Inflammatory injury to the myocardium by infective agents, postinfective immune processes (e.g., Chagas disease, rheumatic carditis), hypersensitivity, and autoimmune conditions can cause myocardial dysfunction. The clinical manifestation of such an inflammatory process is acute myocarditis and cardiac allograft rejection (**see Chapters 27 and 79**). Because myocyte necrosis is an obligatory component of myocarditis (cellular infiltrates, predominantly lymphocytes and macrophages, clustered around necrotic myocytes), radionuclide-labeled agents that target some component of the damaged myocyte have been investigated. Indium-111 (^{111}In)–labeled antimyosin antibody, which specifically targets myosin heavy chain, has been used for the detection of necrosis associated with myocarditis and heart transplant rejection. In patients with biopsy-positive myocarditis, the sensitivity of an antimyosin scan is approximately 95%, with NPV of approximately 95%. However, the specificity and PPV of antimyosin imaging are modest, in the 50% range.[52]

Cardiac Sarcoidosis

Cardiac involvement with clinical manifestations occurs in about 5% of patients with sarcoidosis, but contemporary imaging studies suggest that clinically silent myocardial involvement appears to involve approximately 25% of patients with extracardiac sarcoidosis.[53,54] (**see Chapter 77**). Clinical manifestations may include AV block, ventricular tachycardia, HF, and sudden cardiac death. SPECT perfusion imaging studies have reported that both fixed and reversible defects may be seen, possibly secondary to focal fibromuscular dysplasia found in the small coronary arteries. Perfusion defects involving the left ventricle have been associated with AV block and HF, and defects involving the right ventricle on SPECT have been associated with ventricular tachycardia of RV origin.[53] Gallium-67 scintigraphy is a nonspecific marker of inflammation and has been used in the past to identify patients with active inflammation. It has essentially been replaced by FDG PET imaging, which has superior sensitivity and spatial resolution characteristics.[55]

In contemporary practice, CMR is often used to evaluate patients with suspected cardiac sarcoidosis (**see Chapter 17**). Late gadolinium enhancement and T2-weighted imaging can identify areas of scarring, inflammation, and edema with much higher prevalence than clinical features suggestive of cardiac involvement. CMR imaging cannot distinguish areas of active inflammation from scar,[56] a distinction with important implications for treatment.

FDG PET imaging (with or without anatomic colocalization with CT or CMR) has gained interest for diagnosis and potential follow-up of cardiac sarcoidosis.[55] Because inflammatory cells (e.g., macrophages) contain increased membrane glucose transporters and significantly high hexose monophosphate shunt pathway activity, FDG can accumulate within areas of granulomatous inflammation and cannot diffuse out or be metabolized further (**Fig. 16.39**). As a granuloma matures, the number of macrophages and inflammatory cells decreases, with subsequent fibrous replacement. FDG PET imaging is not highly sensitive for identifying any myocardial involvement, because areas of scarring without inflammation will not be identified by FDG-PET. Nonetheless, the presence of active inflammation identified by FDG PET appears to be associated with an increased incidence of adverse events during

follow-up after imaging.[55]

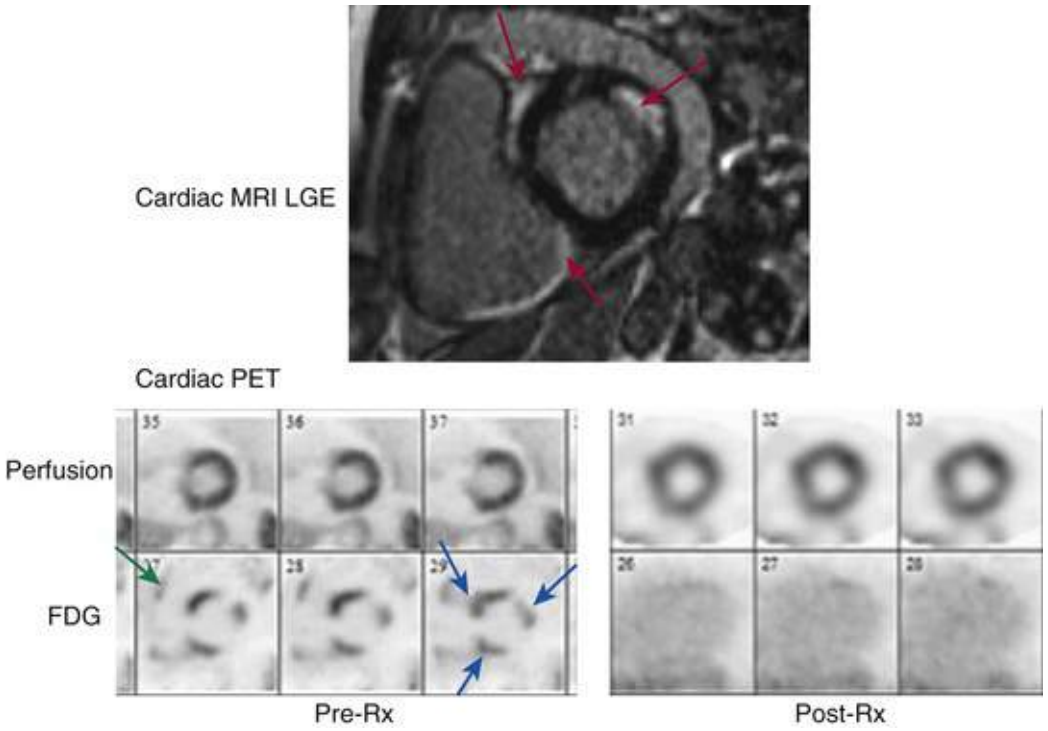

FIGURE 16.39 Example of cardiac MRI and PET findings consistent with cardiac sarcoidosis as well as a reduction in myocardial inflammation following immunosuppressive therapy. In a patient with a history of ventricular tachycardia referred for evaluation, cardiac MRI demonstrates a large amount of subepicardial late gadolinium enhancement (LGE) involving the basal anteroseptum and inferoseptum, most prominently at the RV insertion points, as well as subendocardial LGE involving the basal anterolateral wall. (*red arrows*). Note LGE along the basal inferoseptum extending across into the right ventricle. Because these features were strongly suggestive of cardiac sarcoidosis, the patient was subsequently referred for a rest PET scan. After a high-fat diet to suppress ^{18}F-fluorodeoxyglucose (FDG) uptake from the myocardium, there was intense FDG uptake involving the basal anteroseptum, inferoseptum, and anterolateral segments (*blue arrows*), as well as focal uptake of FDG by the right ventricle (*green arrow*). The rest perfusion images show a perfusion defect along the septum, in part corresponding to the areas of FDG uptake involving the septum. The patient was treated with oral corticosteroids, and follow-up PET 1 year later (*bottom right panel*) shows complete resolution of the myocardial inflammation. Notably, the resting perfusion defect also improved because of less inflammation compression on the microvasculature.
(Images courtesy Dr. Ron Blankstein.)

In concert with either CMR or CT, FDG PET may be optimal for monitoring the efficacy of therapy directed at the active inflammation in cardiac sarcoidosis and for detecting recurrence. In a study using serial FDG PET in patients with cardiac sarcoid undergoing corticosteroid therapy, reduction in FDG uptake after anti-inflammatory therapy was associated with an improvement in EF[55] (**Fig. 16.39**), suggesting potential clinical use to guide magnitude and duration of therapy.

Currently applicable guidelines for the diagnosis of cardiac sarcoidosis suggest two pathways to diagnosis, one involving direct endomyocardial biopsy evidence, but a second pathway that can utilize noninvasive imaging results. A diagnosis of cardiac sarcoid is said to be probable if there is histologic evidence of extracardiac sarcoid, accompanied by abnormal CMR, FDG PET, or gallium-67 imaging.[53]

Cardiac Amyloidosis

Our understanding of the cardiac amyloidosis syndromes has expanded substantially in recent years. Older classification schemes have now evolved to thinking of patients as having either AL amyloid, as part of a light chain protein proliferative disorder, or transthyretin (TTR) amyloid, which can have

several subtypes. Clinical trials of therapeutic agents are underway for both syndrome subtypes. The potential for a specific therapy, coupled with the evolution of cardiac imaging tools such as CMR (**see Chapter 17**), has brought new urgency to making a diagnosis of cardiac amyloid in a patient with the clinical syndrome of HF with preserved EF or unexplained LV hypertrophy.

In the past, ^{99m}Tc-labeled bone-avid tracers such as ^{99m}Tc-pyrophosphate (PYP) were used for diagnosis and localization of MI, even before the availability of the initially used cardiac enzymes such as creatine phosphokinase (CPK). Once serum enzyme diagnostics for MI became widely available, the use of PYP imaging for MI disappeared quickly. At that time. however, case series showed that these bone-avid tracers could also show uptake, sometimes quite substantial, in patients later found to have cardiac amyloidosis. The numbers of patients were modest, however, and patients were highly selected with varying degrees of rigor regarding the gold standard diagnosis. With the increasing use of tissue biopsies for diagnosis, the use of ^{99m}Tc tracers for this purpose remained infrequent.

Recent single-center studies have reexamined the use of ^{99m}Tc-PYP and other bone-avid tracers and suggested that this type of imaging can identify TTR amyloid with high sensitivity and specificity, noninvasively distinguishing that entity from AL amyloid[57] (**Fig. 16.40**).

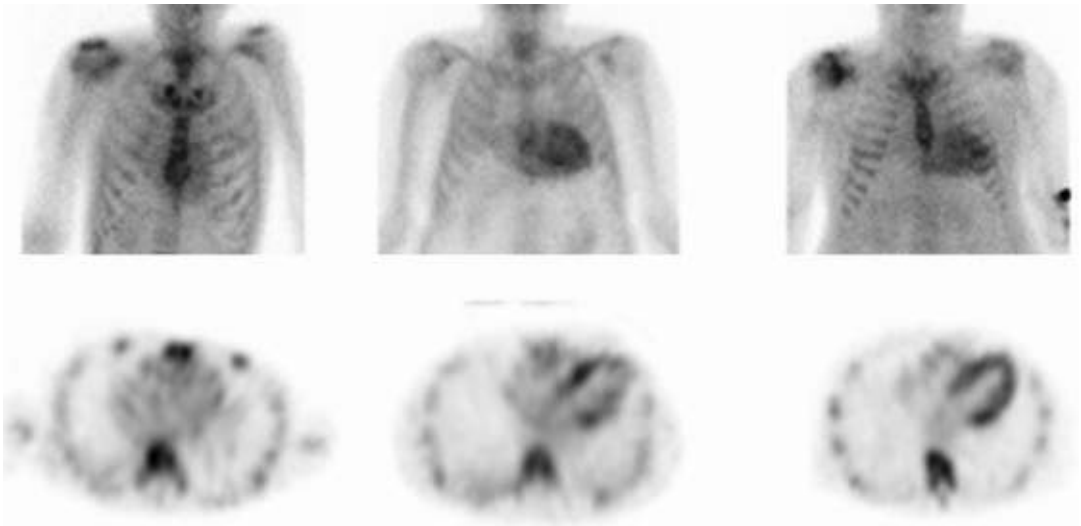

FIGURE 16.40 Sections of whole-body planar **(top row)** and chest SPECT **(bottom row)** ^{99m}Tc-pyrophosphate images. *Left panels,* Grade 0 uptake (no myocardial uptake), effectively excluding transthyretin cardiac amyloidosis. *Middle panels,* Grade 2 uptake (myocardial uptake equal to bone uptake). *Right panels,* Grade 3 uptake (myocardial uptake greater than bone uptake). Uptake of this tracer marks the myocardial deposition of TTR amyloid. (Images courtesy Sharmila Dorbala, MD.)

In a pooled analysis from multiple referral centers in the United States and Europe of almost 1500 patients with suspected cardiac amyloid, more than 800 of whom had a diagnosis of cardiac amyloid established, the sensitivity of any apparent ^{99m}Tc uptake to detect TTR amyloid was greater than 99%, with a specificity of 86%; false positives were most often caused by mild uptake in AL patients. The combination of a more than mildly positive ^{99m}Tc scan and the absence of a monoclonal spike on serum or urine testing was highly specific and predictive for TTR amyloid. Thus a combination of bone scintigraphy and monoclonal gammopathy testing may obviate the need for endomyocardial biopsy in many patients with suspected cardiac amyloid and may allow a “nonbiospy” diagnosis.[58]

Newer radionuclide agents are being developed that specifically bind to amyloid deposits in the heart. ^{18}F-florbetapir can be imaged with PET technology and in early studies shows promise to detect both AL and TTR cardiac amyloid[59] (**Fig. 16.41**).

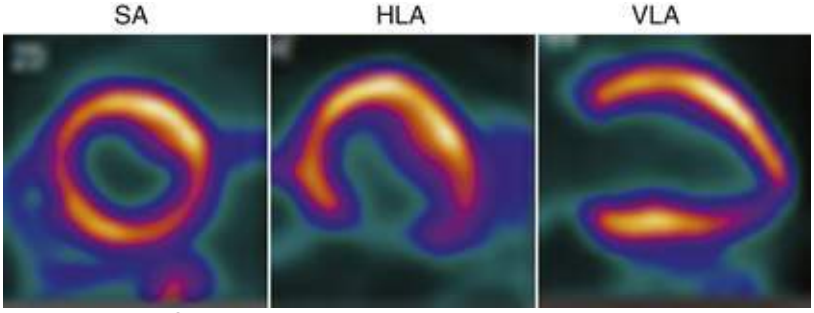

FIGURE 16.41 Myocardial ^{18}F-florbetapir images of patient with light chain cardiac amyloidosis. Standard short-axis (SA), horizontal long-axis and vertical long-axis (VLA) projections show uniform and intense ^{18}F-florbetapir uptake throughout the left ventricle, marking extensive myocardial amyloid deposition. (Images courtesy Sharmila Dorbala, MD.)

Imaging for Assessment of Arrhythmias in Heart Failure

Assessment of Cardiac Sympathetic Innervation.

An emerging area of risk stratification involves the use of ^{123}I-metaiodiobenzylguanidine (MIBG) imaging of cardiac sympathetic innervation in HF. ^{123}I-MIBG shares its reuptake mechanism and endogenous presynaptic storage with norepinephrine. ^{123}I-MIBG is taken up into presynaptic terminal via uptake-1, but as a false neurotransmitter, ^{123}I-MIBG is not catabolized, thereby localizing in high concentration in nerve terminals, allowing for external imaging. The highest density of sympathetic nerves is in the RV and LV myocardium, which can be imaged with single-photon-emitting radiotracer ^{123}I-MIBG, or positron-emitting radiotracers such as ^{11}C-hydroxyephedrine and ^{18}F-fluorobenzylguanidine.[60] PET provides higher-resolution images than planar or SPECT imaging with ^{123}I-MIBG, allowing for regional analysis of the innervation signal and kinetic modeling for true quantification.

In the post-MI setting, the territory of abnormal ^{123}I-MIBG uptake often exceeds the final infarct size, and such patients are at higher risk for subsequent ventricular arrhythmias.[61] In two multicenter prospective phase III studies comprising more than 900 patients with HF and systolic dysfunction, 2-year event-free survival was significantly higher for patients with more preserved ^{123}I-MIBG uptake (i.e., more preserved functional sympathetic innervation) than for patients who showed evidence of more advanced functional denervation on ^{123}I-MIBG imaging.[62] The ^{123}I-MIBG uptake was quantified using the ratio of counts/pixel in whole-heart (H) and in upper mediastinum (M) regions in 4-hour delayed anterior planar images of the chest (**Fig. 16.42**), referred to as the heart-to-mediastinum ratio (H/M). Adverse events were defined as symptomatic progression, potentially life-threatening arrhythmic event, or cardiac death. Two-year event-free survival was 85% in patients with more preserved ^{123}I-MIBG uptake (H/M ratio ≥1.6), compared with 63% in those with an abnormal imaging result (H/M <1.6; hazard ratio [HR]: 0.40; $P < 0.001$). These findings contributed to FDA approval of ^{123}I-MIBG for imaging sympathetic innervation of the myocardium in HF patients to assess risk of mortality. Additional clinical studies may define the role of this agent in optimizing selection of post-MI patients or those with HF who may (or may not) benefit from a defibrillator.

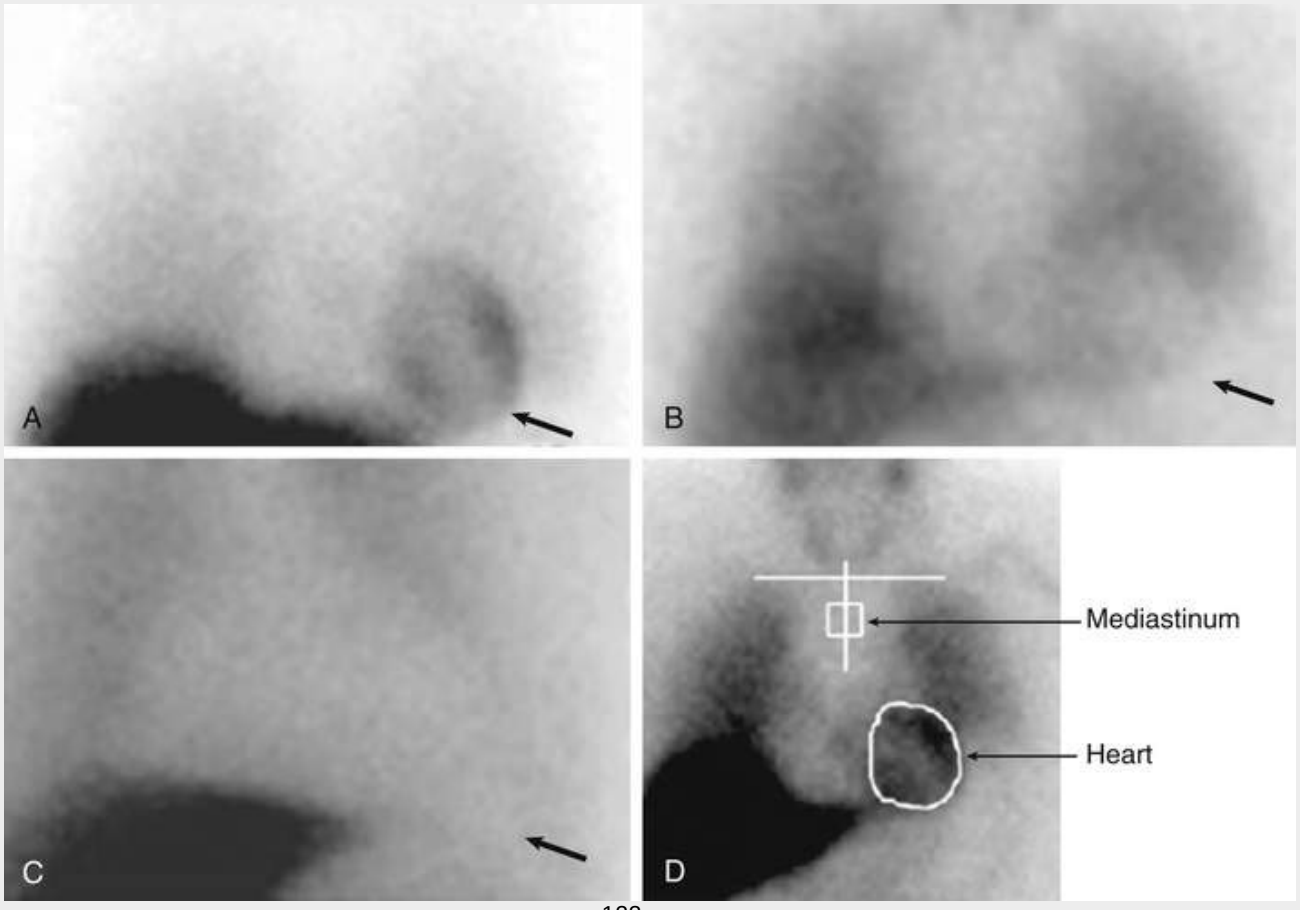

FIGURE 16.42 Examples and quantification of ^{123}I-MIBG imaging of cardiac sympathetic innervation. In these anterior planar images, *arrows* denote area of the heart. **A,** Normal cardiac uptake of MIBG, with uptake in the heart clearly greater than in the lungs or mediastinum. **B,** Abnormal uptake, similar to that in the lungs or mediastinum. **C,** Apparent absence of cardiac uptake, consistent with severe functional denervation. **D,** Method for quantification of MIBG uptake. Region of interest (ROI) is drawn around the cardiac epicardial border, as well as a region within the mediastinum, and a ratio of the counts/pixel in heart ROI and mediastinal ROI (H/M ratio) is calculated. ^{123}I-MIBG Neurocardiac and ^{18}F-FDG Metabolism: Cardiac Imaging to Guide Ventricular Tachycardia Ablation in Heart Failure.

The cornerstone of current techniques for identifying successful ablation sites of ventricular tachyarrhythmias in patients with structural heart disease and HF is the localization of abnormal or scarred myocardium. This tissue usually contains areas of slow conduction, which are critical for maintaining reentrant arrhythmias. Electroanatomic mapping performed in the electrophysiology laboratory identifies the presence of anatomic scar by decreased bipolar voltages measured with roving, steerable catheters. Given the inherent limitations of this technique, such as falsely low voltage recording due to poor catheter contact, the inability to detect intramural scar, and limited mapping density, imaging modalities such as magnetic resonance imaging (MRI), CT, PET, and SPECT have been used to assess scar by demonstrating gadolinium enhancement, thinned walls, and perfusion/metabolic abnormalities. The advantage of PET or PET-CT ^{18}F-FDG metabolic imaging[63] and ^{123}I-MIBG planar and SPECT[64] for scar imaging is that they are not affected by some of the patient restrictions with MRI or CT alone. Although delayed enhanced MRI has been well established to visualize scar tissue, the defibrillators, metal artifacts, and association with nephrogenic systemic sclerosis limit its use in the ventricular tachycardia (VT) patient population. Similarly, although scar imaging with delayed enhanced CT has been described, its applicability in chronic human infarcts is still evolving. The use of three-dimensional scar fusion models with ^{18}F-FDG and ^{123}I-MIBG allows accurate assessment of LV scar and its border

zone. The integration of a three-dimensional scar map into a clinical mapping system is feasible and allows supplementary scar characterization that is not available from endocardial voltage maps (**Fig. 16.43**). This difference could significantly facilitate substrate-based VT ablations.

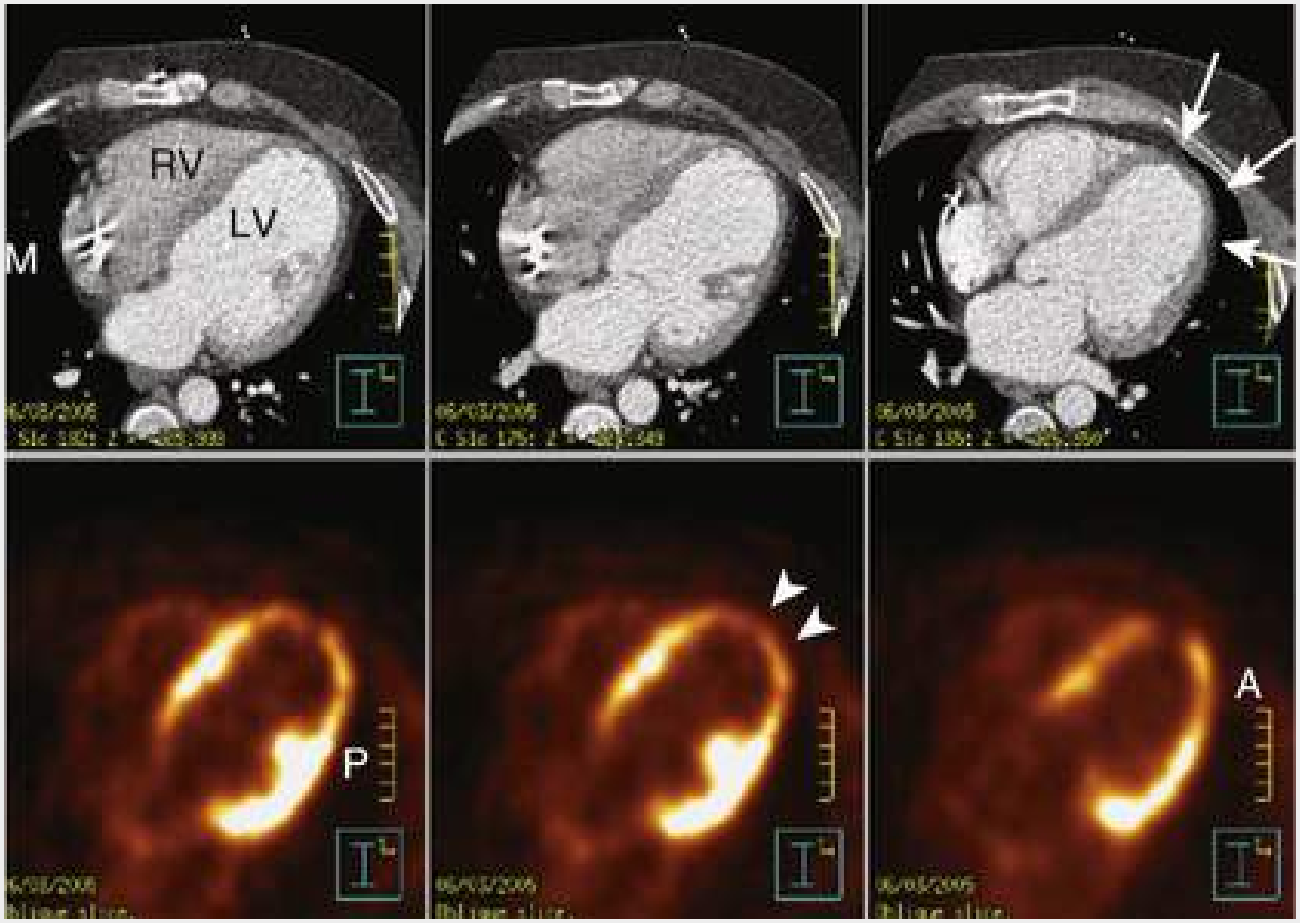

FIGURE 16.43 ^{18}F-FDG PET and CT imaging to identify substrate for ventricular arrhythmias in heart failure. **Top row,** Contrast-enhanced CT demonstrates all cardiac chambers. *RV,* Right ventricle; *LV,* left ventricle; *M,* metal artifact of internal defibrillator lead in right atrium. Significant wall thinning (*arrows*) is noted in the apical and lateral LV wall, consistent with myocardial infarction. **Bottom row,** FDG PET images show a matching decrease in signal intensity in apical and lateral wall segments (*arrowheads*). Preserved metabolism of papillary muscle (*P*) was noted. Note the areas of partially preserved metabolic activity (*A*) within the lateral wall, which appears uniformly thinned on CT images and may represent surviving myocardium within the infarcted area. (Modified from Dickfeld T, Lei P, Dilsizian V, et al. Integration of three-dimensional scar maps for ventricular tachycardia ablation with positron emission tomography-computed tomography. J Am Coll Cardiol Imaging 2008;1:73-82.)

