a secondary prevention study (AVID) trial, a primary prevention trial (MADIT II), and a heart failure sudden death trial (SCD-HeFT); see text for definitions and trial descriptions. Relative risk reductions indicate proportional differences in outcomes between test and control populations, absolute reductions indicate proportional benefits for individuals, and residual risks indicate mortality remaining after accounting for ICD benefits. **B,** Residual risk after accounting for ICD-associated survival benefit in five major primary prevention ICD clinical trials. (**A,** Modified from Myerburg RJ, Mitrani R, Interian AJr, Castellanos A. Interpretation of outcomes of antiarrhythmic clinical trials: design features and population impact. Circulation 1998;97:1514.)

The mortality benefit of ICDs combined with cardiac resynchronization therapy is unclear. Although one study suggested a small mortality benefit in patients with class III and IV heart failure,[187] another study that enrolled class I and II heart failure patients (most of the enrollees being class II) with prolonged QRS duration demonstrated a heart failure hospitalization benefit without a mortality benefit.[188] Several meta-analyses have been inconclusive about the mortality benefit of combined therapy, although reduction of hospitalizations appears consistent. However, a randomized study of patients with nonischemic systolic heart failure suggested no added survival benefit of prophylactic ICDs when appropriate medical therapy is employed.[189]

Primary Prevention in Patients with Less Advanced Common Heart Diseases or Uncommon

Diseases.

Primary prevention trials have been designed to enroll populations of patients with advanced heart disease who were estimated to be at very high risk for SCD and total mortality as a consequence of the severity of the underlying disease. Most clinical trials testing the question of the relative efficacy of antiarrhythmic versus ICD therapy have used the EF as the marker for advanced disease, with the upper limits of qualifying ejection fractions being between 30% and 40% and the majority set at 35%. The mean or median values of those actually enrolled ranged from 21% to 30%,[53,72] and subgroups with EF higher than 30%, particularly those in the range of 35% to 40%, had lower if any benefit (**Fig. 42.21**).