Imaging to Assess Risk Before Noncardiac Surgery

The clinical role of MPI for evaluation of patients before elective noncardiac surgery is important in selected cases, because CAD constitutes a major perioperative and long-term risk in such patients (**see Chapter 11**). The ischemic burden from the stress of surgery and postoperative recovery can result in MI or cardiovascular death. Prospective identification of such patients has important prognostic and preventive implications. Initial cardiac assessment of patients undergoing noncardiac surgery should be based on (1) the urgency of the surgery; (2) the presence or absence of any active cardiac conditions, such as decompensated HF; (3) the type of surgical procedure (low or elevated risk); and (4) the patient's functional capacity.[65]

For patients having non–low-risk surgery who also have limited or unknown functional capacity, current guidelines recommend imaging for risk stratification based on "revised cardiac risk index" factors, which include history of CAD, previous HF, diabetes, renal insufficiency, and cerebrovascular disease. Noninvasive testing may be considered in patients with such risk factors for perioperative events, if this will change management. Asymptomatic patients with known CAD who have had revascularization within the past 5 years generally require no further evaluation.[65]

Normal MPI using pharmacologic stress uniformly predicts a low likelihood (approximately 1%) for perioperative or longer-term postoperative cardiac events.[65] Reversible perfusion defects predict an increased risk of cardiac events, and the magnitude of risk is related to the extent of ischemia. Although fixed perfusion defects (infarct) portend a lower risk than ischemia for perioperative cardiac events, the risk is higher than that with a normal scan, and patients with infarct or LV dysfunction are at higher long-term risk for death or HF.

In clinical practice, most patients in whom extensive ischemia is demonstrated preoperatively undergo catheterization with expectation of revascularization. Clinical trial evidence supporting this practice provides conflicting evidence,[65] however, and the threshold of ischemia extent above which revascularization might reduce short- or long-term cardiac risk is not known. In the contemporary era of PCI, the potential need for prolonged dual-antiplatelet therapy after stenting, and the attendant risk of perioperative bleeding, must also must be factored into the complex benefit-risk ratio in considering whether to pursue stress testing and potential catheterization with subsequent revascularization.

Molecular Imaging of the Cardiovascular System

During the past several decades, radionuclide cardiac imaging has focused primarily on "organ-level" assessment of physiology and pathophysiology, such as myocardial perfusion and ventricular function. However, advances in radiochemistry and imaging technology have enabled the interrogation of many more processes at the cellular and molecular level. Such techniques have the potential to refine the current understanding of mechanisms involved in cardiovascular diseases, such as instability of atherosclerotic plaque in a patient, with the promise of more targeted, individualized therapy.

Imaging of Potentially Unstable Atherosclerotic Plaque and Platelet Activation

Vulnerable atherosclerotic plaques typically have a necrotic lipid core with a thin, fibrous cap and contain a large amount of macrophages (**see Chapter 44**). When such vulnerable plaques rupture, they may cause MI, sudden death, or stroke. Thus the biologic composition and inflammatory state of an atherosclerotic plaque, rather than its size or degree of luminal stenosis, may be the major determinants of the conversion from a stable to an unstable plaque and the precipitation of acute ischemic clinical events.[66] Therefore, development of noninvasive imaging techniques that target plaque inflammation and other processes leading to plaque vulnerability is an area of intense investigation.[67]

Accordingly, recent studies have focused on noninvasive molecular imaging probes that target plaque composition, such as inflammation and microcalcification, using PET-CT technology. ^{18}F-FDG is an excellent probe to target macrophage infiltration as a marker of plaque inflammation, and another molecular probe, ^{18}F–sodium fluoride (^{18}F-NaF), targets active microcalcifications in atherosclerotic plaques.[68] Correlative studies between arterial plaque inflammation (by ^{18}F-FDG), active mineral

deposition (by ^{18}F-NaF), and vascular calcification (by CT) in major arteries (aorta and its major branches including carotid) have shown the ability of these two molecular probes to visualize these distinct biologic processes in atherosclerotic plaque.[69] The feasibility of ^{18}F-NaF PET for the detection of coronary microcalcification in humans was shown in a prospective cohort of healthy volunteers and patients with aortic sclerosis and stenosis.[70] Coronary ^{18}F-NaF uptake was higher in patients with coronary atherosclerosis than the controls and correlated with the CAC score. Similarly, in a study of patients with recent MI and those with stable angina, the highest coronary ^{18}F-NaF uptake was observed in the culprit plaque compared with the nonculprit plaque in the patients with recent MI[71] (**Fig. 16.44**). Among those with stable angina, almost half the patients had plaque with focal evidence of increased ^{18}F-NaF uptake, and these plaques had more high-risk features of plaque vulnerability on intravascular ultrasound (**see Chapter 20**) than plaques without ^{18}F-NaF uptake. These data suggest the potential of imaging to identify plaques and patients at risk of future ACS, paving the way for prevention trials.

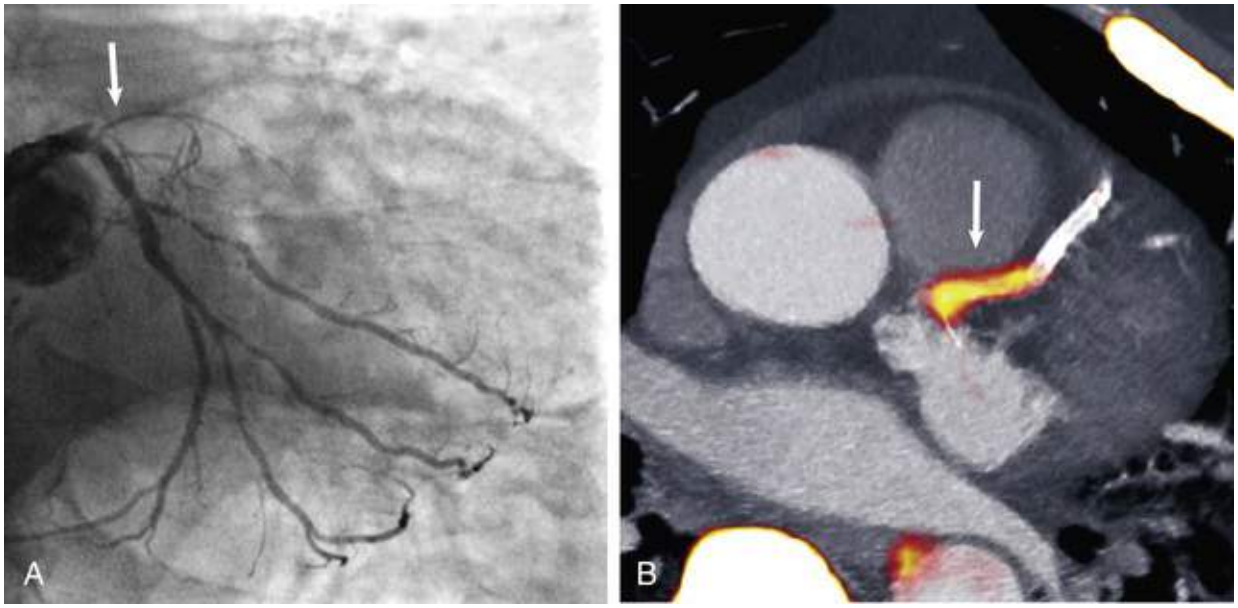

FIGURE 16.44 Uptake of ^{18}F-NaF in high-risk atherosclerotic plaque. **A,** *Arrow* indicates site of acute occlusion of proximal left anterior descending artery in patient with STEMI. **B,** PET-CT imaging performed several days later demonstrates intense focal uptake of tracer at plaque site (*arrow*), consistent with high-risk plaque features. (Modified from Joshi NV, Vesey AT, Williams MC, et al. ^{18}F-fluoride positron emission tomography for identification of ruptured and high-risk coronary atherosclerotic plaques: a prospective clinical trial. Lancet 2014;383:705.)

The integrin αvβ3, which has been investigated for tumor neovascularization, also plays an important role in plaque vasa vasorum neoangiogenesis. An ^{18}F-labeled PET radiotracer that images αvβ3-integrin expression (^{18}F-galacto-RGD) targets both macrophages and intraplaque neovasculature (both implicated in progression and rupture of atherosclerotic lesions) that may be directly involved in the degradation of the protective fibrous cap of atherosclerotic plaques.[72] Whether this agent can ultimately be used to evaluate atherosclerotic lesions in patients remains untested.

It is important to recognize that most of the studies using these molecular imaging probes for atherosclerosis are restricted to larger arterial beds such as those for the carotid arteries and aorta, rather than the coronary arteries. Because of the limitations of the partial volume effect of small plaques, low target-to-background ratio of tracer uptake, and cardiac motion, direct visualization of atherosclerotic plaques in coronary arteries with current PET-CT technology is challenging.[67,68] Whether molecular imaging of noncoronary vascular beds is useful in predicting coronary plaque rupture and acute MI has not been ascertained. If successful, such molecular probes could provide new insights into the complex

development and progression of atherosclerosis, facilitate current understanding of mechanisms of plaque rupture, stimulate development of new medications to prevent or regress atherosclerosis, and provide a noninvasive tool to monitor the treatment effect.

Imaging of Cell- or Gene-Based Regenerative Therapy

Local targeted gene delivery or implantation of skeletal myoblasts, bone marrow–derived stem cells, mesenchymal stem cells, circulating progenitor cells, embryonic stem cells, and cardiac resident cells are all being investigated for potentially revitalizing scarred, noncontractile myocardial regions (**see Chapter 30**). Clinical trials to date, however, have demonstrated only marginal benefits of cell-based therapy in ischemic cardiomyopathy and chronic HF and after acute MI.[73,74]

Molecular imaging tools that can identify the optimal cell type, delivery route, dosing regimen, and timing of cell delivery may be the key to understanding and advancing cardiac stem cell therapy.[75] Imaging can be accomplished by direct labeling of the therapeutic cells (e.g., ^{99m}Tc or ^{111}In radionuclides) or "reporter gene" imaging that allows observation of intracellular or genomic events by PET, SPECT, PET-CT, or optical imaging. In animal studies, transplanted cardiomyoblasts expressing a PET reporter gene have been imaged longitudinally to gain insight into the pattern of cell survival.[75] In an experimental mouse model of MI that included intramyocardial injection of human cardiac progenitor cells, initial cell retention assessed by cardiac micro-PET predicted long-term myocardial functional improvement by CMR[76] (**Fig. 16.45**). Such molecular imaging techniques that track and localize stem cells may provide mechanistic insight into the success (or failure) of future trials.

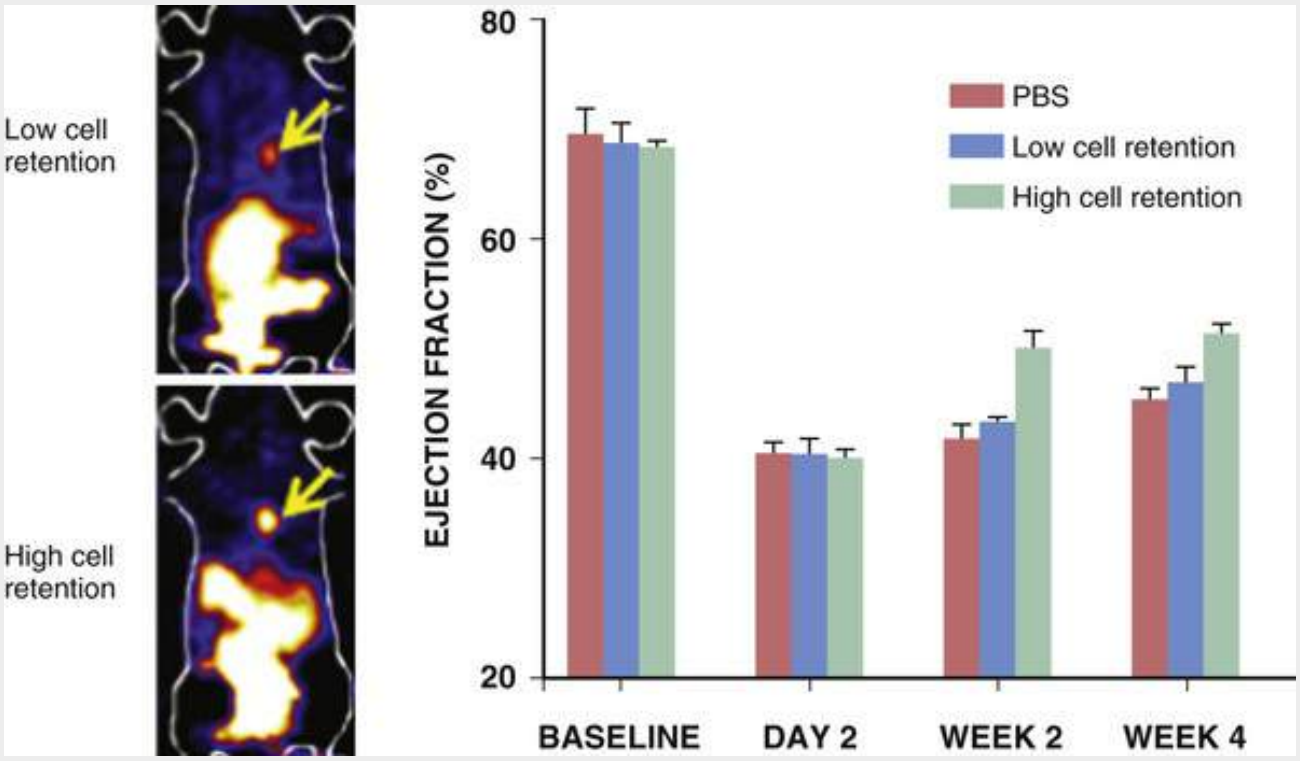

FIGURE 16.45 Early cell retention identified by molecular imaging predicts long-term myocardial functional improvement. Mice underwent experimental myocardial infarction followed by intramyocardial injection of human cardiac progenitor cells expressing a mutant thymidine kinase reporter gene tagged to a PET radionuclide. Serial PET and CMR studies were later performed to assess cell engraftment and LV function. **Left,** Representative coronal PET image is shown for a mouse with low cell retention on day 1 (*top*), compared with that of a mouse with high cell retention (*bottom*). **Right**, Average CMR-derived ejection fraction is greater at both week 2 and week 4 for mouse cohort with high initial cell retention than for cohort with low cell retention or injection of placebo solution (*PBS*). (Modified from Liu J, Narsinh KH, Lan F, et al. Early stem cell engraftment predicts late cardiac functional recovery: preclinical insights from molecular imaging. Circ Cardiovasc Imaging 2012;5:481.)

Imaging of Interstitial Fibrosis and Left Ventricular Remodeling

Activation of the renin-angiotensin-aldosterone system (RAAS), particularly its autocrine and paracrine components within the tissues, occupies a central place in the pathogenesis and progression of LV remodeling, interstitial fibrosis, and HF (**see Chapter 23**). Myocardial fibrosis in chronic HF is a dynamic process that is determined by a balance between collagen synthesis and its degradation by matrix metalloproteinases. In addition, local tissue synthesis of aldosterone appears to be mainly angiotensin II driven and may participate in a positive feedback loop, because aldosterone upregulates the angiotensin type 1 receptor (AT1R) and ACE expression in cardiac cells.

Investigations in animal models and also in humans have shown that radionuclide imaging of the RAAS can be used in experimental systems to study the human tissue ACE and AT1R directly. Use of ^{18}F-fluorobenzyl-lisinopril in human explanted hearts has shown a relationship between ACE and collagen replacement, because ACE was absent in the collagen-stained areas and was increased in the juxtaposed areas of replacement fibrosis.[51] These data suggest that increased ACE may be a stimulus for collagen replacement and remodeling. A subsequent study with ^{99m}Tc-lisinopril in transgenic rats overexpressing human ACE-1 established the specificity of the radioisotope probe to myocardial ACE-1 and demonstrated close correlation between quantitative uptake of ^{99m}Tc-lisinopril and enzyme activity.[77] Moreover, the signal intensity was sufficiently high to allow external imaging by hybrid micro-SPECT-CT (**Fig. 16.46**). Recently, AT1R also was targeted for imaging the human heart.[78] This first-in-human application of receptor ligand ^{11}C-KR31173 combined with PET-CT confirmed the presence of local tissue RAAS in human hearts, proved to be safe, and showed that the signal was high enough to allow

external imaging with PET. However, the myocardial retention of KR31173 was significantly lower in these healthy humans than that observed in normal healthy pigs, with a limited specificity: only 54% of the signal targeted the AT1R.[78,79]

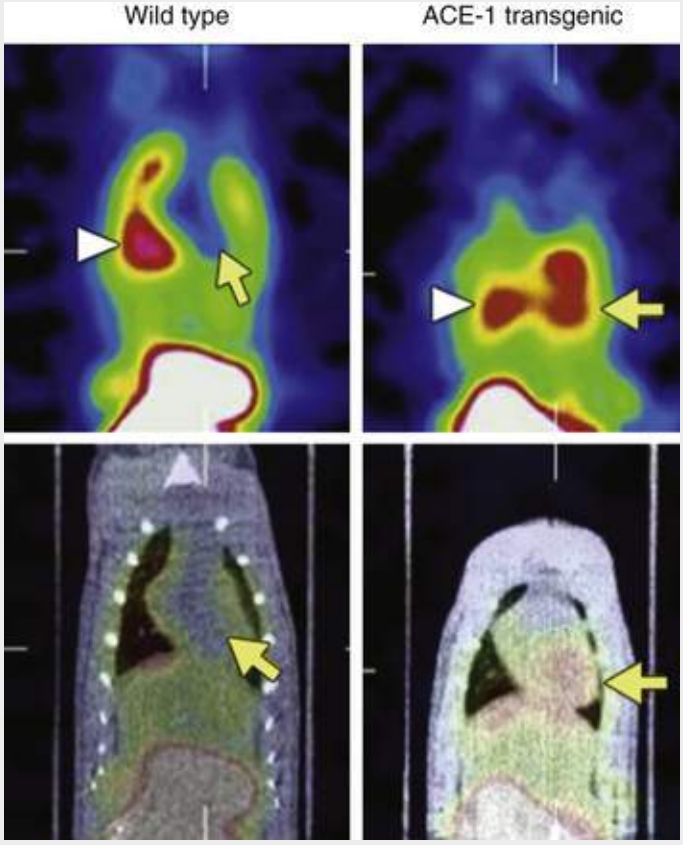

FIGURE 16.46 Noninvasive micro-SPECT-CT imaging of angiotensin-converting enzyme (ACE)-1 activity. **Top row,** Micro-SPECT-CT imaging provides simultaneous scintigraphic and morphologic localization of ^{99m}Tc-labeled lisinopril uptake, 60 minutes after tracer administration, in control animal (*left*) and in ACE-1–overexpressing transgenic animal (*right*). *White arrowheads* indicate intense lung uptake; *yellow arrows,* myocardial ACE-1 activity. ACE-1–overexpressing model shows much higher-intensity uptake in the myocardial region. **Bottom row,** Micro-SPECT data are superimposed on CT data for better myocardial localization in the overexpressing model. (Modified from Dilsizian V, Zynda TK, Petrov A, et al. Molecular imaging of human ACE-1 expression in transgenic rats. J Am Coll Cardiol Imaging 2012;5:409.)

In the future, noninvasive radionuclide imaging in HF patients may allow monitoring of changes in ACE expression patterns in vivo, possibly reflecting progression of disease and the effect of therapies before collagen replacement ensues.

Imaging of Cardiac Valvular Inflammation and Calcification

Beyond imaging vascular atherosclerosis, FDG and ^{18}F-NaF techniques also may identify patients with early valvular inflammation and microcalcification, before progression to severe, calcified stenosis is detectable by echocardiographic and CT imaging (**see Chapter 68**). In oncology patients with echocardiography-defined degenerative aortic stenosis (AS) who had undergone FDG PET–CT, the relationship between aortic valve inflammation and AS was investigated at the leaflet coaptation point.[80] Patients with mild and moderate AS on echocardiography or calcification on CT had significantly increased aortic valve FDG signal compared to controls. Patients with severe AS or calcification did not show increased FDG signal, suggesting an end stage of the inflammatory process. In a subset of patients

with serial echocardiographic studies over a 1- to 2-year period, 82% who exhibited high FDG valve signal intensity demonstrated progression of AS, compared with only 22% with low FDG signal intensity. This observational study suggests a potential role for FDG PET–CT in identifying patients at risk for more rapid progression of AS.

In a subsequent study, in which both FDG and ^{18}F-NaF were administered to assess valvular inflammation and calcification, 91% of patients with AS exhibited increased ^{18}F-NaF uptake.[81] The correlation between the degree of AS and the PET signal was significantly higher with ^{18}F-NaF than with FDG, suggesting different biologic processes of inflammation and microcalcification during the progression of valvular stenosis.

Imaging of Cardiac Device and Prosthetic Valve Infections

Cardiac Pacemaker or ICD Infection

There has been a significant increase in cardiac pacemaker or implantable cardioverter-defibrillator (ICD) implantation worldwide, which has been accompanied by an increase in the absolute number of device infections (**see Chapter 73**). All-cause 12-week mortality could be as high as 35% with cardiac pacemaker or ICD infection, especially for those with methicillin-resistant *Staphylococcus aureus* infection.[82] The 1-year mortality after removal of an infected device has been reported as 12% in patients with pocket infections and 17% in those with endovascular infections.[82] Accurate diagnosis of cardiac device infection is therefore critical for clinical decision making, such as antibiotic therapy alone or device extraction, but represents a challenge for current diagnostic methods. Among patients with suspected cardiac pacemaker or ICD infections, FDG PET-CT can accurately localize the site and extent of the infection.[83] A potential advantage of FDG PET-CT is in its detection of inflammatory cells early in the infection process, before morphologic damage ensues.[84] In contrast to its reported high accuracy in detecting cardiac device pocket infection, FDG PET-CT appears less reliable for lead infection or vegetation evaluation, which may be attributed to the small size of the lead and vegetation or ongoing antibiotic treatment.[85]

Cardiac Prosthetic Valve Infection

Almost half of prosthetic valve endocarditis cases are complicated by periannular extensions and require urgent surgical intervention (**see Chapter 73**). Transesophageal echocardiography (TEE) may fail to recognize this potentially fatal complication. Although ECG-gated CT angiography can improve the diagnostic accuracy in some patients, it is also a purely anatomic technique. The incremental value of FDG PET-CT to the findings on TEE or CT angiography has been shown in observational case series[86] (**Fig. 16.47**). Although these results are encouraging, FDG PET-CT is not advocated as a first-line or confirmatory imaging study for detecting prosthetic valve endocarditis.[87] Rather, it should be reserved for patients with clinical and microbiologic suspicion of endocarditis but indeterminate or negative TEE.

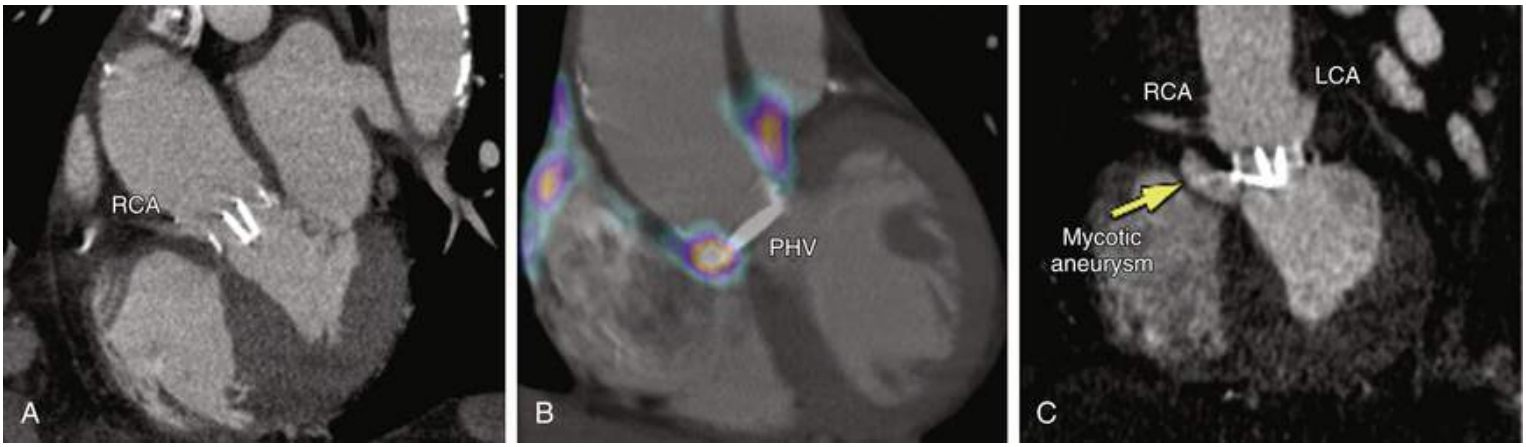

FIGURE 16.47 Periannular prosthetic valve endocarditis detected by FDG PET. Patient with bileaflet mechanical aortic prosthetic heart valve (PHV), placed 20 years earlier, presented with fever and blood cultures positive for *Staphylococcus aureus*. Despite a high degree of clinical suspicion for endocarditis, findings on transthoracic echocardiography and TEE, as well as CT **(A)**, were unremarkable for evidence of infection. **B,** FDG PET–low-dose CT fused image revealed high uptake around aortic PHV (*arrows*), near the proximal right coronary artery (RCA). **C,** Subsequently, CT revealed a mycotic aneurysm beneath the RCA origin, confirmed by urgent operation. In this case, only FDG PET–CT detected these abnormalities at a very early stage. LCA, Left coronary artery. (**A, B,** Modified from Tanis W, Scholtens A, Habets J, et al. Fusion of cardiac computed tomography angiography and ^{18}F-fluorodesoxyglucose positron emission tomography for the detection of prosthetic heart valve endocarditis. J Am Coll Cardiol Imaging 2013;6:1008.)