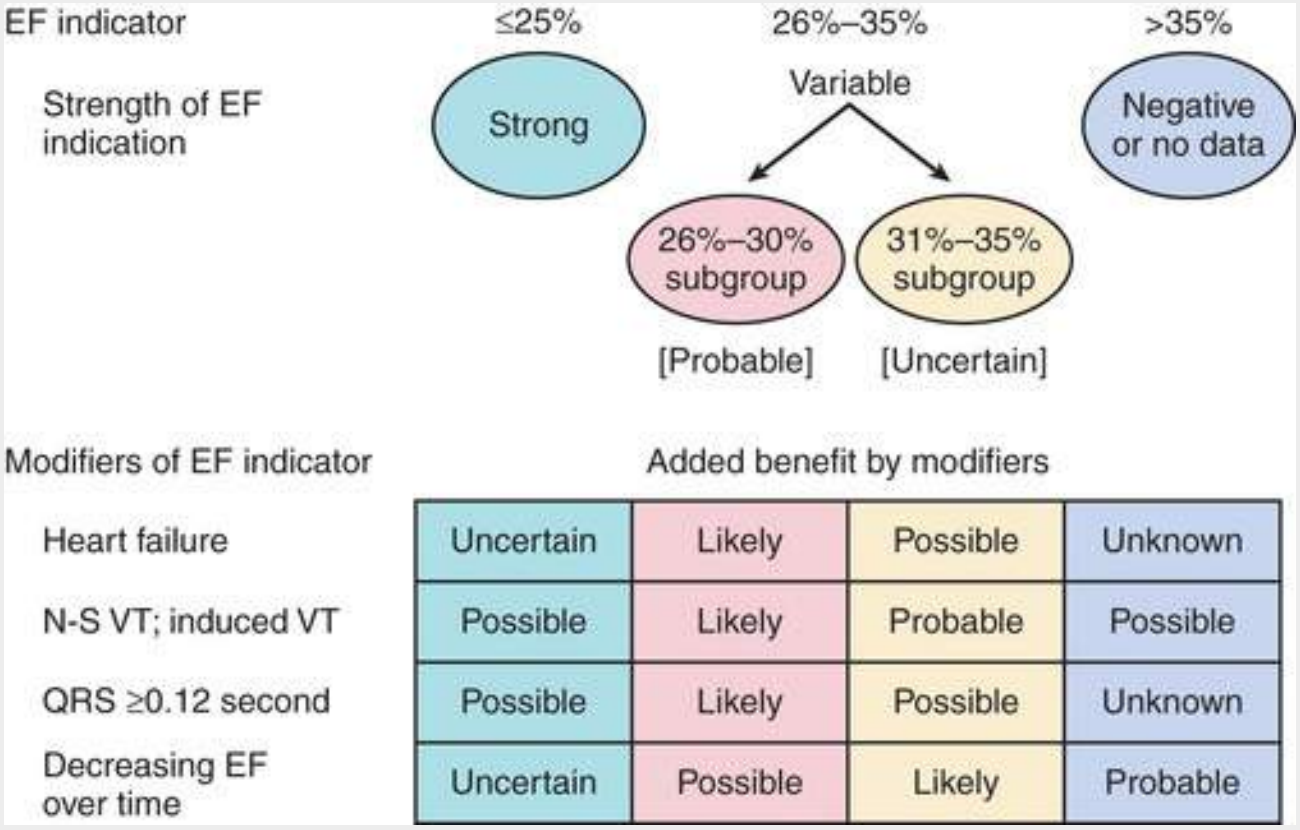

FIGURE 42.21 Modifiers of post-MI ejection fraction (EF) indicators for ICDs. The strength of EF as a primary determinant of indications for an ICD after MI varies and is apparently modulated by a number of clinical factors. Although stratified trial data are not available, indications from subgroup analyses suggest general patterns of modification of EF indicators by other influences. In circumstance in which EF alone appears to be a strong indicator (e.g., 20% to 25%), modifiers that have an effect at other levels of EF (e.g., heart failure) may not add further strength of prediction for total mortality. *N-S VT,* Nonsustained ventricular tachycardia. (Modified from Myerburg RJ. Implantable cardioverter-defibrillators after myocardial infarction. N Engl J Med 2008;359:2245.)

Although the risk for SCD and total mortality is highest in patients with advanced structural heart disease, characterized by low EF, impaired functional capacity, or both, a substantial proportion of the total SCD burden occurs in patients with coronary heart disease or the various nonischemic cardiomyopathies with EF between 35% and 40% and higher. In addition, in patients with heart failure related to various forms of cardiomyopathy, even though the total mortality risk is considerably lower in those with functional class I or early class II than in those with late class III or class IV status, the probability of a death being sudden is higher in the former group[18] (**see Fig. 42.8**). Despite this observation, no data are available to guide therapy for primary prevention of cardiac arrest in such patients.[17] This limitation is confounded by patients in these categories generally having low event rates but cumulatively accounting for large numbers of SCD (**see Fig. 42.2**). In addition, certain other

structural entities associated with some elevation in risk for SCD in the absence of a severely reduced EF, such as some patterns of viral myocarditis, HCM, RV dysplasia, and sarcoidosis, are managed without the benefit of clinical trials to guide therapeutic decisions (**see Table 42.8**). Patients with symptomatic ventricular arrhythmias related to structural disorders such as RV dysplasia, in which most of the mortality risk is arrhythmic, are often advised to have an ICD, even in the absence of a previous cardiac arrest or hemodynamically significant VT. Whether AAD therapy would be just as effective remains unknown, but the judgment of using defibrillators in patients with a disorder whose fatal expression is primarily arrhythmic carries the strength of logic, often supported by risk profiling based on observational data of clinical markers. Among the entities in which the family history is helpful in defining risk, clinical judgment is facilitated in patients with a strong family history of SCD. Specific support for this approach is derived from genetic studies of individuals with HCM. In addition, clinical observational data have supported the use of ICDs in high-risk subsets of patients with HCM.[68]