Left Ventricular Assist Device Infection

Because of the constant shortage of donor hearts, the role of the left ventricular assist device (LVAD) has been expanding in the management of end-stage HF patients both as a bridge to transplantation and as a destination therapy (i.e., alternative to transplantation). Although lifesaving, the LVAD is often complicated with infections. The percutaneous driveline that exits the abdomen can become disrupted by normal activities such as showering, which introduces bacteria. Once bacteria infect the driveline and then the bloodstream, eradication of infection is difficult. Bacteria can infect all areas of the LVAD, including driveline, pump, cannula, and tissues surrounding the pump. Treatment modalities include long-term antibiotics, LVAD replacement, debridement, and urgent transplant. FDG PET-CT imaging of the LVAD is a potential tool to make an early and accurate diagnosis of LVAD infection[88] (**Fig. 16.48**). FDG PET-CT imaging may allow earlier detection of LVAD infection and its extent, as well as evaluation of response to therapy.

FIGURE 16.48 Fused CT and FDG-PET imaging of driveline left ventricular assist device (LVAD) infection. With a history of LVAD implantation, patient presented with symptoms of pain, purulent discharge, and nonhealing at driveline exit site 6 months after implant. The driveline culture revealed coagulase-negative *Staphylococcus aureus* and yeast. PET-CT images show intense linear FDG uptake along the driveline (*open arrowheads*) and percutaneous exit (*white arrowhead*), compatible with driveline LVAD infection. (Modified from Kim J, Feller ED, Chen W, Dilsizian V. FDG PET-CT imaging for LVAD-associated infections. J Am Coll Cardiol Imaging 2014;7:839-42.)

Cardiovascular Magnetic Resonance Imaging

Raymond Y. Kwong

The multicomponent imaging capability of cardiovascular magnetic resonance (CMR) provides morphologic, structural, and physiologic information relevant to a broad array of cardiovascular diseases. CMR offers technical advantages of unrestricted tomographic imaging fields and various types of tissue characterization, without the need for ionizing radiation. This chapter reviews the current cardiac clinical applications of CMR.

Basic Principles of Magnetic Resonance Imaging

Magnetic Field and Gradient Coil System

Magnetic resonance imaging (MRI) is based on imaging of the abundant hydrogen nuclei in the human body. When a patient is placed inside the scanner magnet, producing a static magnetic field (called B_0), the ^1H nuclei, which have a spin magnetic moment, partially align with the direction of the B_0 field. (The degree of alignment depends on the influence of random effects such as thermal motion, which generally cannot be controlled in biologic systems.) The net magnetization produced by the small fraction of nuclear moments aligned along the B_0 direction (the *z* axis in the magnet's coordinate system) is termed the *equilibrium magnetization,* before irradiation of the nuclear spins of any radiofrequency (RF) pulse. An RF pulse can tip the nuclear spins away from the *z* axis, which leaves the ^1H nuclear magnetic moments precessing at a characteristic frequency, called the *Larmor frequency* (ω_0), which is related to the magnetic field strength and the nucleus's gyromagnetic ratio by $\omega_0 = \gamma B_0$, where γ is the gyromagnetic ratio (a constant for protons of hydrogen at a given field strength). The RF pulse should have a frequency that matches the Larmor frequency to have a “resonance” effect on the nuclear spins; otherwise, in terms of reorienting the nuclear spins, the effect is generally negligible.

B_0 is designed to be spatially uniform inside the CMR magnet bore; thus it is a homogeneous magnetic field. The homogeneity of B_0 is fine-tuned by the computer-controlled adjustments of currents in small coils mounted within the magnet, known as “active shimming.” For imaging, the clinician applies so-called magnetic field gradients that introduce a linear variation of B_0 in the direction of the gradient. B_0 gradients along *x, y,* or *z* direction are produced by a different set of coils, and gradients in arbitrary directions can be created by linear superposition of *x, y,* and *z* gradients. When a gradient is switched on, the ^1H nuclei precess at frequencies that depend linearly on the position along the direction of the magnetic field gradient. This means that the Larmor frequency of the nuclear spins is dependent on position, and excitation of the nuclear spins by an RF pulse has an effect only for a range of positions where the excitation frequency approximately matches the Larmor frequency. This center position, as well as the surrounding range where the RF pulse has a noticeable effect, depends on the center frequency and bandwidth of the RF pulse.

Generation of Magnetic Resonance Signal, Contrast, and Image Formation

To create an image, an RF pulse with a frequency matching the Larmor frequency will tip at least partially the net nuclear magnetization from the direction along B_0 into a plane transverse to B_0 (*x-y* plane), where transverse magnetization is left precessing at the Larmor frequency. The key to the generation of a detectable signal is that the nuclear spins precess coherently; that is, at least initially, all have at any moment the same phase in the transverse plane to yield a net transverse magnetic moment, which can induce a voltage in an external antenna. The extent to which the magnetization vector is tipped away from the direction of B_0 (*z* axis) defines the *flip angle,* reflects the amount of energy deposition in tissue, and is a function of the strength and duration of the RF pulse. The magnitude of the transverse magnetization will determine the amplitude of the detected signal, which is received by a set of surface coils surrounding the patient. To image a specific slice plane through the body, a magnetic field gradient is applied perpendicular to the slice plane, which results in a linear variation of the Larmor frequency perpendicular

to the prescribed slice plane. An RF pulse will then only excite the slice plane with magnetic spins precessing at frequencies approximately matching the center frequency of the RF pulse.

The absorbed electromagnetic energy will be released by two coexisting mechanisms, longitudinal magnetization recovery and transverse magnetization decay. *Longitudinal magnetization recovery*, also called T1 relaxation, corresponds to the recovery of the longitudinal component (*z* direction) along B_0 and is generally characterized by an exponential dependence on time after excitation with a time constant, *T1*. T1 is a physical characteristic of tissue and is affected by the field strength of the scanner, with values progressively longer at higher field strengths (in tesla, T). T1 characterization therefore allows generation of images that reflect the differences of T1 between tissue types (e.g., fat with short T1, muscle with longer T1). A T1-weighted scan will keep the time between delivery of two successive flip angles (repetition time) short; thus tissues with different T1 values will demonstrate different signal intensities because they have recovered to different degrees after an RF excitation.

Transverse magnetization decay results from B_0 field inhomogeneities and interactions between neighboring spins (spin-spin interaction), leading to exponential loss of the transverse component of the net magnetization vector, defined by the time constant *T2*. T2 is also a tissue-specific parameter and is defined as the time to lose 63% of the transverse magnetization. The choice of signal contrast weighting of the imaging method is partly dictated by the physiologic characteristics of the tissue being studied. For qualitative interpretation, signal enhancement (from T1 effects) generally is preferred over signal loss (T2*; see later, Imaging Methods) effects; thus most pulse sequences used in CMR are T1-weighted techniques. T2-weighted and T2*-weighted CMR are primarily for imaging of myocardial edema and iron content, respectively. Iron has a strong magnetic moment that disturbs the local magnetic field and speeds up the loss of phase coherence of the transverse magnetization and thus its decay (i.e., shortens T2). With the application of magnetic field gradients in any of the three orthogonal directions, the MR signal can carry spatial localization information, produced by encoding steps known as *slice select*, *phase encoding*, and *frequency encoding*. All relevant information of the MR signal is stored in a data matrix called the *k-space*, from which images can be reconstructed by so-called Fourier transformation.

Contrast Agents

Currently, only gadolinium-based contrast agents (GBCAs) are used clinically in CMR imaging. When injected as an intravenous (IV) bolus, the GBCA transits through cardiac chambers and coronary arteries over 15 to 30 seconds (*first-pass phase*) before it diffuses into the extracellular space. At approximately 10 to 15 minutes after injection, a transient equilibrium between contrast washing into the extracellular space and washing out to the blood pool is reached. Myocardial perfusion CMR and most magnetic resonance angiography (MRA) scans are performed during the first-pass phase, whereas late gadolinium enhancement images are obtained during the equilibrium phase.

GBCA use in CMR is very safe; approximately 1% of patients experience mild reactions (nausea, mild skin rash), and severe reactions are extremely rare. All GBCAs are chelated to render them nontoxic and to facilitate renal excretion. In patients with severe renal dysfunction, GBCA use exposes the patient to the toxic, nonchelated free gadolinium (Gd^{3+}), which can lead to *nephrogenic systemic fibrosis* (NSF), an interstitial inflammatory reaction that can lead to severe skin induration, contracture of the extremities, fibrosis of internal organs, and death. Risk factors for developing NSF include estimated glomerular filtration rate (eGFR) less than 30 mL/min/1.73 m^2, need for hemodialysis, acute renal failure, and presence of concurrent proinflammatory events. With the use of weight-based dosing and avoidance of

GBCA use in patients with eGFR less than 30 mL/min/1.73 m^2, NSF from GBCA now has a near-zero incidence.

Imaging Methods

CMR imaging uses a range of strategies to overcome cardiac, respiratory, and blood flow motion. To overcome blurring from cardiac motion, data acquisition is synchronized to the electrocardiogram (ECG) signal (cardiac gating), which can be either *prospective* (triggering by an ECG waveform followed by a fixed period of acquisition during all cardiac cycles) or *retrospective* (continuous data acquisition with subsequent reconstruction based on ECG timing). For cine imaging, retrospective gating is preferred because it covers the entire cardiac cycle. Many CMR techniques (pulse sequences) fractionate the data acquisition of an image to occur within a narrow window of the cardiac cycle over a few heartbeats (segmented approach). To overcome blurring from respiratory motion, a combination of patient breath-holding, navigator-based techniques (tracking of diaphragmatic motion to control respiratory motions), and respiratory motion averaging are now used clinically. In patients who cannot breath-hold or who have irregular heart rhythms, static single-shot and real-time cine imaging (both involve rapid acquisition of whole images within a cardiac cycle) can achieve diagnostic studies at reduced temporal and spatial resolutions.

Table 17.1 summarizes the most common clinical CMR pulse sequence techniques at our center, Brigham and Women's Hospital in Boston. CMR uses bright-blood cine imaging or dark-blood *fast spin-echo* (FSE) imaging to assess cardiac morphology and structure. Cine *steady-state free precession* (SSFP) is the standard pulse sequence for quantifying cardiac volumes and functions. It can acquire a cine movie at a high temporal resolution of 30 to 45 milliseconds during a breath-hold of less than 10 seconds (**Fig. 17.1**), thus capturing the whole heart in motion volumetrically in 3 to 5 minutes (Video 17.1). For dark-blood techniques, T1-weighted FSE is used for morphology of cardiac chambers, vascular structures, pericardium, and imaging of fat. T2-weighted FSE with fat suppressed is used for imaging of myocardial edema. Tagging assesses myocardial strain by marking the myocardium with parallel dark lines or a grid so that myocardial deformation can be visualized or quantified. Circumferential and radial strain can also be calculated and displayed over a colored scale. *Late gadolinium enhancement* (LGE) involves T1-weighted imaging that detects accumulation of GBCA in the myocardium from infarction, infiltration, or fibrosis. LGE is detected 5 to 15 minutes after IV injection of GBCA (0.1 to 0.2 mmol/kg) (thus the term “late” enhancement). LGE data can be captured in two or three dimensions. *Phase-sensitive inversion recovery* (PSIR) reconstruction is routinely used in LGE imaging to enhance myocardial tissue contrast. In patients who cannot perform breath-holding, LGE imaging can be acquired using either single-shot method or navigator guidance.

TABLE 17.1

Summary of Common Clinical Cardiac Magnetic Resonance (CMR) Pulse Sequence Techniques at Brigham and Women's Hospital

CMR TECHNIQUES	PULSE SEQUENCE OPTIONS	DARK/BRIGHT BLOOD	CONTRAST WEIGHTING	TYPICAL IN-PLANE SPATIAL/TEMP. RESOLUTIONS; OTHER PARAMETERS	BREATH-HOLD REQUIRED	Gd CONTRAST REQUIRED	RELATIVE MERITS OF PULSE SEQUENCE OPTIONS	IMAGE EX
Cine cardiac structure and ventricular	Cine SSFP¥ Cine FGRE Real-time	Bright	T2/T1W for cine SSFP and real-time cine SSFP;	1.5-2.5 mm/30-45 msec per phase	Yes for ECG-gated cine SSFP	No	Cine SSFP has higher SNR and CNR (between	

function	cine SSFP		T1W for FGRE	Adjust number of lines of k-space per cardiac cycle (segments) to balance temporal resolution and duration of patient breath-holds 2.3-3.2 mm/~60 msec for real-time cine	and FGRE Optional for real-time cine		endomyocardium and blood) than FGRE but is sensitive to field inhomogeneity (especially at 3 T), giving rise to banding artifact. FGRE has weaker endocardial definition than cine SSFP but is an alternative when severe artifact exists in cine SSFP. Good shimming or frequency scout would be needed at 3 T to eliminate banding artifact. Real-time cine SSFP: use in patients with significant arrhythmia or difficulty breath-holding; it has lowest spatial and temporal resolution.	 Cine SSFP
Quantitative regional myocardial strain	Myocardial tagging (newer but less widely available techniques for regional strain exist; see text)	Bright	T1W	Tag spacing 5-10 mm Temporal resolution ~50 msec Low flip angle, on order of 10 degrees to limit tag fading	Yes	No	Tissue-tracking quantitation of intramyocardial motion Disadvantages: tag lines fade near end of cardiac cycle, and time-consuming strain analysis (postprocessing)	
Structure, morphology, and fat imaging	Standard FSE[¥] SS FSE (or HASTE)	Dark	T1W ± fat suppression	0.8-1.5 mm/every cardiac cycle	Yes for standard fast SE No for SS FSE	No	Standard FSE has better image quality but relatively long scan time. Fat suppression can be achieved by fat saturation pulse (more specific) or by suppressing tissues with short T1 (STIR, which is less specific for fat, in particular after Gd contrast). SS FSE covers the whole heart quickly and is useful in patients with arrhythmia or limited breath-holding	
Myocardial scar by LGE imaging	Standard 2D segmented FGRE[¥] 2D SS SSFP technique 3D whole-heart techniques (breath-hold or navigator guided) Segmented or SS PSIR	Bright	T1W (10-30 min after 0.1-0.2 mmol/kg GBCA injection)	1.5-2.0 mm/150-200 msec (for standard 2D) Adjust inversion time and time delay after ECG detection to null "normal" myocardium and to image in diastole, respectively	Yes for standard 2D technique No for SS technique	Yes	Standard 2D technique has higher spatial and temporal resolutions than SS technique. 2D SS technique covers the whole heart quickly and is useful in patients with arrhythmia or difficulty breath-holding. PSIR is less inversion time sensitive and gives improved contrast	 2D segmen

							when normal myocardium is not perfectly nulled. New 3D application using navigator guidance yields higher SNR than 2D and can achieve spatial resolution of <1 mm without the need for breath-holding. Refer to **Table 17.2** for patterns of LGE in various cardiomyopathies.	
Myocardial perfusion imaging	Saturation-prepared gradient echo (GE)–based 2D techniques: FGRE[¥], hybrid GE-echoplanar (EPI), and SSFP	Bright	T1W	2.0-3.0 mm 130-180 msec/slice 3-4 locations every cardiac cycle or 6-8 locations every 2 cardiac cycles during vasodilator stress and rest 0.05-0.1 mmol/kg IV GBCA injected at 4 or 5 mL/sec (qualitative assessment only)	No, but breath-hold is preferable	Yes	Breath-holding is useful to track contrast-enhancement in specific segments. Parallel-imaging acceleration and sparse sampling to reduce acquisition time per slice and extend slice coverage of the heart, but carries SNR penalty	
Myocardial edema imaging	T2W FSE[¥] STIR FSE T1W EGE_r T2-prepared SSFP T2 map (SSFP readout)	Dark (FSE based) Bright (SSFP based)	T2W + fat suppression (for T2W techniques) T1W (for EGE_r technique)	In-plane spatial and temporal resolutions similar to standard FSE Slice thickness 7-10 mm to improve SNR For qualitative assessment, algorithm needed to correct for distance of heart from receiver surface coils T2 map for quantification (insensitive to signal nonuniformity)	Yes	No/yes for EGE	Myocardial edema appears as transmural area of high SI on T2W images. In FSE techniques, beware of artifacts from slow flow, especially adjacent to regional wall motion abnormality or LV apex, which may mimic edema. Regional myocardial signal variation from phase array coils may mimic edema. In absence of LGE, T2W edema reflects reversible myocardial injury. Using T2W FSE techniques, SI ratio of myocardium over skeletal muscle >1.9 reported as abnormal in myocarditis. EGE_r between myocardium and skeletal muscle of ≥4 or absolute myocardial SI increase of 45% after contrast are considered abnormal in myocarditis. Bright-blood SSFP-based technique has improved CNR and is less susceptible to slow	

							flow artifact. T2 map is insensitive to surface coil–related signal inhomogeneity and slow-flowing blood–related artifact.	
Myocardial iron content imaging	T2*W multiple echo times FGRE	Bright	T2*W	2.0-3.0 mm/~100-150 msec One short-axis midventricular location Series of images with 6-8 echoes from ~2 to 35 msec Axial ungated acquisition of the liver for comparison	Yes	No	Measurement is most accurate and reproducible in the midseptum. T2* value describes exponential decay of myocardial SI as echo time increases. At 1.5 T, T2* value <20 msec with LV dysfunction (without other obvious cause) indicates iron-overload cardiomyopathy.	
Cardiac thrombus	LGE with long inversion time EGE imaging	Bright	T1W	In-plane spatial and temporal resolutions similar to LGE imaging EGE acquired within first 5 minutes after Gd injection	Yes	Yes	LGE imaging with inversion time set at ≥600 msec or EGE imaging can detect thrombus, indicated by intense “black” regions. Look for thrombus in locations of stagnant flow.	
Cardiac blood flow	Phase-contrast imaging cine GE	Bright	Velocity-related signal phase shift	1.5-2.5 mm/50 msec per phase Keep number of lines of k-space per cardiac cycle (segments) low to improve temporal resolution during free-breathing studies.	No (multiple signal averages used)	No	Multiple averages can reduce ghosting artifacts from respiratory motion during free breathing. Should keep velocity encoding strength slightly above the highest expected flow velocity to avoid velocity aliasing while maximizing accuracy. Background phase correction may be needed for accurate results.	
Coronary MRA	3D whole-heart volume using SSFP or FGRE[¥] Target-vessel approach	Bright	T2-prepared 3D SSFP or FGRE technique	~0.6-1.0 mm in-plane Free-breathing navigator-guided 3D technique is currently most widely used.	No, *but* Yes for target-vessel approach	Yes at 3 T or optional at 1.5 T (no need for contrast with SSFP-based technique)	Compared to target-vessel approach, 3D coronary MRA has higher SNR and provides volumetric whole-heart coverage. T2-prepared SSFP sequence with suppression of adjacent epicardial fat provides strong blood vessel contrast. Contrast-enhanced FGRE-based technique is used in 3 T.	
Anatomy for electrophysiologic mapping of pulmonary vein	3D FGRE MRA of left atrial volume and pulmonary	Bright	T1W FGRE	1.5-2.5 mm isotropic volume Timing bolus is required to	Yes	Yes	Subtraction mask scan is necessary to enhance the MRA images.	

	veins			achieve proper timing of imaging during first-pass transit of contrast bolus. Gating is optional but may improve border definition at expense of prolonging breath-hold. Free-breathing navigator-guided 3D technique is increasingly used.			Coronal (more common) or axial 3D MRA of entire left atrium and pulmonary vein is generated for electrophysiologic mapping. Use same parameters as in the subtraction mask scan.	
T1 mapping for assessment of extracellular volume expansion and diffuse fibrosis	Look-Locker (LL), or modified Look-Locker 2D GE	Varying (depending on TI	GRE LL or SS SSFP (MOLLI)	1.5-2.0 mm in-plane resolution LL requires complete relaxation between repetitions MOLLI has lower TI resolution	Yes	Yes (measurements before and after contrast required)	MOLLI acquires all images during single cardiac phase, to allow calculation of T1 maps. MOLLI requires SSFP readouts. LL can provide high TI resolution for short TIs	

¥More commonly used option.

Note: Dark-blood techniques and myocardial iron content by T2* imaging should be performed before administration of gadolinium contrast.

CNR, Contrast-to-noise ratio; *ECG,* electrocardiogram; $EGE_{(r)}$, early gadolinium enhancement (ratio); *FGRE,* fast gradient-recalled echo; *FSE,* fast spin echo; GBCA, gadolinium-based contrast agent; *Gd,* gadolinium; *HASTE,* half-Fourier acquisition single-shot turbo spin echo; *TI,* inversion time; *LGE,* late gadolinium enhancement; *LV,* left ventricular; *MRA,* magnetic resonance angiography; *PSIR,* phase-sensitive inversion recovery; *SI,* signal intensity; *SNR,* signal-to-noise ratio; *SS,* single-shot; *SSFP,* steady-state free precession; *STIR,* short T1 inversion recovery; *T,* tesla; *T1W,* T1-weighted; *T2W,* T2-weighted.

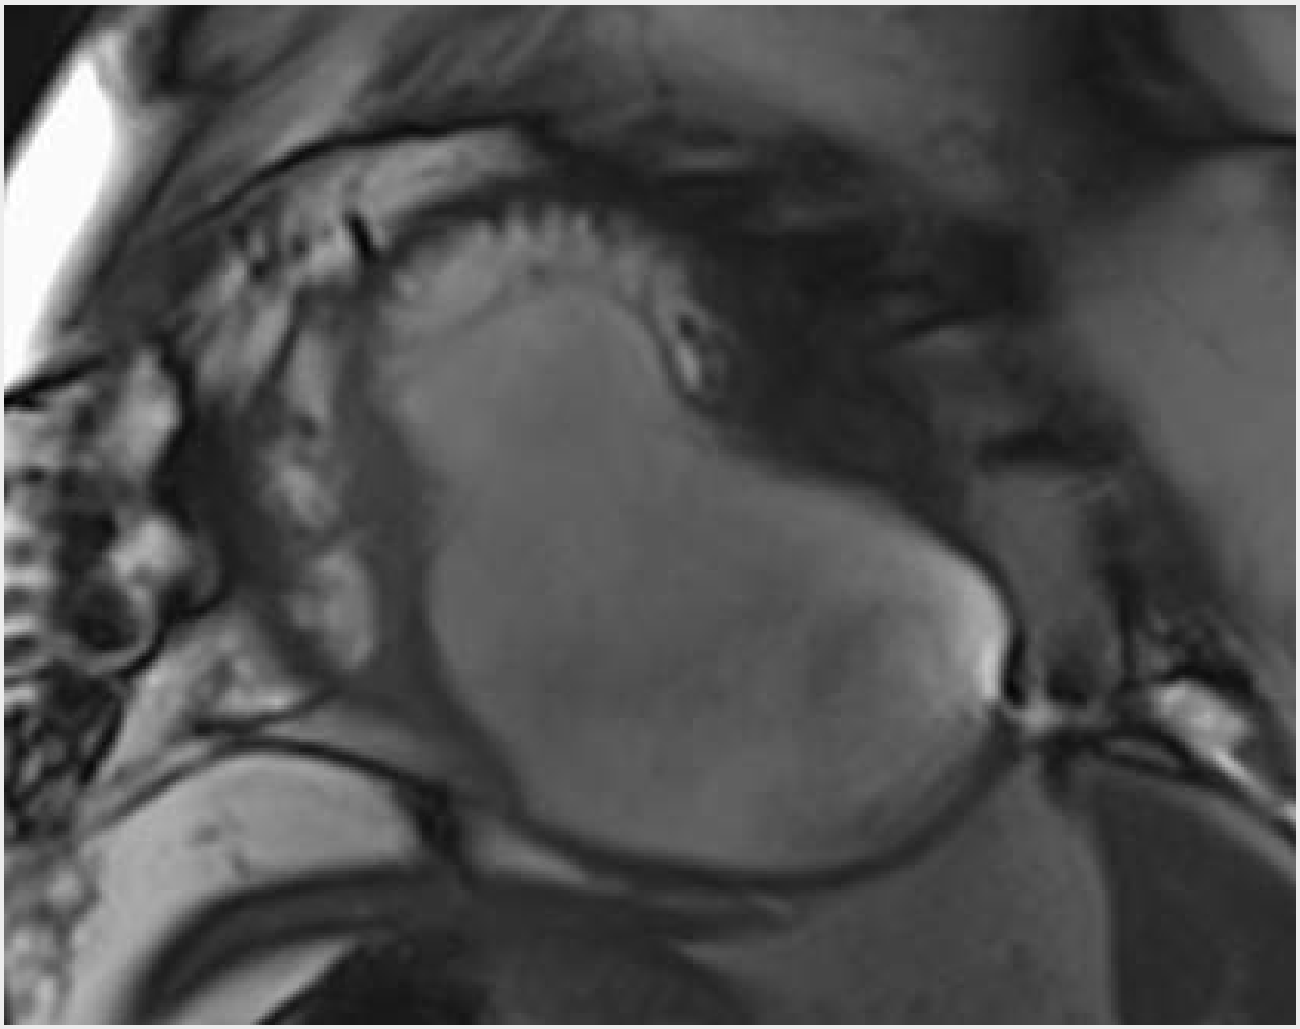

FIGURE 17.1 Massive inferior wall ventricular aneurysm complicating a chronic myocardial infarction. Note the wide neck of the aneurysm and extremely stagnant flow in the left ventricular cavity.

CMR perfusion imaging examines the first-pass transit of an IV bolus of GBCA as it travels through the coronary circulation. Several perfusion techniques are available; fast bright-blood gradient-echo imaging acquires three to five short-axis slices of the heart every cardiac cycle during injection of a GBCA bolus. Gadolinium provides strong signal enhancement in well-perfused regions compared to hypoenhancement (dark regions) in poorly perfused myocardium. At a spatial resolution of approximately 2 mm in-plane, CMR perfusion can provide information on myocardial blood flow at the endocardial/epicardial level or at a segmental level (Video 17.2). T2-weighted imaging detects myocardial edema from ischemic injury or inflammation, and it has been shown to have high correlation to the area at risk after acute myocardial infarction (MI). It also complements LGE in determining the chronicity of an MI and allowing for accurate measurement of *salvageable myocardium*. The pulse sequence options for T2-weighted imaging include black-blood *short T1 inversion recovery* (STIR) FSE and the newer SSFP methods, and their merits are listed on **Table 17.1**.

T2* is a transverse relaxation parameter and well-validated method for measuring tissue iron content. A T2* of less than 20 milliseconds (normal myocardium, approximately 40 to 50 msec) is diagnostic of myocardial iron overload, and a T2* of less than 10 milliseconds is evidence of severe iron overload (Video 17.3). Despite challenges from small luminal size and cardiac and respiratory motion, technical advances in coronary MRA have favored the use of whole-heart three-dimensional acquisition (with or without navigator-guidance), with promising preliminary clinical results.[1] Phase-contrast imaging allows quantitation of velocities of blood flow and myocardial motion and intravascular flow rates. Parallel imaging involves techniques that speed up CMR data acquisition by coordinating data obtained from

different components of the surface receiver coils, now routinely used to reduce acquisition time, improve temporal resolution, or even eliminate artifacts.

T1 and T2 Mapping

T1 mapping estimates in quantitative terms the expansion of the extracellular space in the myocardium where GBCA distributes. This method has demonstrated good correlation with collagen content of the interstitial space in conditions where diffuse fibrosis or infiltration occurs and can serve as a noninvasive method in monitoring disease progression or treatment response. Using both pre- and postcontrast T1 measurements, one determines the change of R1 (= 1/T1) between pre- and postcontrast states in myocardium relative to the change of R1 in blood. This ratio estimates the tissue volume fraction filled by extracellular GBCA. Compared to T1-weighted imaging such as LGE, T1 mapping provides quantitation of the spectrum of extracellular volume expansion from fibrosis or infiltration. T1 mapping techniques in early clinical studies have characterized significant changes in the myocardium not visible by LGE imaging.[2,3] Myocardial T2 mapping, which involves acquisition of a series of images with different T2 weighting, provides a quantitative measurement of regional fraction of free water in the myocardium. Compared to T2-weighted imaging, T2 mapping renders the detection of myocardial edema more reliable and is less prone to artifacts caused by motion or arrhythmia.

Patient Safety

All clinical CMR scanners depend on maintenance of a strong magnetic field that cannot be removed except in emergency situations. Common implants hazardous to CMR scanning include cochlear implants, neurostimulators, hydrocephalus shunts, metal-containing ocular implants, pacing wires, and metallic cerebral aneurysm clips. A full list is available at www.mrisafety.com. However, sternal wires, mechanical heart valves, annuloplasty rings, coronary stents, nonmetallic catheters, and orthopedic or dental implants are safe. Most claustrophobic patients can be managed with oral sedation alone or use of a scanner with large bore size. There are now pacemakers and implantable cardioverter-defibrillators (ICDs) approved by the U.S. Food and Drug Administration (FDA) that allow implanted patients to undergo MRI safely under specific imaging settings.

Standardization of Imaging Acquisitions and Reporting.
Several aspects of CMR imaging are key to delivery of a high-quality clinical service. The Society for Cardiovascular Magnetic Resonance (SCMR) has published guidelines for image interpretation and postprocessing techniques.[4] Normal values of various cardiac functions and chamber sizes can be pulse sequence specific, and recent updates have been published.[5] Furthermore, it is important to be aware of established criteria to assess CMR image quality,[6] as well as common CMR artifacts.[7]

Application in Specific Disorders and Conditions

This section discusses clinical applications of CMR imaging. **eTable 17.1** summarizes the CMR protocols used at our center. **Table 17.2** describes typical CMR findings of common conditions. A detailed description of CMR protocols endorsed by the SCMR can be found at www.scmr.org.

TABLE 17.2

Cardiac Magnetic Resonance Imaging (CMR) Findings That Differentiate Among Causes of Cardiomyopathy

CMR STUDY INDICATION	CINE CARDIAC STRUCTURE/FUNCTION	MYOCARDIAL EDEMA	MYOCARDIAL PERFUSION	LGE MAPPING	ASSOCIATED CMR FINDINGS
Acute myocardial stunning	RWMA	Positive	Normal (at rest)	Normal	Stress perfusion may show perfusion defect during peak vasodilation (if significant residual coronary stenosis exists). Coronary MRA may show luminal stenosis.
Chronic myocardial hibernation	RWMA, regional wall thinning possible	Negative	Usually shows resting subendocardial perfusion defect in a coronary distribution	Normal	Stress perfusion shows larger extent of perfusion defect than at rest (reversible defect) in regions without LGE. Intracavitary thrombus may exist in areas of stagnant flow.
Acute myocardial infarction	RWMA	Usually, transmural bright region in segments subtended by infarct-related artery	Subendocardial perfusion at rest (given revascularization of infarct-related artery) represents "no-reflow" zone of infarction	Subendocardial or transmural LGE in coronary distribution	Microvascular obstruction in "no-reflow" zone may be seen by LGE or myocardial perfusion imaging. Evidence of myocardial hemorrhage by T2 and T2* imaging has been described. Intracavitary thrombus may exist in areas of stagnant flow.
Chronic myocardial infarction	RWMA, chronic remodeling changes	Negative	Subendocardial defect at rest matching thinned infarcted region, but can be normal in small infarcts after coronary revascularization	Thinned subendocardial or transmural LGE in a coronary distribution	Intracavitary thrombus may exist in areas of stagnant flow.
Myocardial ischemia	Normal or RWMA	Negative	Reversible subendocardial perfusion defect in a coronary distribution	Normal	Subendocardial perfusion defect from significant coronary stenosis should persist beyond peak myocardial enhancement during first-pass transit of GBCA bolus. Coronary MRA may show luminal stenosis.
Idiopathic dilated cardiomyopathy	Dilated hypocontractile LV/RV	Negative	Normal	Midwall LGE often in the septum	Mitral regurgitation secondary to dilated ventricle and mitral annulus may be present.
Hypertrophic cardiomyopathy (HCM)	Increased ventricular mass Asymmetric septal hypertrophy in some cases with or without LV outflow obstruction Spade-shaped LV chamber in apical HCM	Often abnormal	Abnormality in thickened myocardial segments may represent abnormal microcirculation.	LGE at RV insertion into LV or patchy midwall involvement in hypertrophied segments	Outflow or midventricular obstruction by phase-contrast imaging Systolic anterior motion of mitral leaflet with or without mitral regurgitation May show reduced intramyocardial motion in hypertrophic regions Reversible perfusion defect may indicate abnormality of coronary microcirculation.
Arrhythmogenic right ventricular cardiomyopathy (ARVC)	RV dilated/aneurysmal	Negative	Normal	RV often full-thickness LGE matching location of RV aneurysm with or without LV focal LGE	Fatty infiltration of RV and LV focally may be seen by T1W FSE imaging and confirmed by fat suppression techniques. "Nulling" of normal myocardium of RV and LV needs different inversion time (TI).
Acute myocarditis	RWMA and/or hypocontractile LV	Usually, transmural bright regions are seen; can be patchy or diffuse.	Normal	Epicardial and midwall LGE involving inferolateral wall or septum	Pericardial involvement or effusion possible
Cardiac sarcoidosis	RWMA and/or hypocontractile LV/RV	Bright regions representing myocardial edema are variable.	Normal	Multifocal intense LGE often involving septum, inferolateral wall of LV, right atrium, and RV free wall	Mediastinal lymphadenopathy
Cardiac amyloidosis	Restrictive morphology, reduction of systolic thickening in LGE segments	Negative	Diffuse perfusion defect common	Diffuse circumferential (often subendocardial) LGE	Rapid gadolinium washout from LV blood pool after injection Difficulty in finding right TI in "nulling" normal myocardium during LGE imaging Low endocardium/blood T1 ratio several minutes after contrast injection Thickened atrial walls with atrial

					LGE, loss of atrial contraction
Iron overload cardiomyopathy	Hypocontractile LV with dark myocardium	Negative	Normal	Normal	Very low hepatic T2* value
LV noncompaction	Hypocontractile LV with spongelike trabeculae often in lateral wall and apex	Negative	Normal	Midwall or focal LGE	May see intracavitary thrombi
Apical ballooning syndrome	Circumferential ballooning and RWMA of all apical segments	Bright regions primarily involve apical segments	Normal	Normal or only minimal subendocardial LGE	Patchy intermediate-intensity LGE without loss of wall thickness and T2W evidence of myocardial edema can be seen. Reversal of abnormal findings after stressful events helps diagnosis.
Endomyocardial disease	Dilated hypocontractile LV and/or RV	Negative	Normal	Diffuse subendocardial LGE of LV or RV with or without thrombus	Cavitary thrombus can be seen on cine SSFP or LGE imaging with long TI. May be extensive to obliterate LV or RV apex
Fabry disease	Concentrically thickened LV ± RWMA with wall thinning	Negative	Normal	Midwall LGE often in inferolateral wall	Associated evidence of CAD possible
Chagas disease	Often presents as dilated and severe hypocontractile LV during latent period of the disease	Negative in latent period; positive if presented acutely	Normal	Resembles pattern of healed viral myocarditis, with epicardial LGE often involving inferolateral wall Apical aneurysmal changes have been described.	—
Acute pericarditis	Often normal; pericardial effusion	Positive if myocardial involvement	Normal	Often normal but may see diffuse pericardial enhancement	Pericardial thickness often normal CMR is better than echocardiography in assessing extent and loculation of pericardial effusion.
Chronic pericardial constriction	Small heart, large atria, and abnormal septal motion with respiratory variation during real-time cine imaging	Negative	Normal	Diffuse pericardial enhancement Myocardial involvement possible	Diffuse thickening (>3 mm) of pericardium seen by T1W FSE Constrictive tricuspid inflow pattern by phase contrast Bilateral pleural effusions Enlarged venae cavae and tubular-shaped RV
Cardiac mass	Proximity to RWMA or catheter, atrial fibrillation, and recent endovascular procedure are associated with thrombus.	Thrombus is dark on T2W imaging. High SI may indicate edema with tumor mass.	Thrombus is dark on first-pass perfusion imaging. Cardiac tumors have variable degree of enhancement on first-pass perfusion.	Mural thrombus may have an “etched” appearance on LGE imaging. May see LGE within tumor mass from fibrosis	Most malignancy is metastatic rather than primary. Recognize common normal structures: eustachian valve, Chiari network, crista sagittalis or terminalis, RV moderator band, and interatrial septal aneurysm. Beware of “pseudotumors”: coronary or aortic aneurysm, lipomatous hypertrophy of interatrial septum, hiatal hernia, catheters, etc.

ARVC, CAD, coronary artery disease; *FSE,* fast spin echo; *LGE,* late gadolinium enhancement; *LV,* left ventricle/ventricular; *MRA,* magnetic resonance angiography; *RV,* right ventricle/ventricular; *RWMA,* regional wall motion abnormality; *SI,* signal intensity; *SSFP,* steady-state free precession; *T1W,* T1-weighted; *T2W,* T2-weighted.

ETABLE 17.1

Typical Cardiac Magnetic Resonance (CMR) Protocols at Brigham and Women's Hospital

CMR STUDY INDICATIONS	CMR TECHNIQUES OF HIGH RELEVANCE	TYPICAL SCAN PLANES	OPTIONAL TECHNIQUES
Myocardial viability for benefit from coronary revascularization	Cine cardiac structure/function Low-dose dobutamine cine (may depend on local expertise) Myocardial perfusion at rest LGE imaging for myocardial scar	Short-axis stack and selected long-axis locations Cine and LGE locations should match each other.	Stress myocardial perfusion Phase contrast for coexisting valvular heart disease Imaging for cardiac thrombus
Myocardial ischemia Vasodilating stress Dobutamine stress Exercise stress	Cine cardiac structure/function Myocardial perfusion at peak vasodilating stress and at rest LGE imaging for myocardial scar Cine function at baseline, during escalating stages of dobutamine infusion ± atropine, and recovery LGE imaging for myocardial scar	Short-axis stack and selected long-axis locations 3 short-axis and 2 or 3 long-axis locations for stress cine	Myocardial perfusion during dobutamine stress
Acute myocardial infarction	Cine cardiac structure/function Myocardial edema imaging Myocardial perfusion at rest LGE imaging for myocardial scar	Short-axis stack and selected long-axis locations	Imaging for cardiac thrombus and microvascular obstruction (no-reflow)
Detecting ACS or other causes of myocardial injury	Cine cardiac structure/function Myocardial edema imaging Myocardial perfusion at rest LGE imaging for myocardial scar	Short-axis stack and selected long-axis locations	Stress myocardial perfusion
Assessing etiology of undiagnosed CMP or specific CMP	Cine cardiac structure/function Myocardial edema imaging (if acute myocarditis, ACS, or infiltrative CMP suspected) Myocardial perfusion at rest LGE imaging for myocardial scar	Short-axis stack and selected long-axis or axial locations	Myocardial and hepatic iron content (if cardiac hemochromatosis suspected): myocardial T2* map Stress myocardial perfusion (if CAD suspected) FSE with and without fat suppression (if ARVC suspected) Phase-contrast flow imaging (if outflow obstruction suspected in HCM) Myocardial T1 quantitation (amyloidosis)
Pericardial disease	Cine cardiac structure/function T1W FSE without fat suppression to assess pericardium (low-intensity linear structure that lies between high-intensity mediastinal and epicardial fat) Myocardial edema imaging (if acute myocarditis, ACS, or infiltrative CMP suspected) LGE imaging for myocardial scar	Short-axis stack and selected long-axis or axial/oblique locations	Myocardial tagging to assess perimyocardial adhesions in region of reduced strain Imaging for sizes of venae cavae Real-time cine SSFP (to see septal motion) and phase-contrast flow across tricuspid valve for pericardial constriction T1W and T2W techniques to assess fluid content of significant pericardial effusion; transudative effusion is gray or dark on T1W and bright on T2W images; exudative effusion is bright and subacute hemorrhage is inhomogeneous on T1W images.
Valvular heart disease	Cine cardiac structure/function Phase-contrast flow of dysfunctional valve of interest. Use appropriate encoding velocity (V_{ENC}) strengths to obtain peak velocity (valvular stenosis) and forward/regurgitant flows (valvular insufficiency) Imaging of the great vessels (FSE, MRA, others) for anatomy	Short-axis stack and selected long-axis or axial/oblique locations	LGE for myocardial scar (e.g., severe aortic stenosis)
Cardiac mass or thrombus	Cine cardiac structure and function (size, attachment, motion pattern of mass) T1W FSE without and with fat saturation to assess fat content and structure T2W FSE to look for tissue edema or simple cyst T1W imaging before and after contrast to assess vascularity of mass	Short-axis stack and selected long-axis or axial/oblique locations	EGE or LGE with long inversion time to assess for thrombus First-pass perfusion to assess mass with high vascularity LGE to detect necrosis
CMR for left atrial mapping and pulmonary vein ablation	Cine cardiac structure/function 3D FGRE MRA imaging of left atrial volume and pulmonary veins	Short-axis stack and selected long-axis locations Coronal 3D locations for MRA	Phase-contrast imaging prescribed as cross section of origin of pulmonary veins from coronal MRA images; use encoding velocity of 30 cm/sec for normal flow, and increase if pulmonary stenosis suspected or aliasing detected. High-resolution LGE imaging of left atrial scar (with navigator guidance) reported by experienced centers in patients with radiofrequency ablation of left atrium

ACS, Acute coronary syndrome; *ARVC,* arrhythmogenic right ventricular cardiomyopathy; *CAD,* coronary disease; *CMP,* cardiomyopathy; *EGE,* early gadolinium enhancement; *FGRE,* fast gradient-recalled echo; *FSE,* fast spin echo; *HCM,* hypertrophic obstructive cardiomyopathy; *LGE,* late gadolinium enhancement; MRA, magnetic resonance angiography; *SSFP,* steady-state free precession; *T1W,* T1-weighted; *T2W,* T2-weighted.

Coronary Artery Disease

Myocardial Infarction

CMR provides a comprehensive assessment of the spectrum of coronary artery disease (CAD) using cine imaging for cardiac structure and function, perfusion imaging for myocardial blood flow, LGE for infarction, and in patients with acute coronary syndrome, T2-weighted or mapping imaging for myocardial edema. At a spatial resolution of 1.5 to 2 mm and a high contrast-to-noise ratio, LGE imaging detects subendocardial infarction of either the left or the right ventricle at a higher sensitivity than any other current cardiac imaging techniques, and its tissue contrast capability allows visualization of necrotic and non-necrotic myocardium. Infarct size determined by LGE imaging has been well validated against histologic pattern, and commercial software is available to perform infarct size quantification. CMR is valuable in assessing complications from MI (**Fig. 17.2**).

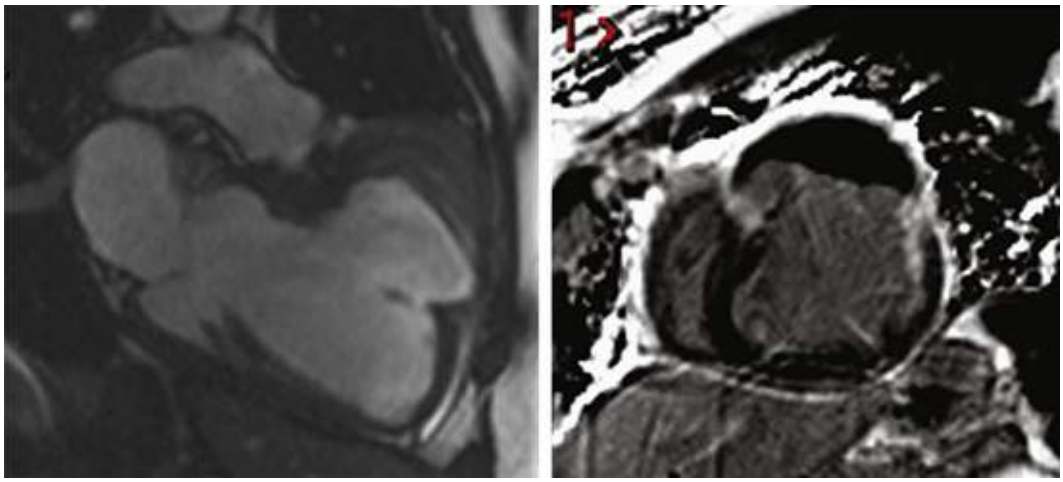

FIGURE 17.2 **Left,** Two-chamber long-axis steady-state free precession (SSFP) cine image at end-diastole in patient 5 years after anterior myocardial infarction (MI) demonstrates a chronic anterior pseudoaneurysm. Note narrowed neck of the pseudoaneurysm. **Right,** Short-axis phase-sensitive inversion recovery (PSIR) late gadolinium enhancement (LGE) image from same patient shows enhancement of fibrous outer layer of the pseudoaneurysm, which is lined with thrombus that appears black. (Courtesy Drs. Christopher Kramer and Michael Salerno, University of Virginia Health System.)

In patients with an acute reperfused MI, ischemic areas at risk (using either T2-weighted or precontrast T1 mapping) that surround an endocardial infarction and microvascular obstruction (no reflow) within an infarction are often seen and can be quantified (**Fig. 17.3** and Video 17.4). T2* imaging detects intramyocardial hemorrhage after acute MI (**Fig. 17.4**). These measurements along with right ventricular (RV) infarction may provide prognostic values incremental to clinical risk scores, left ventricular (LV) infarct size, and LV ejection fraction (EF).[8,9] More recently, characterization of remote myocardial fibrosis using serial T1 mapping has been shown to provide insights in post-MI cardiac remodeling and assess response to novel therapies.[10] In community-based studies that used CMR, MI detected by LGE imaging but unrecognized by either clinical examination, including ECG (thus untreated), was found in 6% to 17% of patients, with a marked increase in mortality consistently reported in these patients with unrecognized MI.[11,12] An interpretive algorithm incorporating various CMR imaging components can classify the age of an infarction as less than 1 month, 1 to 6 months, or more than 6 months.[13]

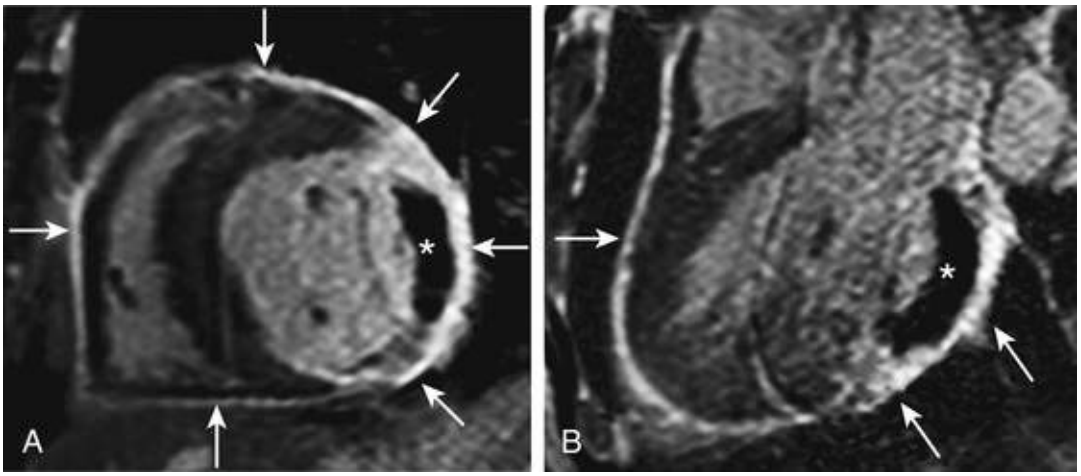

FIGURE 17.3 Acute pericarditis associated with transmural lateral MI. Short-axis **(A)** and long-axis **(B)** LGE views demonstrate a large transmural infarct with microvascular obstruction (*asterisks*) associated with severe acute pericarditis with diffuse LGE within the pericardium (*arrows*). (Courtesy Dr. Otávio Coelho Filho, University of Campinas, São Paulo, Brazil.)

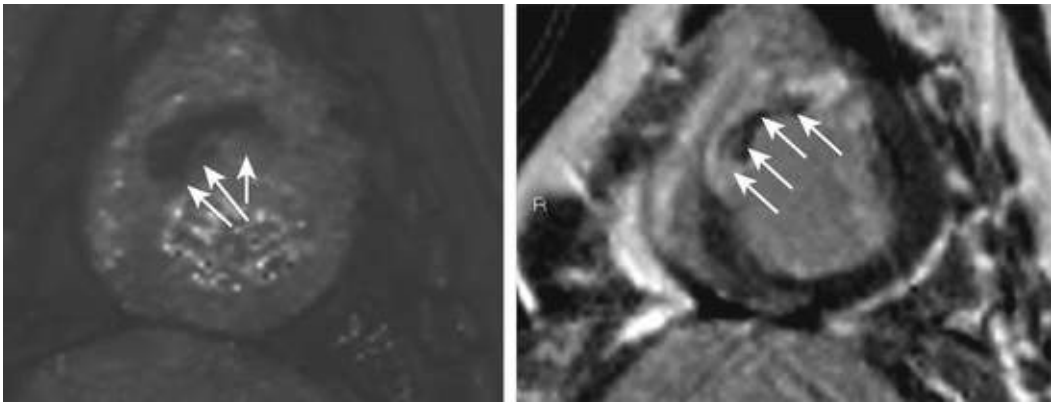

FIGURE 17.4 **Left,** Short-axis T2*-weighted image from a porcine model of reperfused MI demonstrates intramyocardial hemorrhage in anteroseptum. **Right,** Short-axis PSIR LGE image (*right*) in the same animal shows transmural LGE with a midwall region of intramyocardial hemorrhage. (Courtesy Drs. Christopher Kramer and Michael Salerno, University of Virginia Health System.)

Assessment of Myocardial Viability and Benefit from Coronary Revascularization

CMR imaging offers a multicomponent assessment of structure and physiology to evaluate myocardial viability. From early cine CMR studies, end-diastolic wall thickness of 5.5 mm or more and dobutamine-induced systolic wall thickening of 2 mm or more have excellent sensitivity and specificity in the prediction of segmental contractile recovery after revascularization. In addition, the transmural extent of myocardial scar detected by LGE imaging accurately depicts a progressive stepwise decrease in functional recovery despite successful coronary revascularization, especially in myocardial regions of akinesia or dyskinesia. Compared with dobutamine cine CMR, LGE is easy to perform and interpret, and a 50% transmurality cutoff is sensitive in detecting segmental contractile recovery. On the other hand, low-dose dobutamine cine imaging provides a highly specific physiologic assessment of the midmyocardial and subepicardial contractile reserve and early after acute MI, when tissue edema is prominent.

Detecting Acute Coronary Syndromes and Differentiating from Noncoronary Causes

CMR imaging has high sensitivity and specificity for detecting acute coronary syndromes and risk-stratifying patients presenting with acute chest pain. Specifically, CMR is a valuable diagnostic tool in patients who present with acute elevation of serum biomarkers consistent with myocardial injury but with nonobstructive coronary arteries, because it may provide diagnostic information to direct therapy and improve prognosis.[14] T2-weighted imaging (or T2 mapping) can detect the extent of the salvageable myocardium days after emergent restoration of coronary flow by percutaneous coronary intervention (PCI). Furthermore, CMR can capture various noncoronary abnormalities used to diagnose the causes of chest pain.