Primary Prevention in Patients with Structurally Normal Hearts or Molecular Disorders of Cardiac Electrical Activity

Clinically subtle or inapparent structural disorders and entities with pure electrophysiologic expression, such as the congenital long-QT syndromes, Brugada syndrome, and idiopathic VF, are receiving increasing attention with regard to preventive activities (**see Chapter 33**). The decision-making process for cardiac arrest or symptomatic VT survivors with LQTS is similar to that for other entities in that survivors of a potentially fatal arrhythmia generally receive ICD therapy (**see Table 42.9**). In contrast, individuals who express the electrocardiographic phenotype of LQTS in the absence of symptomatic arrhythmias generally receive beta-blocker therapy. Beta blockers are also considered useful for affected family members who have not had an event and for subgroups of LQTS patients with syncope of undocumented mechanism.[72] Between these extremes are asymptomatic affected family members of patients with symptomatic LQTS. The threshold for consideration of ICD therapy is decreasing,[39] primarily among carriers who break through with symptoms while receiving beta-blocker therapy. Currently, many such clinical therapeutic decisions are still based on judgment rather than driven by data.[72] In this context, a family history of premature SCD in affected relatives is often considered in the decision-making process for preventive therapy in this general category of patients, although it is uncertain whether family history is applicable to LQTS syndrome.

Among the other molecular arrhythmia syndromes, management strategies for Brugada syndrome remain problematic and debated.[93-95] An ICD is accepted as the secondary prevention strategy in SCA survivors and as the primary prevention therapy in symptomatic patients with type I Brugada patterns, even though based largely on observational data. Studies have suggested that syncope associated with ECG changes suggestive of this disorder at baseline is a marker of risk sufficient to warrant ICD therapy, and that baseline ECG changes associated with inducibility of ventricular tachyarrhythmias during EPT may also be a marker of risk in some subgroups.[94] Conversely, the absence of right bundle branch block and ST-T wave changes without provocation suggests low risk. The appropriate role of EPT is still debated, complicated in part by the absence of uniform protocols and selection biases based on subgroups studied at various centers. However, a family history of SCD is often considered in judgment-based decisions. Similar arguments, but supported by even fewer data, apply to affected family members of patients with RV dysplasia.

Prediction and Primary Prevention in the General Population

Because SCD is frequently the first clinical expression of underlying structural heart disease or occurs in identified patients profiled to be at low risk (**see Fig. 42.2B**), there has been longstanding interest in risk profiling and therapeutic strategies targeted to primary prevention. To have a major impact on the problem of SCD in the general population, including adolescents and young adults, physicians need to move beyond the identification of high-risk patients who have specific clinical entities, advanced or subtle, that predict high risk for SCD. Rather, it is necessary to find small subgroups of patients in the general population at specific risk for SCD as a manifestation of underlying heart disease, if and when that disease manifests. For example, studies that demonstrate familial clustering of SCD as the first expression of underlying coronary artery disease and thus suggest a genetic or behavioral predisposition may provide some help for the future.[9] If highly specific markers related to electrophysiologic properties or along multiple points in the cascade of coronary events can be found (**see Fig. 42.4**), preventive therapy before the first expression of an underlying disease may have a major effect on the population burden of SCD. Otherwise, success will be limited to community-based intervention and to subgroups who are easier to identify and in whom it is more justifiable to use prophylactic interventional therapy on the basis of population size and magnitude of risk.[2,72]