Detecting and Quantifying Myocardial Ischemia

Stress CMR imaging is performed using pharmacologic stress agents (vasodilating or positive inotropic) in many centers, and less often using treadmill exercise in highly specialized centers. As summarized by the recent AHA/ACCF guidelines for stable ischemic heart disease, vasodilating stress CMR *myocardial perfusion imaging* (MPI) is an effective clinical tool in diagnosing CAD and risk-stratifying patients with suspected myocardial ischemia.[15] Many single-center studies have shown that a negative CMR MPI predicts an annualized cardiac event rate of less than 1% in patients with an intermediate pretest likelihood of CAD. In addition, multiple clinical studies and a meta-analysis demonstrated excellent correlation of CMR MPI assessment of ischemia with invasive measurement of fractional flow reserve, illustrating the high accuracy of CMR in determining the physiologic significance of coronary stenosis[16] (**Fig. 17.5**).

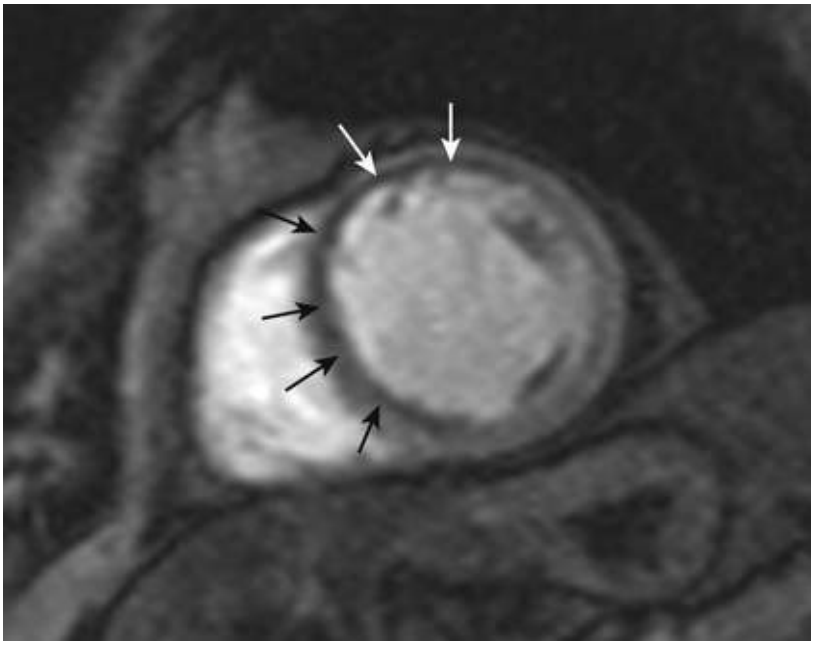

FIGURE 17.5 Patient who presented with chest pain underwent stress CMR perfusion with pharmacologic vasodilating stress. Note large subendocardial perfusion defect involving the anterior, septal, and inferior walls (*arrows*). On angiography, there is a critically stenosed proximal left anterior descending artery and right coronary artery.

Compared to single-photon emission tomography (SPECT) imaging (**see Chapter 16**), CMR MPI has several technical advantages: It is not limited by attenuation artifacts, is free from ionizing radiation, and

has a three- to fourfold higher spatial resolution than SPECT (Video 17.5). A stress CMR study that includes stress and rest perfusion imaging, cine cardiac function, and myocardial viability takes 35 to 45 minutes (versus >2 hours for dual-isotope SPECT). CMR MPI also can characterize the dynamic range of myocardial blood flow without being limited by plateau effect of counts at high flow rates, as seen in some nuclear tracers. Several clinical studies have reported that CMR MPI performed better than SPECT in detecting single- or multivessel CAD (area under curve, 86% to 89% versus 67% to 70%).

Dobutamine stress CMR (both perfusion and cine function) has excellent sensitivity and specificity in detecting CAD and is superior to dobutamine stress echocardiography (**see Chapter 14**). Such favorable results were consistent and maintained despite the presence of underlying resting wall motion abnormality. Multiple clinical studies have shown that dobutamine cine CMR provides strong prognostic value in risk assessment of patients. Accelerated real-time cine CMR imaging can eliminate the need for patient breath-holding or ECG gating during dobutamine stress in selected patients.

There are several promising technical developments in CMR MPI. First, quantitative CMR MPI is becoming the standard of care in some experienced CMR centers, with its potential advantages over qualitative methods including minimization of reader's bias and improved diagnostic accuracy, especially in patients with possible multivessel CAD.[17] Second, dynamic three-dimensional perfusion can provide larger myocardial coverage, can improve image quality, and has shown promising preliminary clinical results compared with invasive fractional flow reserve (FFR).[18] At a more investigational level, CMR can image for the change in myocardial oxygenation at rest and stress without the need for GBCA injection; deoxygenated hemoglobin in blood can act as an intrinsic contrast agent, changing proton signals in a way that can be imaged to reflect the level of blood oxygenation.[19]

Imaging of Atherosclerotic Plaques.

MRI of the carotid artery and the descending aorta remains the most comprehensive noninvasive method to characterize plaque structure and activity. Most studies used a standardized protocol of multiple contrast-weighted imaging sequences to identify carotid plaque fibrous cap, hemorrhage, calcifications, and loose matrix. Gadolinium-enhanced T1-weighted imaging helps to discriminate fibrous cap from necrotic or lipid core. Carotid plaque neovascularization can be assessed with contrast-enhanced dynamic MRI by measuring the transfer constant between blood and the extracellular space and may provide prognostic information. Ultrasmall superparamagnetic particles of iron oxide (USPIO) may target macrophage activity based on histologic and electron microscopic analyses of atherosclerotic plaques, and this may be imaged using T2*-weighted MRI. Similar to assessment of carotid plaque contents, CMR offers accurate quantitation of plaque size and extent and composition of thoracic aortic plaques and can complement plaque imaging with three-dimensional MRA over a large thoracic volume. Common to all modalities, imaging of the coronary plaque is challenged by both cardiac and respiratory motion and the small vessel size, but future technical improvements using exogenous targeted contrast agents, intravascular coils, and high-field CMR may offer promise.

Cardiomyopathy

Overall Approach

CMR imaging is an invaluable tool for assessing various cardiomyopathies given its multifaceted interrogation of ventricular structure and myocardial physiology in matching arbitrary scan planes. **Table**

17.2 summarizes the CMR features using rest and stress myocardial perfusion, regional function, LGE, and T2-weighted CMR, in differentiating causes of cardiomyopathies and severity of the conditions. In patients with valvular disease, volumetric cine CMR can assess the loading impact onto the heart and the resultant ventricular compensation, which determines appropriateness of surgery. Tissue tagging may help to resolve any suspected regional wall motion abnormality at rest or stress or when myocardial adhesion from pericardial diseases becomes part of the assessment. Current investigational CMR may offer unique guidance for cardiac resynchronization therapy in heart failure patients by demonstrating LV dyssynchrony, scar extent, and coronary venous anatomy in a single study.

Hypertrophic Cardiomyopathy

Compared to echocardiography, CMR provides a more precise three-dimensional pattern of LV hypertrophy and tissue characteristics in patients with hypertrophic cardiomyopathy (HCM) (**Fig. 17.6**) (**see Chapter 78**). Echocardiography missed hypertrophic segments and underestimated the magnitude of hypertrophy in the basal anterolateral wall by as much as 33% compared to CMR. In addition, 40% of apical aneurysms are missed by echocardiography. In HCM patients with severe septal hypertrophy and symptomatic dynamic LV outflow tract obstruction, CMR has the advantage over echocardiography of assessing the reduction in septal thickness from surgical myectomy or alcohol septal ablation (Video 17.6). LV mass index varies widely with maximal LV wall thickness because of the heterogeneity of the HCM phenotype. Markedly elevated LV mass index (males >91g/m^2 and females >69g/m^2) was sensitive (100%), whereas maximal wall thickness greater than 30 mm was specific (91%) for cardiac deaths. Presence of LGE is indicative of heterogeneous fibrosis and myofibril disarray and has been associated with ventricular arrhythmias and progressive ventricular dilation. Its extent provides prognostic value to patient risk beyond cardiac structures and function, particularly in patients considered at low clinical risk.[20] The multifaceted approach by CMR may allow an individualized characterization of abnormal myocardial pathophysiology secondary to coronary microvascular dysfunction (Video 17.7), fibrosis, and hypertrophy.

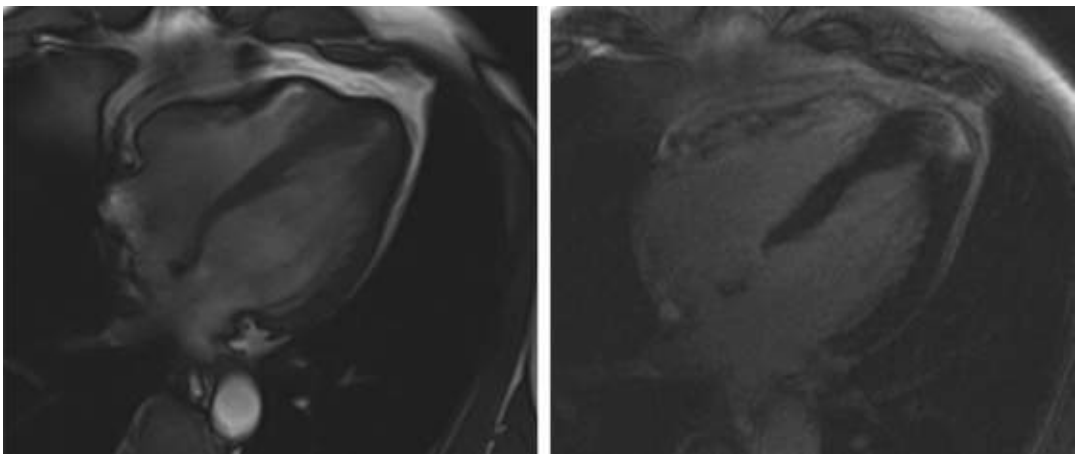

FIGURE 17.6 CMR images in 58-year-old man with history of palpitations and abnormal ECG shows evidence of apical increased wall thickness **(left)** and LGE involving apical inferior wall and true apex, consistent with fibrosis **(right).** These morphologic features are diagnostic of apical hypertrophic cardiomyopathy.

Arrhythmogenic Right Ventricular Cardiomyopathy

Arrhythmogenic right ventricular cardiomyopathy (ARVC) distinguishes itself from other cardiomyopathies by (1) a predisposition toward ventricular arrhythmia that precedes overt morphologic abnormalities and even histologic substrate and (2) diverse phenotypic manifestations despite the success in isolating the causative desmosomal mutations (**see Chapter 77**). CMR offers advantages over echocardiography with its quantitative and volumetric assessment of RV function and its fibrofatty tissue characterization of myocardium. Recent evidence indicates that early and predominant LV disease exists in variant groups. Enthusiasm in CMR was somewhat curbed by a lack of standardized imaging protocol in the past and inherent subjectivity in interpreting myocardial fat and wall motion abnormality of the thin-walled crescent-shaped right ventricle. Recent efforts in standardization of CMR protocols have nonetheless affirmed the value of CMR as an integral component in the workup of ARVC. Currently, task force guidelines consider localized aneurysms, severe global dilation with systolic dysfunction, and severe segmental dilation of the right ventricle as major criteria for ARVC (Video 17.8). These abnormalities are typically observed in predilection areas, including the subtricuspid region, basal RV free wall, and LV posterolateral wall.[21] Fat-suppressed LGE imaging of RV fibrosis has shown a high correlation with endomyocardial biopsy and the inducibility of ventricular arrhythmias. However, fat infiltration of the right ventricle as an isolated finding is of limited specificity for diagnosing ARVC. In patients suspected to have ARVC, CMR had a sensitivity of 96% and a specificity of 78% in detecting ARVC, according to diagnostic criteria that included genotype. This approach suggested that CMR potentially detected patients with early disease not characterized by task force guidelines.

Myocarditis

CMR targets the three main pathophysiologic components of myocarditis: myocardial edema by T2-weighted imaging, regional hyperemia and capillary leak by early gadolinium enhancement ratio (EGE_r), and myocardial necrosis or fibrosis by LGE imaging (**see Chapter 79**). **Table 17.1** and a published expert consensus summarize the diagnostic criteria of these techniques for acute myocarditis. From pooled data of the single-center studies, T2-weighted imaging, EGE_r, and LGE have sensitivity and specificity of 70% and 71%, 74% and 83%, and 59% and 86%, respectively. A combined approach using T2-weighted images and LGE provides high diagnostic accuracy for acute myocarditis (**see Table 17.2**). The subepicardium and midmyocardium of the inferolateral walls are usually involved, and *Parvovirus* has been implicated in these cases, but septal involvement is associated with human herpesvirus 6 with potentially more serious sequelae (**Fig. 17.7**). In recent studies, T1 mapping appears to offer promising improvement to the current diagnostic criteria. A proposed diagnostic algorithm using native (precontrast) T1 mapping has demonstrated higher diagnostic consistency than T2-weighted imaging in sizing the inflammatory myocardial region and staging disease activity.[22] Assessing the expansion of extracellular volume (ECV) using T1 mapping combined with LGE imaging can provide higher diagnostic accuracy than the current published criteria.[23]

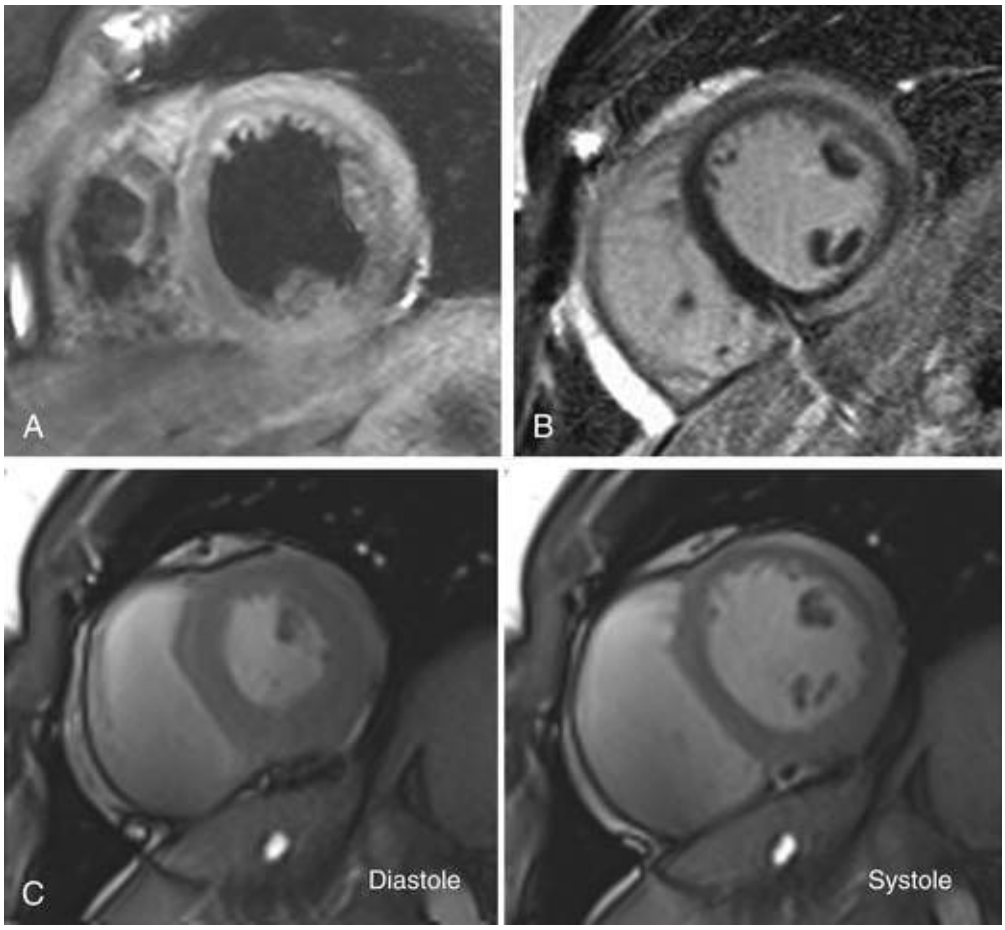

FIGURE 17.7 In 30-year-old man presenting with fever and pleuritic chest pain, troponin T was mildly elevated and serum C-reactive protein greatly elevated. **A,** CMR image show T2 enhancement involving basal and midanterior, anterolateral, inferolateral, and midinferior walls of LV myocardium, in subepicardial and midmyocardial distribution with sparing of subendocardium, suggestive of myocardial edema from a noncoronary inflammatory condition. **B,** Postcontrast LGE image shows LGE of corresponding segments in epicardial lateral wall segments. **C,** On cine images in diastole and systole, LV function globally and regionally was not impaired. These findings are characteristic of acute viral myocarditis. Patient was treated with ibuprofen with improvement of symptoms.

Cardiac Sarcoidosis

The CMR techniques and corresponding findings in cardiac sarcoidosis are listed in **Table 17.2 and eTable 17.1** (**see Chapter 77**). CMR may enhance disease detection through the successive histologic stages of disease: tissue edema, noncaseating granulomatous infiltration, and patchy myocardial fibrosis. LGE imaging has been reported to identify myocardial abnormalities caused by sarcoidosis at a higher sensitivity than the modified Japanese Ministry of Health guidelines. Most often, cardiac infiltration based on LGE imaging is seen in multiple locations involving the septum and basal anterior part of the right ventricle (**Fig. 17.8**). In cases where septal LGE are seen, CMR may also guide sampling during endomyocardial biopsy and increase tissue yield. LGE-positive patients had a ninefold increase in the risk of death or major dysrhythmic events. In patients with extracardiac sarcoidosis, LGE and RV dysfunction are high-risk markers for cardiac death or serious ventricular arrhythmias independent of LVEF.[24,25]

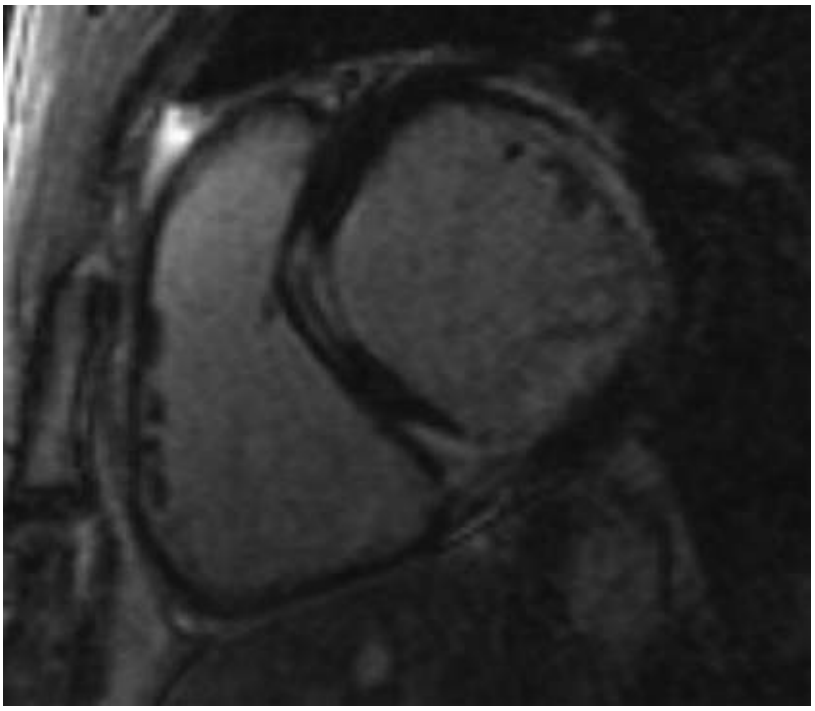

FIGURE 17.8 A 38-year-old man with no past medical history presented to hospital with syncope and was found to have runs of nonsustained ventricular tachycardia. His regional and global LV function was normal on echocardiography. On CMR, multiple regions of LGE are seen involving the septum (epicardial and midlateral wall). Focal expansion of the inferoseptal wall thickness is seen in this segment with LGE, consistent with myocardial infiltration. These patterns are characteristic of cardiac sarcoidosis.

Cardiac Amyloidosis

The typical features of CMR techniques in cardiac amyloidosis are summarized in **Table 17.2** (**see Chapter 77**). This characteristic circumferential pattern of LGE involving the LV and even the RV subendocardium had been reported to have high diagnostic accuracy and in some cases even to obviate the need for endomyocardial biopsy (**Fig. 17.9**). Furthermore, the pattern of LGE may differentiate the subtype of amyloidosis: cardiac amyloidosis caused by ATTR is more likely to show transmural LGE and RV involvement than the AL subtype.[26] The transmurality and extent of LGE represent advanced cardiac amyloidosis, and these findings are associated with patient mortality incremental to common risk markers, including systolic and diastolic function.[27] LGE is easy to interpret for diagnosing cardiac amyloidosis, but myocardial ECV may become a part of the standard diagnostic algorithm because it offers a more complete quantitation of the regional and global severity of amyloid infiltration, as well as in monitoring treatment response. Recent reports indicated that native myocardial T1 value is prolonged from amyloid protein of either AL or ATTR subtype,[28] and this measurement may be useful in diagnosing early cases of cardiac amyloidosis.[29]

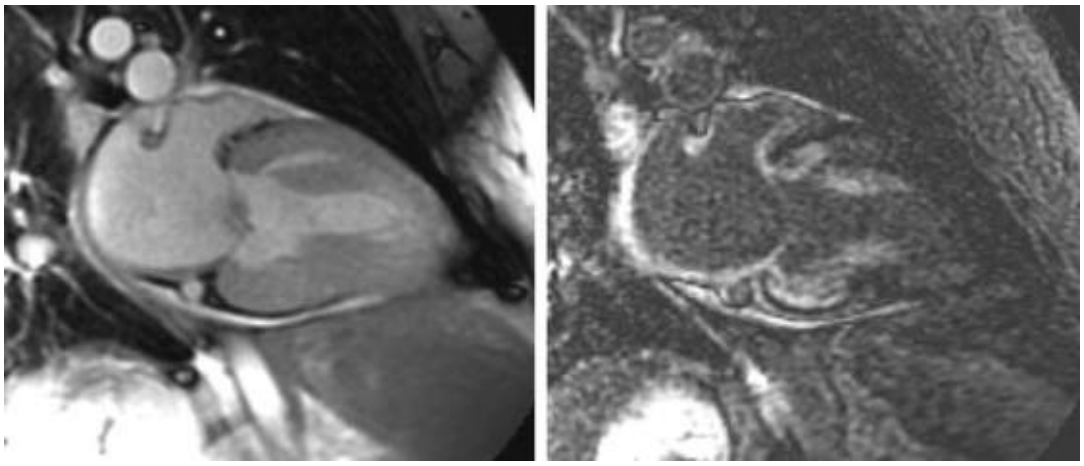

FIGURE 17.9 End-diastolic cine imaging **(left)** and a matching LGE image **(right)** of a patient with cardiac amyloidosis. Note the increase atrial wall thickness, which enhances on LGE imaging. Blood pooling is also remarkably dark after contrast injection, indicative of rapid blood pool washout caused by contrast sequestration into other organs.

Idiopathic Dilated Cardiomyopathy

Major advantages of CMR in evaluating suspected idiopathic dilated cardiomyopathy include ruling out ischemic cardiomyopathy; characterizing the LGE pattern, which has diagnostic and prognostic implications; and monitoring treatment response and disease progression (**see Chapter 77**). In up to 13% of patients diagnosed with nonischemic dilated cardiomyopathy on the basis of nonobstructive coronary angiography, subendocardial or transmural LGE consistent with infarction was seen. On the other hand, current evidence indicates that in the absence of LGE, an ischemic cause of LV dysfunction is highly unlikely. In a prospective randomized study, CMR using a combination of LGE and coronary MRA had a sensitivity of 100% and specificity of 96% in diagnosing ischemic etiology of new-onset heart failure and provided substantial cost-savings when used as a gatekeeper to invasive investigation. Furthermore, in patients with cardiomyopathy but without angiographic coronary stenosis, 28% had patchy or linear midwall striae on LGE most often seen in the basal septum. LGE extent is associated with a lack of response to medical therapy[30] and has been associated with sudden death and inducible ventricular tachycardia, independent of LV size and function.

Iron Overload Cardiomyopathy.

Iron overload cardiomyopathy is either inherited or acquired. In patients with transfusion-dependent thalassemia major, cardiac death as a result of myocardial iron toxicity occurs in 50% of patients. Global systolic LV function is usually preserved, especially in anemic thalassemic patients, until severe cardiac toxicity has developed, and thus provides little if any guidance to use of chelation therapy. The CMR T2* technique for quantifying myocardial iron is summarized in **Table 17.1**. CMR T2* quantitation has been shown to improve delivery of iron chelation therapy and has led to a substantial reduction in mortality for patients with thalassemia major. In patients with reduced ventricular function, a T2* less than 20 milliseconds is consistent with iron overload. Patients with a myocardial T2* less than 10 milliseconds are at the highest risk of developing heart failure within 1 year.

Other Cardiomyopathies.

Chagas disease is a myocarditis caused by infection from the protozoan *Trypanosoma cruzi* endemic in Central and South American countries. Most cases have a self-limiting course, but about 30% of patients

will have persistent parasitemia and latent infection that manifest years later as a dilated cardiomyopathy, often associated with ventricular arrhythmias. CMR is useful in diagnosing (**see Table 17.2**) and monitoring patients infected during the latent period. A diastolic noncompacted-to-compacted thickness ratio of more than 2.3 measured in a long-axis view was reported to be diagnostic for LV noncompaction. However, given the low specificity of this finding alone for genetic cardiomyopathy or adverse outcomes, it remains unclear whether the myocardial morphology is representative of LV noncompaction or merely an epiphenomenon associated with increased cardiac preload[31] (**Fig. 17.10**). Concurrent evidence of clinical heart failure, family history of cardiomyopathy, neuromuscular disorders, embolic events, or ventricular arrhythmias should be considered before diagnosing LV noncompaction.

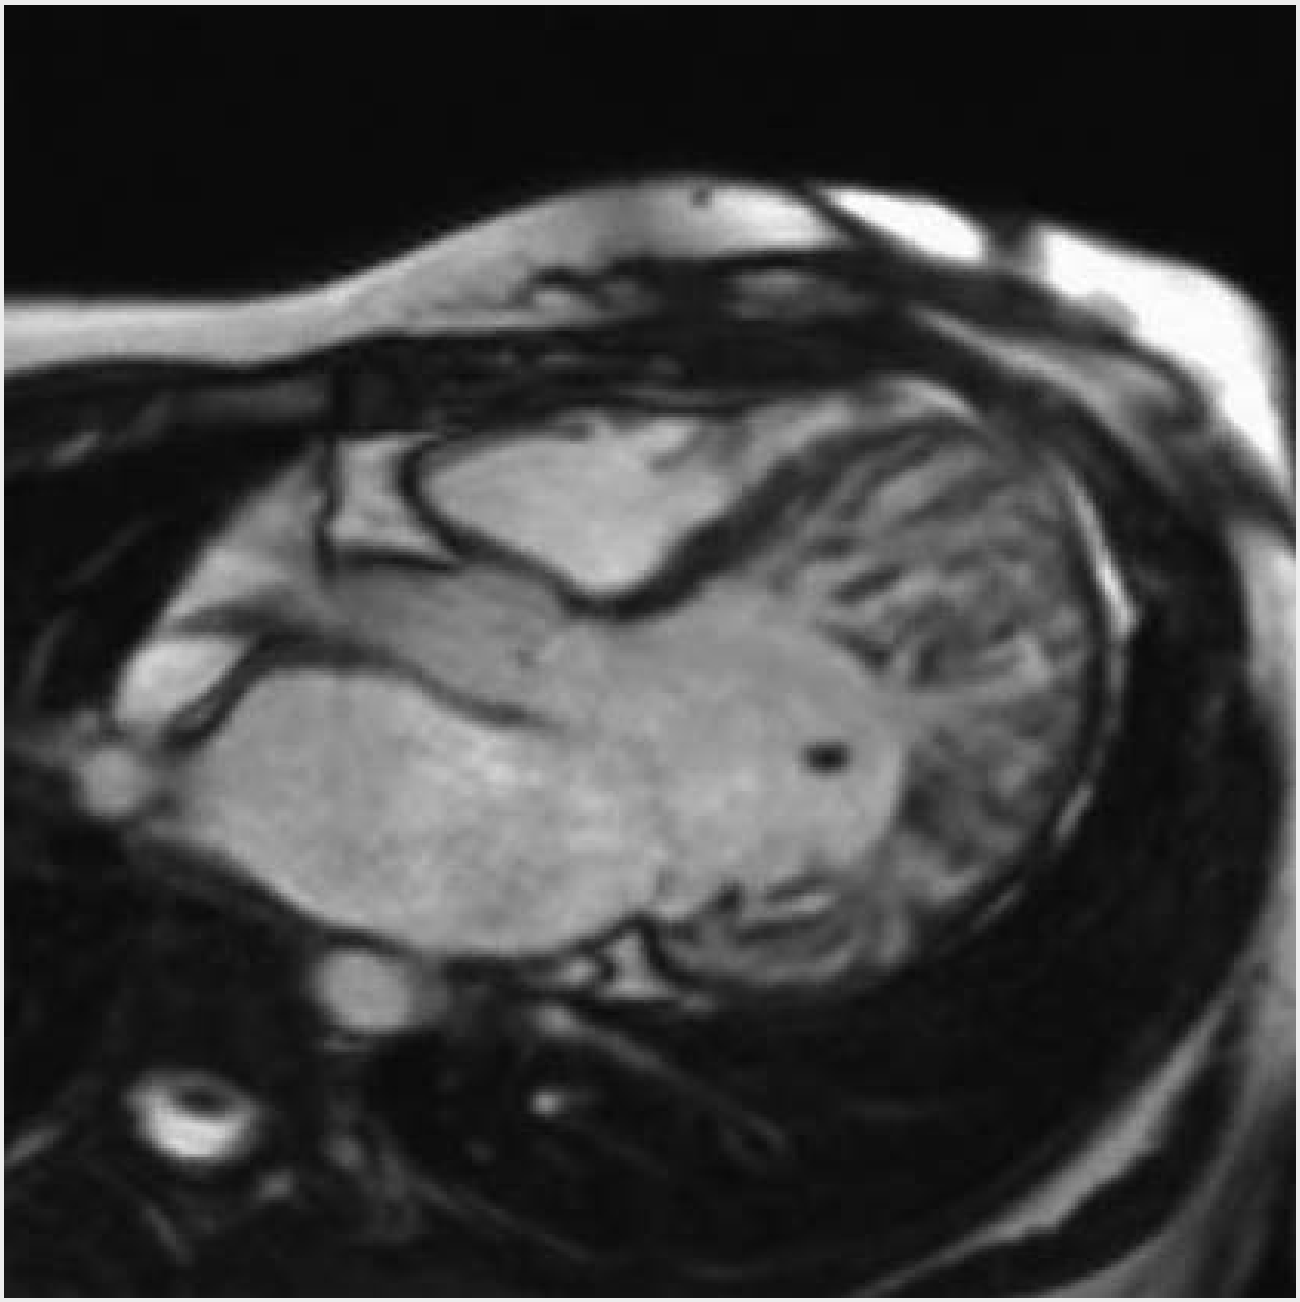

FIGURE 17.10 Left ventricular noncompaction in patient diagnosed with clinical heart failure. Note the pattern of the extensive spongelike appearance of the myocardium.

Transient LV apical ballooning syndrome, or *takotsubo cardiomyopathy*, is characterized by a transient contractile dysfunction of the apex, caused by elevated catecholamines from severe emotional or physical stress (Video 17.9). CMR can be useful in differentiating apical ballooning syndrome from

an acute coronary event. Endomyocardial disease is a restrictive cardiomyopathy that consists of two variants, *endomyocardial fibrosis* and *Löffler endocarditis*, both considered the result of direct toxic effects of eosinophils on the myocardium. Hypereosinophilia, regardless of its cause, has been suggested to lead to cardiomyopathy in three stages: necrosis, thrombosis, and fibrosis. Hypereosinophilia is the hallmark of Löffler endocarditis, whereas it is variable in endomyocardial fibrosis, which has characteristic features on CMR (**see Table 17.2**).

Arrhythmias

Imaging of Patients Before Electrophysiologic Procedures

CMR is helpful in planning electrophysiologic procedures given its ability to identify the potential site of ablation or scar and to provide three-dimensional volume mapping of the atria or ventricles. For patients with atrial fibrillation (AF) undergoing pulmonary venous isolation (PVI), left atrial emptying function and evidence of LV fibrosis on CMR are strong markers of AF recurrence[32,33] (**see Chapter 38**). In addition, in patients with recurrent AF after an ablation attempt, LGE of the atrial walls from prior ablation can guide repeated PVI procedures by identifying and localizing gaps and may reduce procedural duration and radiofrequency application time.[34] In a multicenter trial of patients with AF undergoing catheter ablation, a proprietary commercial LGE method was reported to successfully quantify native atrial tissue fibrosis and predict recurrent arrhythmia.[35] The validity of this method remains to be tested in other centers.

Although still early in development, CMR offers promise for characterizing mechanical dyssynchrony in heart failure patients[36] and providing information relevant to placement of the LV pacing lead, such as coronary venous anatomy and LV scan location. In both ischemic and nonischemic ventricular tachycardia (VT), critical isthmus sites are typically located in peri-infarct regions identifiable by LGE. These findings suggest that CMR can provide guidance to critical isthmus sites during VT ablation.[37]

Risk Stratification of Patients at Risk of Sudden Cardiac Death

CMR contributes to assessment of patients at risk of sudden cardiac death (SCD) by quantitation of LVEF and RV pathology, detection of myocardial scar using LGE, identification of anomalous coronary arteries, and less frequently, use of T2* mapping for iron overload.[38] LV structures and LGE pattern in combination differentiate most patients in this setting as having ischemic, nonischemic, or infiltrative disease, which provides clinical guidance and a patient risk profile. In one study of patients who presented with SCD, LGE identified unexpected myocardial scar and a potential arrhythmic substrate in more than 70%.[39] For patients with CAD, multiple single-center studies report that LGE size is a robust risk marker for SCD independent of LVEF. More than 5% of LV mass has been reported to be a risk marker in both ischemic and nonischemic cardiomyopathies.[40] In addition, it appears that heterogeneity in the scar tissue, characterized by LGE core and peri-infarct signal intensities, may further define the risk of SCD in patients who do not have an indication for ICD therapy.[41] In nonischemic cardiomyopathy, a midwall septal LGE pattern has been noted in many patients with dilated cardiomyopathy, and its size has been associated with inducibility of ventricular arrhythmias and SCD. LV LGE in patients with systemic sarcoidosis has been associated with a high risk of SCD. More research is needed to define how the LGE extent can improve the current practice guidelines, specifically for ICD therapy.

Pericardial Disease

At our center, a typical CMR assessment includes cine SSFP imaging, T1- and T2-weighted double-inversion black-blood FSE (half-Fourier acquisition single-shot turbo spin-echo, HASTE), and LGE imaging of the whole heart to assess for pericardial changes (**see eTable 17.1**). Real-time cine SSFP and phase-contrast flow across the tricuspid valve are often added to the examination to enhance the detection of cardiac constriction (Video 17.10). First-pass perfusion and pre- and postcontrast T1-weighted techniques may also be necessary to determine vascularity of a pericardial mass (e.g., differentiate tumor from thrombus). Cine myocardial tagged (dark lines or grids) imaging may be useful to identify any regional concordance caused by perimyocardial adhesions. Pericardial thickness is easily assessed by either black-blood FSE or cine imaging, and up to 3 mm is accepted as normal. The transverse sinus (lies dorsal to the ascending aorta) and the superior pericardial recess (a curvilinear space to the right of the ascending aorta) may be mistaken for an aortic dissection or a mediastinal mass. The oblique sinus behind the left atrium may be misinterpreted as an esophageal lesion or bronchogenic cyst. Enhancement of the thickened pericardium after administration of GBCA suggests active inflammation or pericardial fibrosis.

CMR is the current test of choice in differentiating constrictive pericarditis from restrictive cardiomyopathy, based on assessing pericardial thickness and constrictive physiology from pericardial disease and the pattern of any myocardial infiltration from restrictive cardiomyopathy (**see Fig. 17.3**). Computed tomography can demonstrate pericardial calcifications but is inferior to CMR because of limited hemodynamic data and tissue characterization. Pericardial cysts usually have thin, smooth walls without internal septa. Their homogeneous transudative contents appear dark on T1-weighted images and bright on T2-weighted images, with no enhancement from GBCA (**Fig. 17.11**). Proteinaceous cysts appear very bright on T1-weighted images. Pericardial metastases are much more common (from lung, breast, and lymphomas) than primary pericardial tumors. Malignant invasion of the pericardium often shows focal obliteration of the pericardial line and a pericardial effusion. Most neoplasms appear dark or gray on noncontrast T1-weighted images, except metastatic melanoma, because its paramagnetic metals are bound by melanin. Partial absence of the pericardium is usually left sided and may be associated with other congenital defects. Absence of pericardium is suspected when lung tissue is seen interposed between the aorta and pulmonary artery or between the heart and diaphragm (**see Chapter 83**).

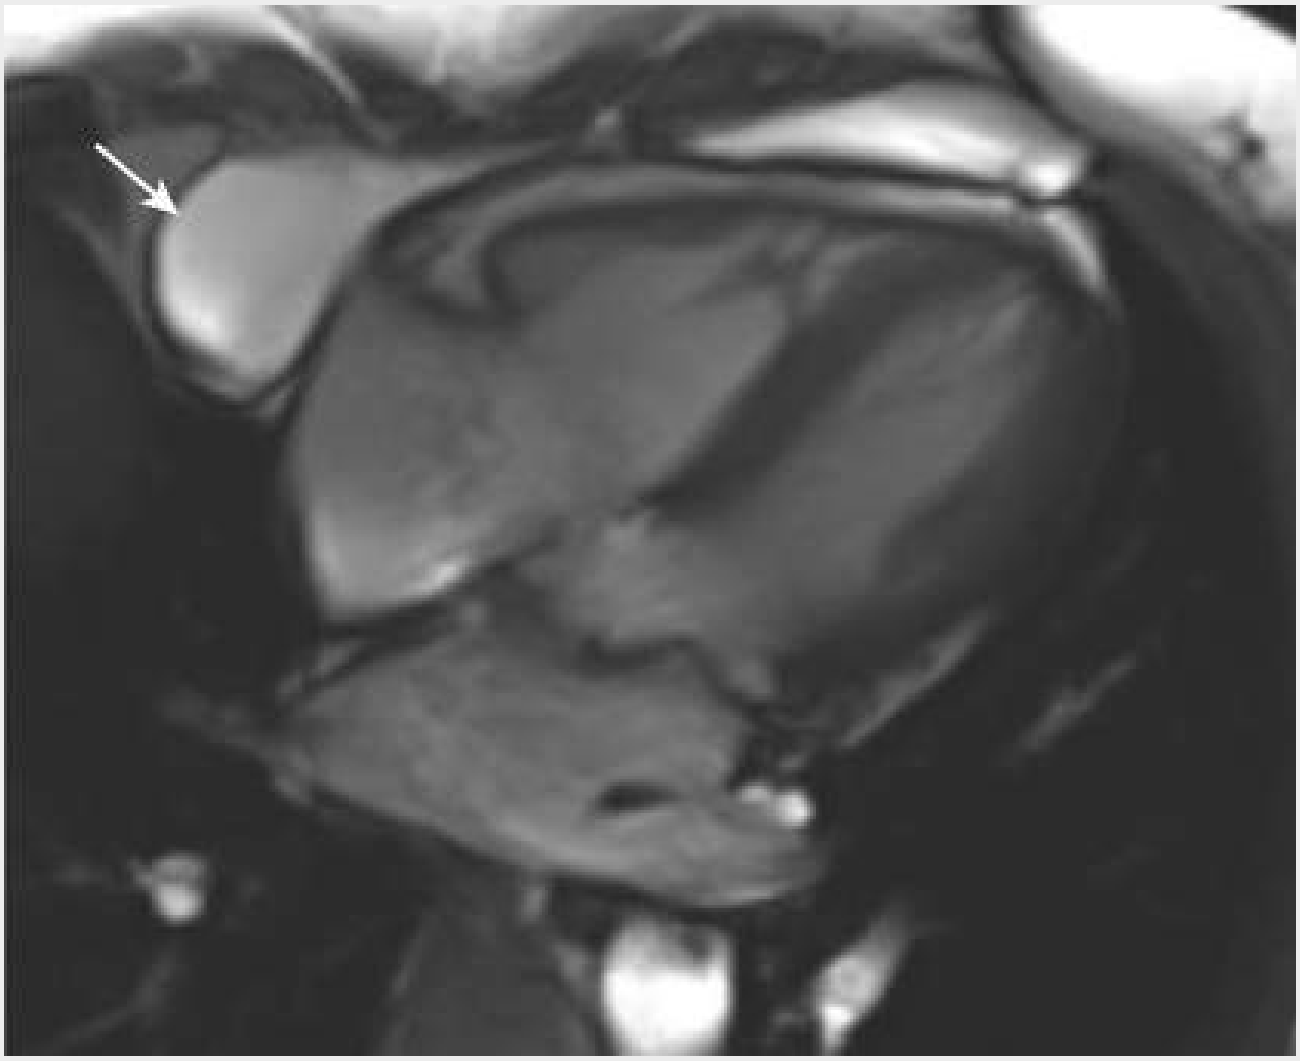

FIGURE 17.11 Pericardial cyst in 47-year-old woman presenting with a history of shortness of breath and palpitations and found to have a mass next to the right atrium on chest radiograph and then referred for CMR. Homogeneous mass (*arrow*) is seen abutting the right atrium and upper right ventricle without significant mass effects. Matching T2 images showed that this mass is bright, indicative of a simple fluid content (**see eFig. 17.1A**), which does not enhance after contrast (**eFig. 17.1B**).

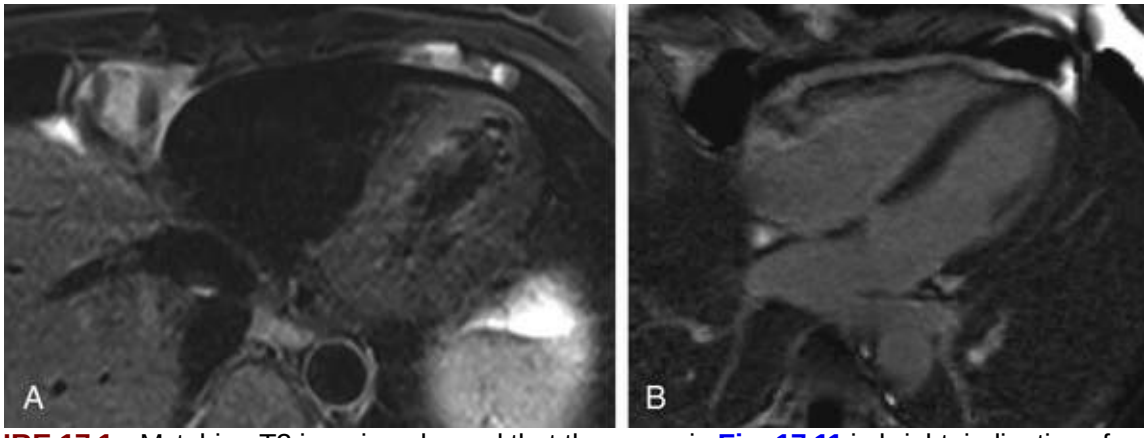

EFIGURE 17.1 Matching T2 imaging showed that the mass in **Fig. 17.11** is bright, indicative of a simple fluid content **(A),** which does not enhance after contrast **(B).**

Adult Congenital Heart Disease

CMR can provide key additive data beyond other imaging methods in assessment of congenital heart disease based on (1) no need for ionizing radiation, (2) three-dimensional tomographic imaging of thoracic structures and anatomy (versus more limited echocardiographic windows with body growth), and (3) correlation of complex anatomy with blood flow and physiology (**see Chapter 75**).

Atrial and Ventricular Septal Defects

CMR offers a less invasive alternative to transesophageal echocardiography (TEE) and even diagnostic catheterization for patients presenting with right-sided volume overload from a suspected left-to-right shunt. A CMR study can detect the presence of an atrial septal defect (ASD) (**Figs. 17.12 and 17.13**; Video 17.11), assess suitability for transcatheter ASD closure, quantify right heart size and function by cine SSFP, determine pulmonary-to-systemic shunt ratio (Qp/Qs) using velocity-encoded phase contrast, and identify any coexisting anomalous pulmonary venous return using three-dimensional contrast-enhanced MRA. Phase-contrast imaging positioned in a plane parallel to the atrial septum and set at a low-velocity range (100 cm/sec) can visualize the ASD en face with good correlation with defect size measured invasively. Phase-contrast imaging of the tricuspid regurgitation can estimate the pulmonary artery systolic pressure. Since most closure devices are MRI compatible, CMR can be used to assess for residual shunt and proper device deployment. Patients with a ventricular septal defect (VSD) can be assessed using similar CMR techniques. In addition, LGE imaging may help to determine if a VSD developed as a complication of MI.

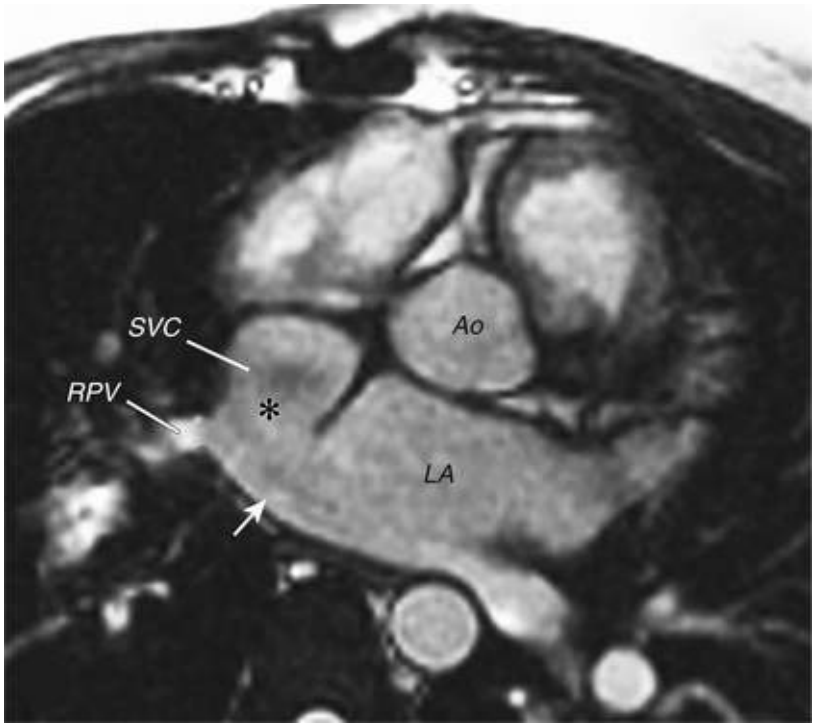

FIGURE 17.12 ECG-triggered SSFP cine CMR in the axial plane showing the defect (*) between the right upper pulmonary vein (*RPV*) and superior vena cava (*SVC*). Left-to-right shunt results from drainage of the RUPV to the SVC and from left atrial blood entering the right atrium through the orifice of the RUPV (*arrow*) and the unroofed wall between RPV and SVC (*). *Ao,* Ascending aorta; *LA,* left atrium.

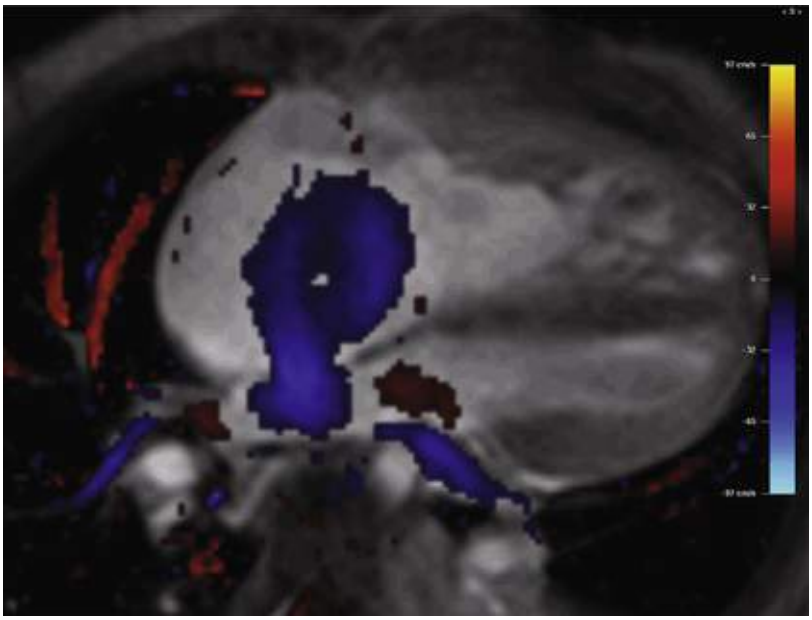

FIGURE 17.13 Patient with secundum atrial septal defect. Color-coded phase-contrast imaging demonstrates extensive left atrial–to–right atrial flow with resultant right atrial and ventricular dilation. (See Video 17.11.) (Courtesy of Drs. Andrew J. Powell and Rahul H. Rathod, Boston Children's Hospital.)

Anomalous Pulmonary Venous Connection

Using a large field of view, three-dimensional MRA can capture abnormal intrathoracic structures and vascular dynamics in anomalous pulmonary venous return. Near-isotropic in-plane resolution can be achieved, allowing reformatting in any plane to detect anomalous venous structures as small as 1 mm (**Fig. 17.14**). The magnitude of any left-to-right shunt can be assessed by either direct blood flow measurement in the anomalous pulmonary vein or by Qp/Qs ratio described previously, which generally is more accurate than invasive oximetry measurements because of the errors from mixed venous return in the right atrium.

FIGURE 17.14 Gadolinium-enhanced 3D MRA (oblique coronal subvolume maximal intensity projection) in an adult with scimitar syndrome. Notice the partial anomalous pulmonary venous connection of the right lung (the curvilinear structure) to the inferior vena cava. (Courtesy of Drs. Andrew J. Powell and Rahul H. Rathod, Boston Children's Hospital.)

Coarctation of the Aorta

Gadolinium-enhanced three-dimensional MRA is sufficient in defining the site of aortic narrowing in most cases (**Fig. 17.15**). Cine SSFP in a long-axis "candy cane" view can further delineate the aortic anatomy, the degree of obstruction, and aortic valvular dysfunction. Cine SSFP is the gold standard for LV size, LV function, and myocardial mass. Black-blood FSE is useful to evaluate the entire aorta, particularly since it is affected less by metallic artifacts from implanted endovascular stent than gradient-echo techniques. Phase-contrast imaging can characterize the descending-to-ascending aorta flow ratio and estimate pressure gradient across the coarctation and collateral formation.

FIGURE 17.15 Volume-rendered gadolinium-enhanced three-dimensional MRA in a patient with aortic coarctation revealing several tortuous collateral vessels and dilated internal mammary arteries. (See Video 17.15.) (Courtesy of Drs. Andrew J. Powell and Rahul H. Rathod, Boston Children's Hospital.)