Adolescents and young adults, including athletes (**see Chapter 53**), constitute a group for special consideration. Risk for SCD in these groups is approximately 1% of the risk in the general adult population older than 35 years[10,72] (**see Fig. 42.3**). However, most causes of SCD in these populations are not characterized by advanced, life-limiting structural heart disease, and therefore, with appropriate long-term therapy, cardiac arrest survivors can be expected to have significantly extended life. Because most deaths are arrhythmic, the ability to identify individuals at risk before a life-threatening arrhythmic event offers more long-term impact than in older populations. For both the general young population and athletes, identification of individuals at risk may lead to prevention of events triggered by physical activity. One study demonstrated a reduction in SCDs in athletes with the use of widespread ECG screening.[190] In the United States, strategies for screening of adolescents, young adults, and athletes to identify entities that create risk have largely been limited to medical and family histories and physical examination,[191] although a consensus statement spearheaded by the National Collegiate Athletic Association (NCAA) has taken a more permissive position on ECG screening.[192] The European and the International Olympic Committee recommendations add ECG screening for athletes, which continues to be debated in the United States[193] despite data indicating both feasibility and suggestions of cost-effectiveness.[194] ECG screening of the general adolescent population, including athletes, can identify many of those at potential risk because of congenital LQTS, HCM, RV dysplasia, and Brugada syndrome. In Japan, where ECG screening of first- and seventh-grade schoolchildren is routine, the apparent incidence of LQTS is considerably higher than recognized in the United States and Europe: 1 in 3298 first graders and 1 in 988 by the seventh grade, versus 1 in 2000 to 2500 in the general population elsewhere.[38] Although ECG screening in the adolescent and athletic subgroups is imperfect and usually accompanied by depolarization and repolarization patterns that may be difficult to interpret, this strategy can lead to further testing in appropriate individuals. Echocardiography has also been suggested as a screening method, but it is more expensive and less cost-efficient and does not recognize conditions such as LQTS and Brugada syndrome.

Risk for SCD must be evaluated in competitive athletes with previously known cardiovascular disorders or those discovered during preparticipation screening, as well as in those with known disorders who want to participate in recreational sports. Recommendations for competitive athletes are available based on the intensity of exercise,[195] the nature of the diseases,[74,196] response stragegies,[197] and legal considerations.[198] Issues for recreational athletes are more complex because of the absence of

organizational infrastructure in most cases.

Sudden Death and Public Safety

The unexpectedness of SCD has raised questions concerning secondary risk to the public created by people in the throes of cardiac arrest. No data from controlled studies are available to guide public policy regarding people at high risk for potentially lethal arrhythmias and for abrupt incapacitation. In a report of observations on 1348 sudden deaths caused by coronary heart disease in people 65 years or younger during a 7-year period in Dade County, Florida, 101 (7.5%) of the deaths occurred in people who were engaged in activities at the time of death that were potentially hazardous to the public (e.g., driving a motor vehicle, working at altitude, piloting aircraft), and 122 (9.1%) of the victims had occupations that could create potential hazards to others if an abrupt loss of consciousness had occurred while they were at work. No catastrophic events occurred as a result of these cardiac arrests, only minor property damage in 19 and minor injuries in five.

In specific reference to private automobiles, a study from Seattle, Washington, identified 33 SCDs per year while driving the estimated 1.32 million vehicles in the community. An analysis of recurrent events in cardiac arrest survivors has suggested limitation of driving privileges for the first 8 months after the index event on the basis of the clustering of recurrent event rates early after the index event.[199] Therefore, although there are likely to be isolated cases in which cardiac arrest causes public hazards, the risk appears to be small, and because it is difficult to identify specific individuals at risk, sweeping restrictions to avoid such risks appear to be unwarranted. The exceptions are people with multisystem disease, particularly senility, and individual circumstances that require specific consideration, such as patients with documented or substantial risk for loss of consciousness associated with the onset of arrhythmias and high-risk patients who have special responsibilities—school bus drivers, aircraft pilots, train operators, and truck drivers.

Among patients with primary prevention ICDs, it was originally suggested that driving be avoided for 6 months after implant, but revised recommendations reduced that to 1 week or more, depending on individual circumstances.[199] Once a therapy has been delivered, the post-therapy guideline of up to 6 months still prevails, again with modification based on individual circumstances and preshock symptoms. A study of temporal patterns of recurrent ICD shock therapies identified an acceleration of time to recurrent events after a first event has occurred, an observation that may have implications for driving depending on associated symptoms in individual patients.[200]