Conotruncal Anomalies

Tetralogy of Fallot (TOF) is an increasingly common referral. In patients planned for surgical repair, key elements provided by CMR include depiction of all sources of pulmonary blood flow (e.g., pulmonary artery, aortopulmonary collateral, ductus-arterial) in the presence of RV outflow obstruction, quantitation of the severity of infundibular or pulmonary stenosis, assessment of RV function, and ruling out a coexisting anomalous coronary artery. In patients who have undergone surgery for TOF, CMR provides relevant assessment of any RV outflow aneurysm, pulmonary regurgitation fraction (patients who underwent patching of pulmonic valve with postoperative pulmonary regurgitation), biventricular size and function, and any residual shunt. LGE imaging has been proposed for detection of myocardial fibrosis, which is associated with ventricular dysfunction, exercise intolerance, and arrhythmias. The principal physiologic abnormality in dextro- ("D-loop") transposition of the great arteries (D-TGA, the most common TGA) is profound hypoxemia caused by a ventriculoarterial discordant connection where systemic venous blood flows to the aorta and oxygenated pulmonary venous blood returns to the lung. Survival depends on systemic-pulmonary circulatory mixing through a ductus arteriosus, an ASD, or a VSD. An *arterial switch* operation is now the most common corrective surgery, although many adult patients have undergone an *atrial switch* procedure. CMR is useful in monitoring these patients after surgical correction by serially assessing ventricular size and function, flow across the postoperative LV and RV outflow tracts, and aortopulmonary collaterals. Systemic RV LGE is strongly associated with an adverse clinical outcome, especially arrhythmia in TGA. Thus LGE CMR should be incorporated in risk stratification of these patients.[42]

Valvular Heart Disease

With the capability to quantify cardiac volumes, valvular and great vessel flow hemodynamics, and angiography in three dimensions, CMR is complementary to echocardiography by being more sensitive to

changes in cardiac volume and structure. For aortic stenosis (**see Chapter 68**), CMR can visualize and achieve direct planimetry of the aortic valve orifice at high spatial resolution. Aortic valve area on CMR correlates well with TEE, although the reliability of CMR decreases when the aortic valve is heavily calcified. For aortic regurgitation, CMR phase-contrast imaging has higher reproducibility than echocardiography in quantifying the regurgitant volume and is more suitable for serial monitoring.[43] CMR quantification of aortic regurgitation has high accuracy and complements LV volumes in characterizing the progression of the regurgitant disease toward clinical need for surgery.[44] The ability of CMR to provide high-quality imaging of structure and physiology of the great vessels complements the assessment of valvular dysfunction (Videos 17.12 and 17.13). Four-dimensional flow imaging can identify a vortical (swirling) blood flow pattern in the pulmonary artery and estimate mean pulmonary artery pressures noninvasively. In addition, in patients with bicuspid aortic valve, visualization of vascular "vector" flow can determine vascular wall shear stress and systolic flow eccentricity, potentially predicting development of bicuspid aortic valvular aortopathy[45] (**Fig. 17.16**).

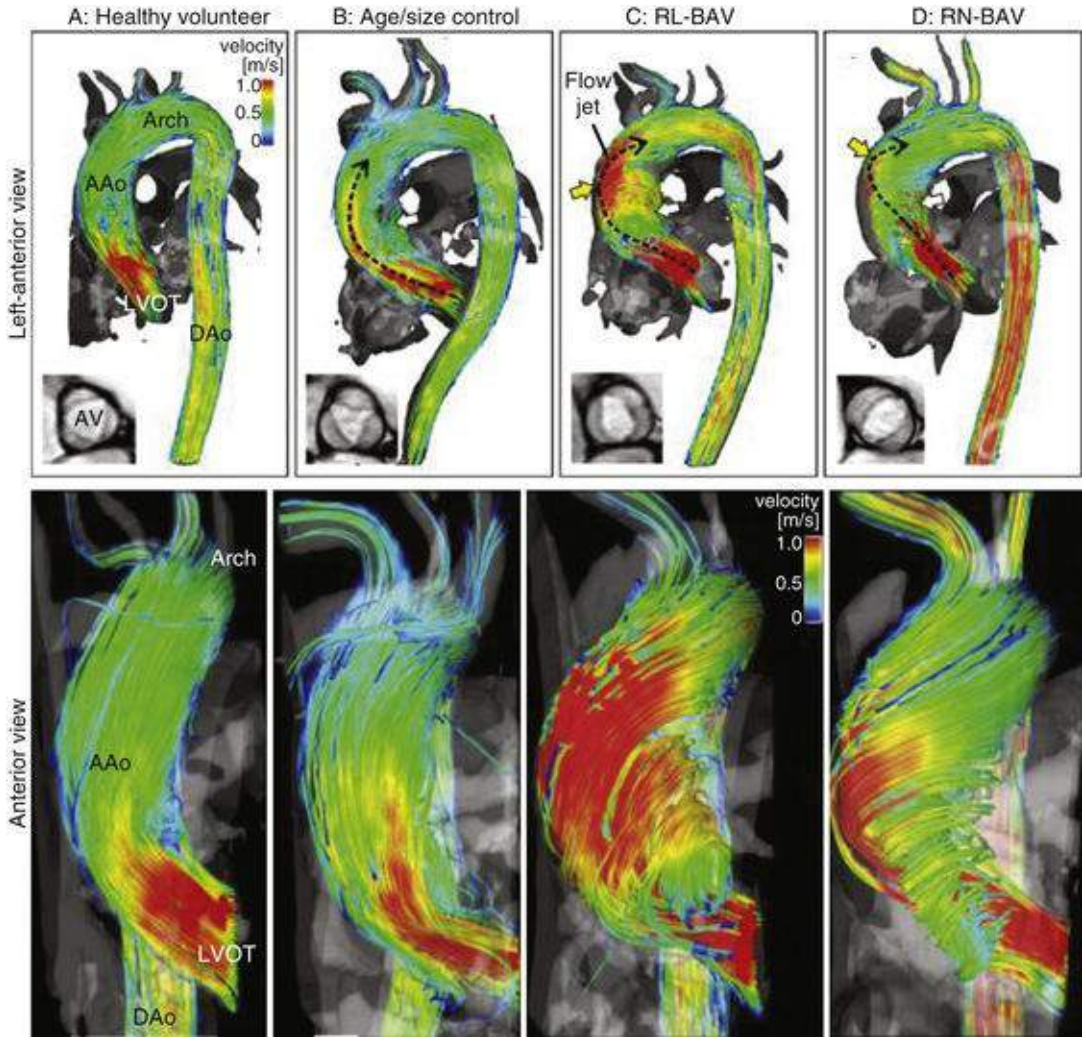

FIGURE 17.16 **Top row,** Three-dimensional (3D) streamline visualization of peak systolic blood flow in patients with bicuspid aortic valve (*BAV*) **(C, D)** compared to an aorta size–matched control **(B)** and a healthy volunteer **(A).** Note the presence of distinctly different 3D outflow flow jet patterns (*black dashed arrows*) in the ascending aorta (*AAo*) for patients **B** and **C. Bottom row,** 3D flow patterns in the left ventricular outflow tract (*LVOT*) and AAo distal to the aortic valve. Note the different systolic atrioventricular outflow flow jet patterns (*red* indicates high velocities >1 m/sec) and wall impingement zones, which correspond to variable exertion of high wall shear forces between different valve groups **(C, D)** and aorta size–matched controls **(B)** and healthy volunteers **(A).** *DAo,* Descending aorta. (From Mahadevia R, Barker AJ, Schnell S, et al. Bicuspid aortic cusp fusion morphology alters aortic three-dimensional outflow patterns, wall shear stress, and expression of aortopathy. Circulation 2014;129:673-82.)

CMR is a useful tool in assessing patients before or after transcatheter aortic valve replacement (TAVR) (**see Chapter 72**). Compared to transthoracic echocardiography (TTE), CMR is more accurate in sizing the aortic annulus before the procedure, which predicts the severity of aortic regurgitation after TAVR. CMR has also been shown to be more sensitive in detecting significant paravalvular aortic regurgitation at TAVR.[46] New ischemic-type myocardial LGE after TAVR has been observed in subsets of patients and is assumed to be of coronary embolic origin, which has clinical implications because it is associated with a decrease in LV function after TAVR.[47]

Cardiac Thrombus and Mass

The differential diagnoses of an intracardiac mass includes a thrombus, tumor, and vegetation. LGE imaging can detect thrombus at a higher sensitivity than echocardiography by depicting high contrast between the dark thrombus and its adjacent structures and by imaging in three dimensions. Mural

thrombus does not enhance on first-pass perfusion and often has a characteristic “etched” appearance on LGE imaging, thus providing higher diagnostic specificity than anatomic information alone. Multiple pulse sequences can be used to detect vascularity of tumor after contrast injection and allow differentiation from thrombus (Video 17.14). One study found that a pattern of hyperintensity/isointensity (compared with normal myocardium) with short TI and hypointensity with long TI was common in thrombi (94%), rare in tumors (2%), and had the highest accuracy (95%) for the differentiation of both entities[48] (**Fig. 17.17**). Common benign cardiac tumors include atrial myxoma, rhabdomyoma, fibroma, and endocardial fibroelastoma. Atrial myxomas are often seen as a round or multilobar mass in the left atrium (75%), right atrium (20%), or ventricles or mixed chambers (5%). They typically have inhomogeneous brightness in the center on cine SSFP imaging due to gelatinous contents and may have a pedunculated attachment to the fossa ovalis. Metastatic cardiac malignancy is much more common than primary cardiac malignancy. Malignant lesions include cardiac involvement from direct invasion (lung and breast), lymphatic spread (lymphomas and melanomas), and hematogenous spread (renal cell carcinoma) (**Fig. 17.18**). Primary cardiac malignancies occur more often in children or young adults and include angiosarcoma, fibrosarcoma, rhabdomyosarcoma, and liposarcoma. CMR in a multicenter trial correctly diagnosed 97% of these cases, although a differential diagnosis was necessary in 42%.

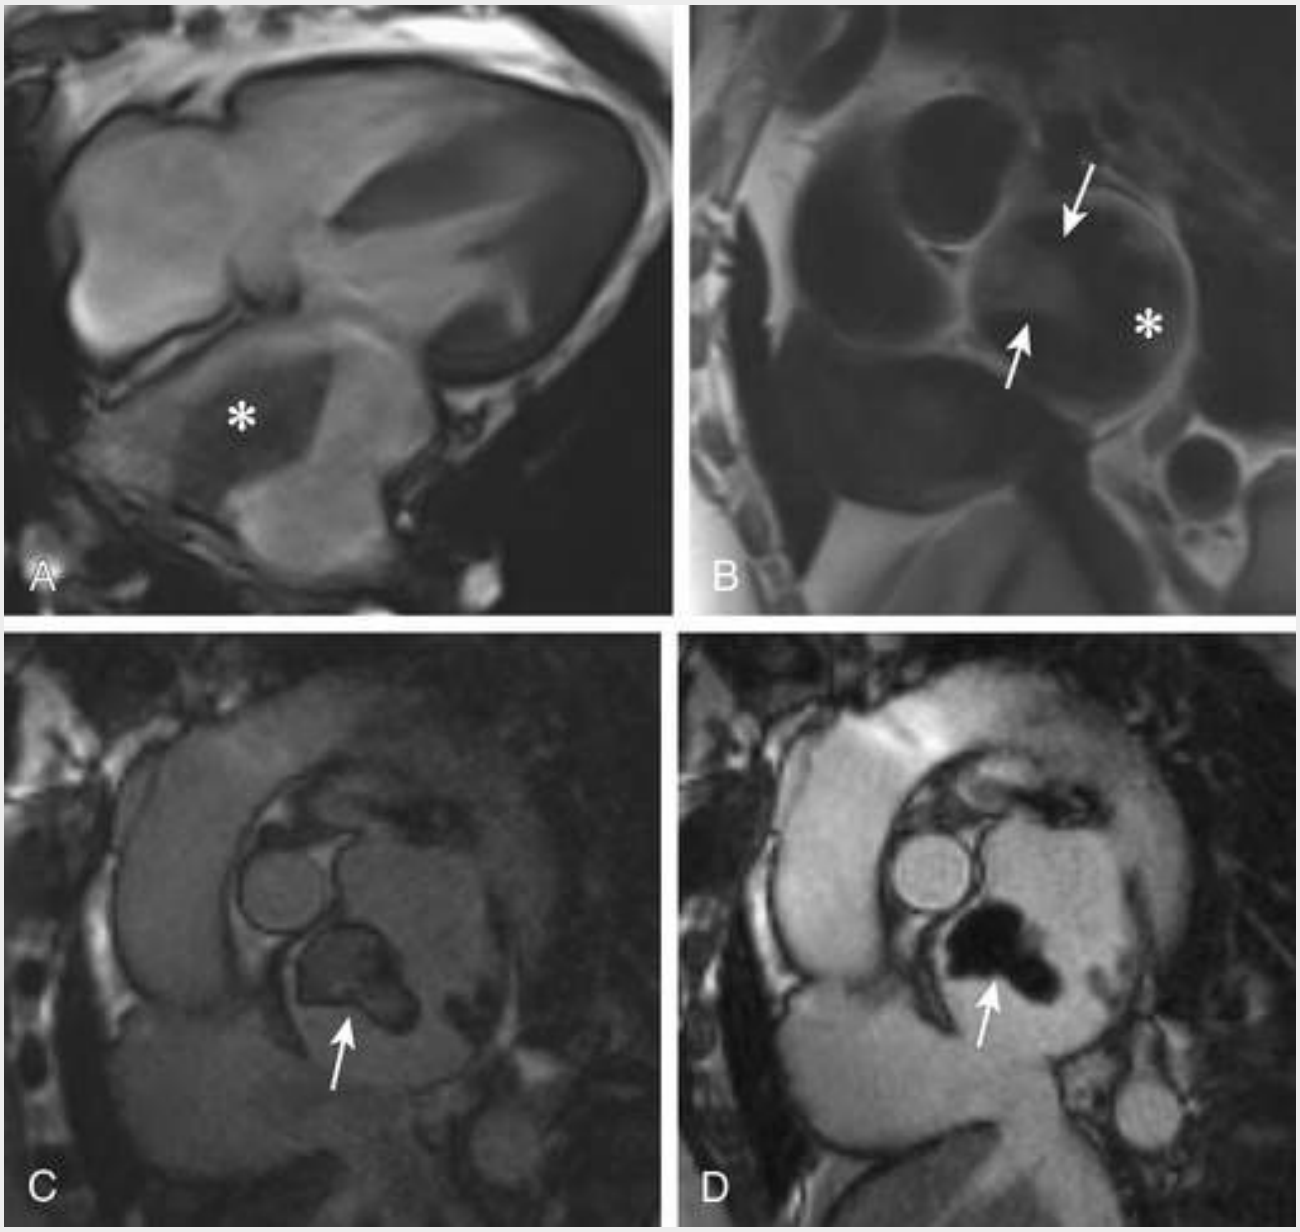

FIGURE 17.17 A 66-year-old woman with factor V Leiden mutation and antiphospholipid syndrome was found to have a mass on echocardiography and was then referred for CMR evaluation. **A,** SSFP image, four-chamber view, demonstrates an isointense mass in the left atrium posterior wall (*asterisk*). **B,** T1-weighted double–inversion recovery (DIR) image, short-axis view, shows an isointense mass attached to the left atrial wall *(arrows).* There is another small mass in the posterior wall of the atrium *(asterisk)*. **C,** On LGE image, short-axis view, the mass appears to be heterogeneously hyperintense. **D,** However, on LGE, long inversion time (TI) image (600 msec), short-axis view, the mass was nulled completely, suggesting lack of enhancement. These findings are consistent with an intracardiac thrombus.

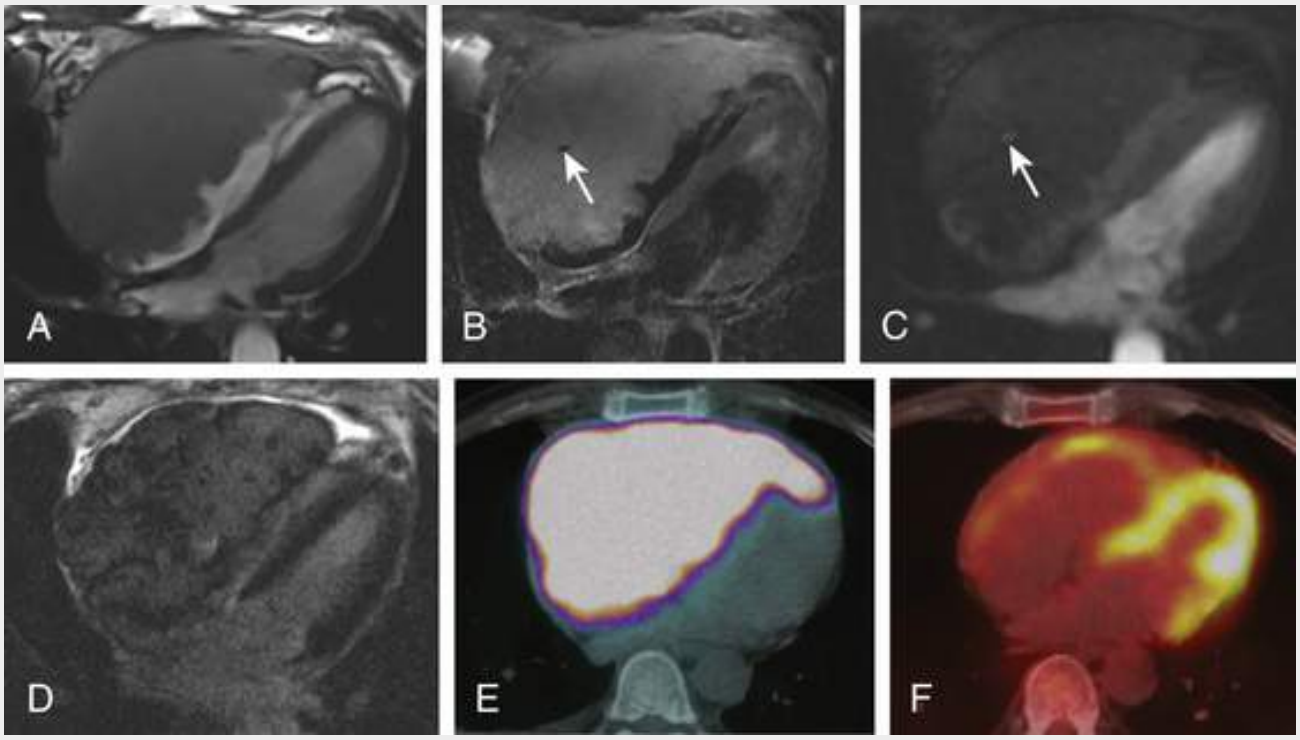

FIGURE 17.18 A 55-year-old man presented with chest pain and shortness of breath. Echocardiography revealed a large mass arising from the right ventricular free wall. **A,** SSFP image, four-chamber view, demonstrates a large, isointense mass along the right ventricular and atrial wall. **B,** Mass is hyperintense on fat-suppressed, T2-weighted DIR image, four-chamber view, and right coronary artery (RCA) appears to be patent, which can be seen as a flow void (*arrow*). **C,** Early cycle of first-pass perfusion (FPP) image, four-chamber view, demonstrates the patent RCA (*arrow*) as well. **D,** Heterogeneous enhancement on LGE. Histopathology of the mass revealed a large B cell lymphoma with high-grade features. **E,** Pretreatment PET-CT image demonstrates intensely FDG-avid mass, which is completely resolved on post-treatment image **(F)**. (Courtesy of Drs. Michael Steigner and Ayaz Aghayev, Brigham and Women's Hospital, Boston.)

Detection of Subclinical Cardiovascular Disease in Systemic Conditions

Subclinical cardiovascular disease is common in rheumatoid arthritis (**see Chapter 94**), including focal and diffuse myocardial fibrosis and inflammation, which are associated with impaired strain and right atrial disease activity.[49] Comprehensive cardiac imaging revealed cardiac steatosis, alterations in cardiac function, and a high prevalence of myocardial fibrosis in a contemporary group of asymptomatic HIV-infected patients undergoing combination antiretroviral therapy (**see Chapter 82**). Cardiac steatosis and fibrosis may underlie cardiac dysfunction and increased cardiovascular morbidity and mortality in patients with human immunodeficiency virus (HIV) infection.[50] Patients with systemic lupus erythematosus (SLE) and no cardiac symptoms show evidence of subclinical perimyocardial impairment. By using T1 mapping, subclinical myocardial involvement in patients with SLE may be detected.

Novel CMR Imaging Techniques

Magnetic Resonance Spectroscopy

Magnetic resonance spectroscopy (MRS) provides information regarding cellular metabolism. Free energy in adenosine triphosphate (ATP) is produced and stored primarily in mitochondria and carried to sites of energy consumption (e.g., myofibrils or ion channels) as phosphocreatine (PCr) through diffusion. Phorphorus-31 MRS assesses energy metabolism and thus the integrity of cellular function by quantifying the ratio of PCr to ATP. MRS is currently limited by the low signal-to-noise ratio caused by low

concentration of the high-energy phosphate molecules resulting in a limited sensitivity in detecting viable myocardium beyond the anterior left ventricle. However, ^{1}H MRS has up to 20-fold improved sensitivity than ^{31}P MRS and thus can quantify both phosphorylated and unphosphorylated creatine in any part of the left ventricle. Myocardial triglyceride, quantified by ^{1}H MRS, increased with an increasing amount of hepatic fat and visceral adiposity and has been associated with subtle systolic LV dysfunction.[51]

Molecular CMR Imaging

Molecular CMR imaging can theoretically provide dramatic improvement of sensitivity and specificity of disease detection by characterizing cellular process and allowing preclinical disease detection. Gadolinium chelates combined with a fibrin-specific peptide ligand can detect thrombi in the left atrium and coronary stents under experimental conditions. Other examples include the use of nanoparticles to target the adhesion molecule αvβ3-integrin as a marker of angiogenesis in atherosclerosis, USPIO particles to detect macrophages in inflamed carotid plaques, and tracking of intramyocardial transplanted mesenchymal stem cells in experimental infarction. Hyperpolarization results in a substantially increased signal that overcomes the sensitivity limitations of some multinuclear CMR applications. When combined with the metabolic tracers [$^{1\text{-}13}$C] and [$^{2\text{-}13}$C] pyruvate, this has resulted in unparalleled real-time imaging of myocardial substrate metabolism in vivo.[52]

Future Perspectives

Further technological advances in CMR will likely focus on improving the study throughput, protocol consistency, and patient tolerability. Combining rapid data collection using parallel imaging and better surface coil designs can eliminate the need for patient breath-holding and reduce CMR scan time. As a result, time-resolved techniques such as cine imaging may be replaced by real-time imaging. Data undersampling from parallel imaging leads to a reduction of signal-to-noise ratio, but three-dimensional pulse sequence and increased field strength at 3 T compensate for the signal/noise loss and are already in selected clinical use, replacing some two-dimensional methods (**Fig. 17.19** and Video 17.15). Automated motion correction reduces blurring from cardiac motions and has become standard in many pulse sequences because it not only improves qualitative visual displays, but also facilitates quantitative measurements. Semiautomated cardiac localization and scanning algorithms have been developed to reduce the time required in training physicians and technologists. New contrast agents hold promise in improving the assessment of myocardial or vascular physiology. For example, blood pool contrast agents may improve delineation of coronary stenosis by whole-heart coronary MRA and assessment of myocardial perfusion. Further development is needed in interventional instrumentation and MRI hardware, but CMR-guided interventions, especially for electrophysiologic applications, hold promise in improving ablative procedures.

Cardiac Computed Tomography

James K. Min

Since the advent of computed tomography (CT) by Sir Godfrey Hounsfield in 1971, technological advances of CT systems have generated vast improvements in the detection and exclusion of anatomic and physiologic pathology in virtually all body systems. One such improvement was the 64–detector row CT scanner in 2005, which afforded the necessary temporal and spatial resolution for capturing almost

motion-free studies of the heart and coronary arteries that, when coupled with adequate volume coverage, reduced breath-hold times such that a cardiac CT study was achievable by most patients. In the last decade, further iterative improvements in CT have been introduced, which allow for comprehensive assessment of coronary and cardiac structure and function. This chapter provides an overview of the applications of CT for such indications.

Basics of Cardiac and Coronary Computed Tomography

At its core, CT is a relatively simple imaging modality that consists of an x-ray tube that emits photons directionally toward a patient, with photon attenuation occurring as a likelihood function of differential organ-specific densities within a patient (**Fig. 18.1**) (see Classic References, Kalender). These differences result in higher tissue densities generating higher attenuation coefficients, whereas higher photon energies will result in lower attenuation coefficients. In short, the combination of organ density and photon energy determines the number of photons that pass through a patient, which can then be quantified by a series of detector arrays located 180 degrees across from the x-ray tube. After being struck by photons, a scintillation reaction occurs at the level of the detector that encourages light formation from x-rays. The resultant scintillation pattern becomes digitized to a string of binary numbers that can be reconstructed to two-dimensional (2D) and three-dimensional (3D) images and that may be visualized for medical use on an imaging computer workstation. To enable 3D imaging, x-rays must be emitted from a series of angles. At a minimum, a 180-degree rotation of the gantry with x-ray emission is required to generate a 3D image, a process known as *half-scan integral reconstruction.* Important for optimal image generation are the CT *tube potential,* measured in kilovolt peaks (kVp), and *photon counts,* measured in milliamperes (mA). Higher tube potential (kVp) allows for greater tissue penetration, whereas higher photon count (mA) increases the total number of photons that ultimately reach the detector elements. Both higher kVp and higher mA increase the radiation dose associated with cardiac CT imaging.

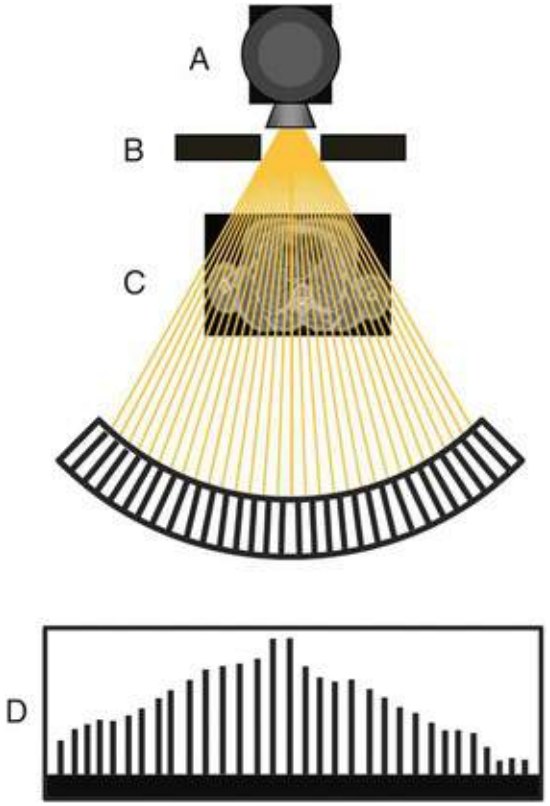

FIGURE 18.1 Computed tomography (CT) imaging requires an x-ray source (*A*) that directs photons past a collimator (*B*). Photons are attenuated by organs in a differential pattern related to their material densities. Photons not attenuated reach multiple detectors (*C*) at which a scintillation reaction occurs. At each detector, a photon flux is generated that is a product of the number of photons emitted from the x-ray tube (milliamperes, mA), the photon energy (kilovolts, kV), and the organ tissue properties. These are calculated for every detector element (*D*).

Three elements are required for acquisition of high-fidelity cardiac and coronary CT images: spatial resolution, temporal resolution, and volume coverage. When released, 64–detector row scanners across vendor platforms were generally similar, with in-plane (*x* and *y* directions) resolution of 0.5 to 0.8 mm, temporal resolution of approximately 160 to 220 milliseconds for 180-degree rotation of the gantry, and 2 to 3 cm of volume coverage. This corresponds to a spatial resolution approximately two to four times lower and a temporal resolution approximately four times worse than cineangiography (**see Chapter 20**). Since the introduction of 64–detector row CT scanners, spatial resolution, temporal resolution, and volume coverage have been improved individually across different vendor platforms, although a CT scanner that integrates all three advancements into a single scanner is currently lacking.

Spatial resolution, which depends on both the size of the detector elements and the material properties of the detector, has been improved by addressing the latter. Exchanging traditional CT detector materials made of gadolinium oxysulfate with garnet and phosphor elements, typically used in surgical lasers and xenon automobile headlights, improves spatial resolution to approximately 230-micron (μ) in-plane resolution. This is achieved by two basic advantages: improvements in the primary speed of the scintillation reaction and reduction of the "afterglow," or the recovery time of the scintillation response, which reduces light artifacts.

Temporal resolution improvements have been achieved by improved gantry rotational speed, dual-source CT (DSCT) scanning, and combined image- and projection-based solutions for motion correction. Improved gantry rotational speeds have resulted in half-scan temporal resolution to 100 to 140 milliseconds. In addition to a faster gantry rotation, DSCT scanners now effectively allow for image acquisition at twice the speed of single-source CT scanners. DSCT scanners comprise two x-ray sources and two detector arrays that are 90 degrees perpendicular to one another. By this method, gantry rotation

needs to occur only through one-fourth (rather than one-half) the gantry revolution to generate a 3D image, and this method has achieved temporal resolution rates as low as 67 milliseconds. Software-based postprocessing techniques for selective reduction of coronary motion, also known as intracycle motion correction algorithms, are used to correct coronary motion artifacts by exploiting the trajectory data across time and "backtracking" to create motion-free images.

Improvements in volume coverage by imaging greater lengths in the *z* axis, or craniocaudal direction, have been achieved by increases in the number of detector rows. This has been termed *volumetric* CT imaging, because with enough detector elements to cover its entire length, the heart can be imaged in a single gantry rotation in less than 1 second. At present, 320– and even 640–detector row CT scanners are now available for commercial use.

New Technologies

In addition to the CT hardware improvements previously described, other advances allow for enhanced CT image acquisition and reconstruction parameters. *Iterative reconstruction* (IR) has been introduced as an improvement over traditional filtered backprojection (FBP) methods used in CT and employs system statistics to reconstruct high-quality, noise-reduced images. Compared to FBP, an inverse method of image reconstruction, IR methods attain images by iterative forward steps, a method dependent on intense computational power.[1] IR improves image quality by accentuating signal-to-noise (SNR) and contrast-to-noise (CNR) ratios without increased radiation. An IR image can be acquired at a much lower radiation dose and can still achieve similar quality to images reconstructed by FBP.

Dual-energy computed tomography (DECT) techniques have also been recently introduced to improve material discrimination. This method acquires simultaneous, or near-simultaneous, imaging at a low and high kVp.[2] The use of widely disparate energies allows for harnessing two polychromatic spectra (e.g., 80 and 140 kVp) to discriminate between the material densities of two basic materials by examining their attenuation characteristics at different x-ray energies. Methods of DECT acquisition have used DSCT (one detector array offering a low-energy spectra and the other a high-energy spectra), fast kVp switching (with microsecond changes in polychromatic spectra from low and high kVp), and energy-dependent dual detectors. From each of these methods, tissues can be reconstructed into a single monochromatic energy (in kiloelectron volts, keV), which may be used to improve current coronary and cardiac imaging interpretation. For example, the use of a monochromatic single energy, such as 40 keV, is closer to the k-edge of iodinated contrast, enabling a higher signal that cannot be achieved by traditional polychromatic spectral single-energy CT imaging, potentially allowing for more accurate assessment of contrast-enhanced structures (e.g., coronary arteries). In addition, two materials that have sufficient differences in their attenuation patterns, iodinate and water, can be fully separated for absolute quantification of their material properties, unlike the relative separation of attenuation densities conferred by single-energy CT. Absolute quantification of material densities allows any given material to be "subtracted" from an image. One potential application of this is myocardial perfusion, in which contrast enhancement of the heart may exhibit different kinetic uptake in normal, ischemic, and infarcted myocardium. Because most tissues, including the myocardium, are composed primarily of water, reconstruction of water-free images from DECT will allow for absolute quantification of iodinated contrast and, in theory, absolute quantification of myocardial perfusion.

Image Acquisition Optimization

Prior to scanning, proper patient preparation is essential to a high-quality cardiac CT scan.[3] With the

constant movement of the heart and coronary arteries, coupled with the fixed temporal resolution of the CT scanner, a low heart rate permits less motion contamination of images, which improves diagnostic interpretation. Most often, beta-blocking agents such as metoprolol or atenolol are used. In our laboratory, metoprolol is given by both oral and intravenous (IV) administration. On the night before the CT, metoprolol is administered in oral form. At the CT scan, IV metoprolol is administered for "rescue" in individuals with heart rates greater than 65 beats/min. In my experience the use of other heart rate–lowering agents, such as calcium channel blockers, are generally ineffective in further lowering heart rate in individuals not reacting to metoprolol. A newer sinoatrial nodal–blocking agent, ivabradine, has been used with moderate efficacy in heart rate lowering.[4] Recommendations to abstain from caffeine and nicotine in the hours before CT scanning are also prudent.

Because the opacification of the coronary arteries requires the administration of contrast, any contraindication to iodinated contrast should be carefully ascertained. These include chronic kidney disease, elevated serum creatinine levels, and increased risk of contrast-induced nephropathy (CIN). Even among individuals not at risk of CIN, it is generally common practice to encourage ample hydration after CT scanning.

Other patient-specific factors that may degrade CT image quality include very high levels of coronary artery calcium (CAC), which can obfuscate visualization of the coronary arteries because of the "blooming," or partial volume, effects of highly attenuating structures such as calcium. Some laboratories refrain from cardiac CT if a greatly elevated CAC level is noted, although with the aforementioned improvements in CT technology, this practice is less common. To maximize visualization of the coronary artery lumen, 0.4 to 0.8 mg of sublingual nitroglycerin is often administrated for its coronary vasodilatory effects at CT scanning. Contraindications to nitroglycerin administration include low blood pressure or use of phosphodiesterase inhibitors (e.g., sildenafil, tadalafil) within 48 hours of CT scanning.

Electrocardiographic Gating Techniques

Electrocardiographic (ECG) gating is a requirement for cardiac CT scanning to allow for functional assessment of the heart, as well as image acquisition at a motion-free period within the cardiac cycle that optimizes visualization of the coronary arteries.[5] Traditionally, two ECG gating techniques have been applied to cardiac CT for synchronization of image acquisition to the proper phase of the cardiac cycle: retrospective helical gating and prospective axial triggering (**Fig. 18.2**). *Retrospective gating* allows for redundant imaging of the structure of interest. For cardiac CT imaging, this offers two advantages. First, the continuous overlapping sample of data enables gap-free imaging. Second, because this method is performed by continual scanning through the cardiac cycle, it allows four-dimensional (4D) imaging for volumetric assessment of heart motion over time. A disadvantage of retrospective gating is that it requires a generally low scan *pitch*, defined by the table feed per gantry rotation divided by the volume coverage in the *z* axis, which significantly increases the radiation dose of the examination.

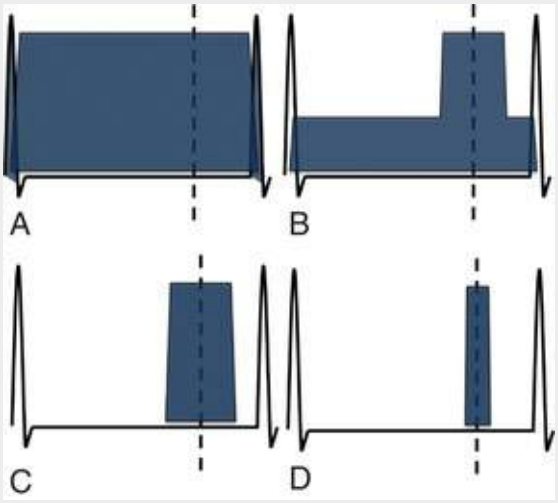

FIGURE 18.2 Electrocardiographic (ECG) gating of coronary CT angiography (CCTA). **A,** Retrospective helical acquisition imparts radiation (*dark area*) at a constant dose during the entire R-R interval. **B,** Retrospective helical gating with dose modulation imparts radiation throughout the cardiac cycle but reduces radiation doses during systole. **C,** Prospective ECG triggering is an axial imaging method that imparts radiation only during diastole, where motion-free coronary imaging is most often identified. **D,** Prospective ECG triggering with a narrow window imparts radiation at a single point within diastole. Prospective ECG triggering methods are associated with an 80% reduction in CCTA radiation dose.

In contrast to retrospective gating, *prospective triggering* allows for selective radiation exposure during only a brief period of the cardiac cycle. This technique images the heart during the mid-diastolic phase of the cardiac cycle, at a point when coronary motion is generally the least. In this mode, image acquisition relies on the prior R-R interval to estimate the present R-R diastolic period for scanning; thus, images are acquired every other heartbeat. Historically, this mode has been called “step and shoot” because the CT scanner table will move, and the image acquisition will then occur with no overlap. The advantage of prospective triggering is the profound reduction in radiation dose, which is 80% lower than that of retrospective gating methods. A disadvantage of this technique is the loss of 4D data. Importantly, for patients with higher heart rates, prospective triggering is often avoided, given the lower rate of coronary quiescence in the diastolic period. For these patients, retrospective gating techniques are more useful for evaluating the coronary arteries at every phase of the cardiac cycle, including the end-systolic period, another common period of coronary stillness.

A third method of ECG-gated CT scanning, known as *fast-pitch* (high-pitch) *helical scanning*, has been recently introduced on DSCT scanners. Historically, the pitch for cardiac CT imaging has ranged between 0.15 and 0.3, which results in high radiation dose because of overlapping image acquisition of body structures. In contrast, high-pitch helical scanning uses a very fast table movement, which allows for helical imaging of the *z* axis of the heart (i.e., direction of table movement) without overlap and thus rapid scanning at very low radiation dose. The rapid movement of the table enables cardiac CT imaging within a single heartbeat.

Image Interpretation

Once acquired, cardiac CT images can be viewed and interpreted in a variety of ways, including axial methods, oblique methods, multiplanar reformats, maximum and minimum intensity projections, and volume-rendered viewing (**Fig. 18.3**). Before 3D reconstruction methods, CT images were evaluated solely on *axial* imaging, with each image viewed in sequence of acquisition in the *z* axis. In cardiac imaging the heart is not typically located in the axial plane, and 3D oblique views are often constructed to align the heart for optimal viewing. Similarly, the coronary arteries are often tortuous and unaligned to the

axial plane. One technique to visualize the coronary arteries comprehensively is a *multiplanar reformat* technique that combines the multiple planes of the coronary artery into a single view that allows visualization of the entire artery in a single image. This technique helps to identify the spatial relationship of coronary stenoses or atherosclerosis within any given vessel and is particularly useful for coronary CT scans when the degree of stenosis is unclear in oblique images, for coronary stent assessment, and for very calcified coronary artery segments. *Volume-rendered* images depict structures in a surface-shaded view using 3D data in a cartesian manner where scalar values are assigned to points in the image space. Volume-rendered images are less often used for diagnostic purposes but can be useful when spatial orientations are important, such as for coronary artery anomalies, coronary artery bypass graft (CABG), and complex congenital heart disease.

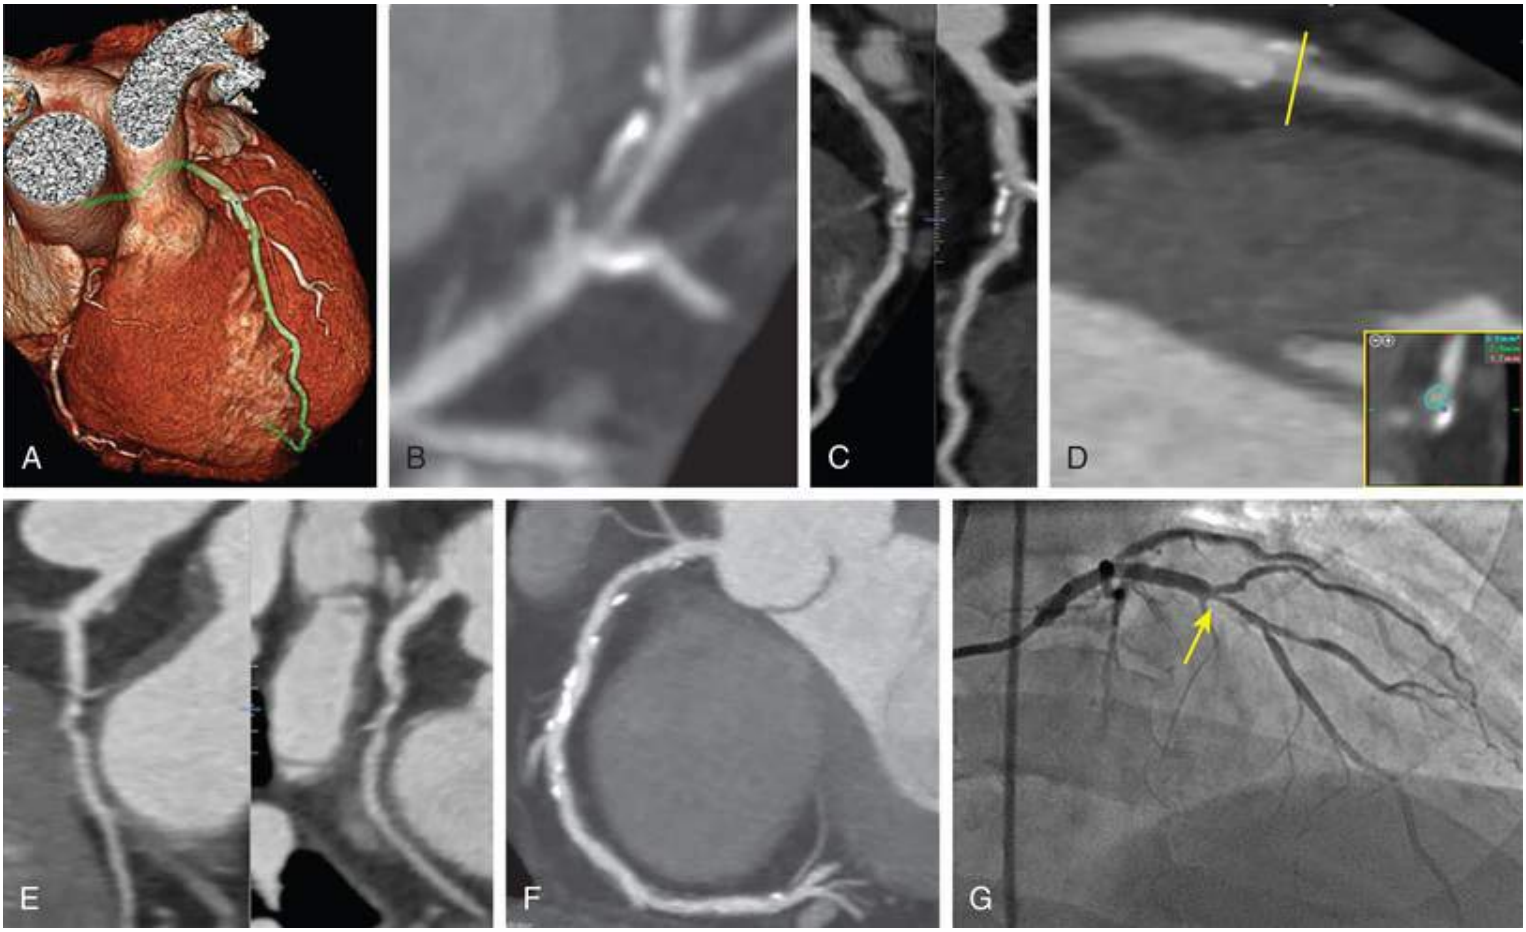

FIGURE 18.3 Common image postprocessing techniques for CCTA. Beyond 2D axial images, CCTA allows for 3D visualization of the coronary arteries by a number of different postprocessing formats. **A,** Cartesian view can be seen in a surface-shaded display of the volume-rendered technique. The left anterior descending artery can be visualized by **B,** maximum intensity projection (MIP) view; **C,** two curved multiplanar reformat views 180 degrees from each other to enable whole-vessel imaging; and **D,** curved multiplanar reformat view with orthogonal cross section of the vessel (*yellow line, inset*). **E,** The left circumflex artery in this patient is viewed in curved multiplanar format, whereas **F,** the right coronary artery is visualized as an oblique MIP. **G,** The corresponding invasive coronary angiogram confirms the high-grade stenosis visualized by the CCTA (*yellow arrow*).

Although high spatial resolution is valuable for detecting fine structures such as a coronary stenosis in a small artery, it is often so fine as not to allow concurrent visualization of a sufficient volume of data of the coronary artery to render an accurate diagnosis. To address this, a common technique is a “thin” maximum intensity projection (MIP) view of 3 to 5 mm. This postprocessing technique is done by increasing the thickness of the observed image by combining multiple 3D pixels, or *voxels*, of data into a larger single

cube. Within this larger cube, the most intense attenuation, or the “brightest” voxel, would be projected as the attenuation density of the entire cube. While commonly used for coronary artery visualization, the MIP technique can lead to diagnostic errors because it can obfuscate lower-attenuation-density materials, such as noncalcified coronary artery atherosclerosis. Similar to the generation of MIP, one can reconstruct cubic data as averages (AverageIP) as well as minimum attenuations (MinIP). The latter is particularly useful when trying to visualize data that are less bright than the iodinated contrast used in the examination. For example, in cardiac valve imaging, MinIP allows for accentuation of the valve structures.

Patient Safety

One major concern of cardiac CT imaging has been the effective dose of radiation required.[6] Potential harm from radiation can be considered in the type of risk it confers, which can be either deterministic or stochastic. *Deterministic risk* is a threshold measure, above which harm can occur and below which it does not. An example of a deterministic risk is a skin burn, which can occur at very high radiation doses. In contrast, *stochastic risk*—a concern expressed for cardiac CT imaging—is the potential of radiation to increase risk at any level of exposure. Potential future fatal and nonfatal cancer development is the primary concern of the stochastic risk of radiation, and approaches to reduce radiation to as low as reasonably achievable (ALARA) are considered highly important in cardiac CT imaging.

The units of measurement of radiation in cardiac CT imaging have varied.[6] On any given CT scanner, measures of radiation are often reported as the *dose-length product* (DLP) or the *CT dose index* (CTDI). The latter is a measurement of the total radiation dose absorbed by a patient's body and is typically reported in gray (Gy) or radiation absorbed dose (rad) units. In contrast, the DLP represents the CTDI multiplied by the scan length, reported as Gy × cm or rad × cm. In the literature, radiation from cardiac CT has usually been reported as the *effective dose*, measured in sieverts (Sv). This unit represents the biologic effects of imparted radiation weighted relative to the organ that is exposed to radiation. For cardiac CT scans, the organ weight used is from the thoracic density weight conversion constant of 0.014, with cardiac CT radiation calculated as DLP × 0.014.

At its introduction, 64–detector row cardiac scanning was associated with high radiation doses and with high variability among practice sites. From large-scale studies during the early period of cardiac CT, radiation doses were as high as 20 millisieverts (mSv).[6] These doses contrast unfavorably with the average annual background radiation dose experienced by an individual living at sea level, which is approximately 3 mSv and occurs primarily from radon exposure. Since 2005, advances in cardiac CT imaging have significantly reduced radiation doses,[5] including the following:

1. ECG dose modulation for retrospective helical scanning, in which full radiation doses are imparted only during diastole, with lower radiation doses throughout the remainder of the cardiac cycle
2. Prospective axial triggering, which constrains radiation exposure to only a short period during diastole and imparts no additional radiation throughout the remainder of the cardiac cycle
3. Reduction of the “padding” in prospective axial triggering, in which the heart is imaged at only a single point in diastole (rather than a range)
4. Minimization of the *z* axis only to the field of view of the heart
5. Reduction of tube current to reduce exposure to the total number of x-ray photons
6. Reduction of tube voltage, using lower kVp (e.g., 100 or 80)
7. Increasing scan pitch to avoid overlapping images, as done for high-pitch helical techniques

8. Applying IR techniques to achieve similar image quality to FBP methods while using lower radiation doses

Collectively, these techniques allow for significantly reduced radiation doses, with recent reports demonstrating the feasibility of cardiac CT imaging with less than 1 mSv radiation. In clinical practice, routine imaging using these methods can reliably reproduce radiation doses less than 3 mSv.

CIN is a serious complication in patients with preexisting kidney disease or those at risk for kidney disease. In two large single-center studies, 0.2% and 1.75% patients experienced CIN, defined by a greater than 25% increase in serum creatinine. For both of these studies, no requirement for hemodialysis was required.[7,8]

In addition to the heart, cardiac CT scanning also images portions of the thoracic cavity, which may result in the identification of important (or potentially irrelevant) noncardiac imaging findings (**Table 18.1**). A recent meta-analysis of 19 studies that included 12,922 patients found the pooled prevalence of incidental findings was 13%. There was large interstudy variability in these findings, and no outcomes were reported.[9] Whether these findings should be routinely reported remains unclear. To reduce the number of incidental findings, many cardiac CT laboratories have narrowed the visualized field of view (FOV) to limit evaluation to only the heart and its immediately adjacent structures. It is important to note, however, that the *direct* FOV in this case is not the same as the *scanned* FOV, which includes all structures that pass through the CT gantry. Thus, although the remaining thoracic cavity may not be reconstructed for cardiac CT image evaluation purposes, it has nevertheless been scanned and is able to be reconstructed. Future studies are required to determine the optimal approach to image reconstruction and reporting of incidental findings.

Coronary Artery Calcium Scoring

History and Overview

Before the advent of multidetector row CT (MDCT) scanners, electron beam CT (EBCT) scanners offered another method for cardiac evaluation. These CT scanners achieved 40-millisecond temporal resolution, image acquisition speeds similar to cine-angiography and significantly faster than current MDCT scanners. However, spatial resolution of EBCT scanners was 2 to 3 mm, which did not provide adequate characterization of the coronary arteries. Therefore, EBCT scanners have become largely extinct. In 1990, Agatston and Janowitz first demonstrated the use of ECBT scanners for the quantification of coronary artery calcium, extending the importance of the CAC concept to define coronary artery disease (CAD) risk, as previously observed using x-ray fluoroscopy (see Classic References). CAC findings on cardiac CT have been shown to be a strong, reliable marker of coronary atherosclerosis. In a study of coronary specimens imaged by CAC scanning and subject to histopathologic analysis, CAC on CT correlated strongly to the overall atherosclerotic plaque area. CAC represented one fifth of the overall plaque burden and demonstrated high linear correlation to the square root of the sum of pathologic plaque areas ($r = 0.90$; $P < 0.001$) (see Classic References, Rumberger). In this regard, it is often suggested that CAC may be a more sensitive and specific determinant of CAD risk than traditional CAD risk factors that may both over- and underdiagnose manifest coronary atherosclerosis.

CAC scanning is a non–contrast-enhanced image acquisition technique that is performed during a single breath-hold. Current guidelines recommend prospective ECG-triggered scanning from the bifurcation of the main pulmonary artery to the apex of the heart, with a 2.5- to 3-mm slice thickness and a tube voltage 120 kVp. No beta blockade is required, and the scan time is 3 to 5 seconds.[10] Both MDCT and EBCT scanners allow for adequate CAC scoring, although MDCT CAC imaging is the predominant method for contemporary CAC testing.

To date, almost every large-scale clinical study evaluating the clinical utility of CAC has relied on the *Agatston score,* which quantifies CAC as a function of CAC surface area and density (**Fig. 18.4**). This weighted sum of CAC is defined by areas within coronary arteries with Hounsfield unit (HU) values greater than 130 comprising three or more adjacent pixels. Each calcified voxel is then multiplied by a weighting factor from 0 to 4 based on the maximum HU within the calcified area. Standardized CAC categories have been established based on prior studies, and it is generally agreed that a CAC score of 0 indicates the absence of calcified plaque and that scores of 1 to 10, 11 to 100, 101 to 400, and greater than 400 indicate minimal, mildly elevated, moderately elevated, and severely elevated CAC level, respectively. In some studies a CAC score of 300 or greater has been used as an alternative threshold to describe severely elevated CAC level. Alternative scores, such as the volume score and mass score, have been proposed to reduce interstudy and interscanner variability but lack the prognostic evidence of the Agatston score for translation into clinical practice and are not typically reported[11,12] (see Classic References, Callister).

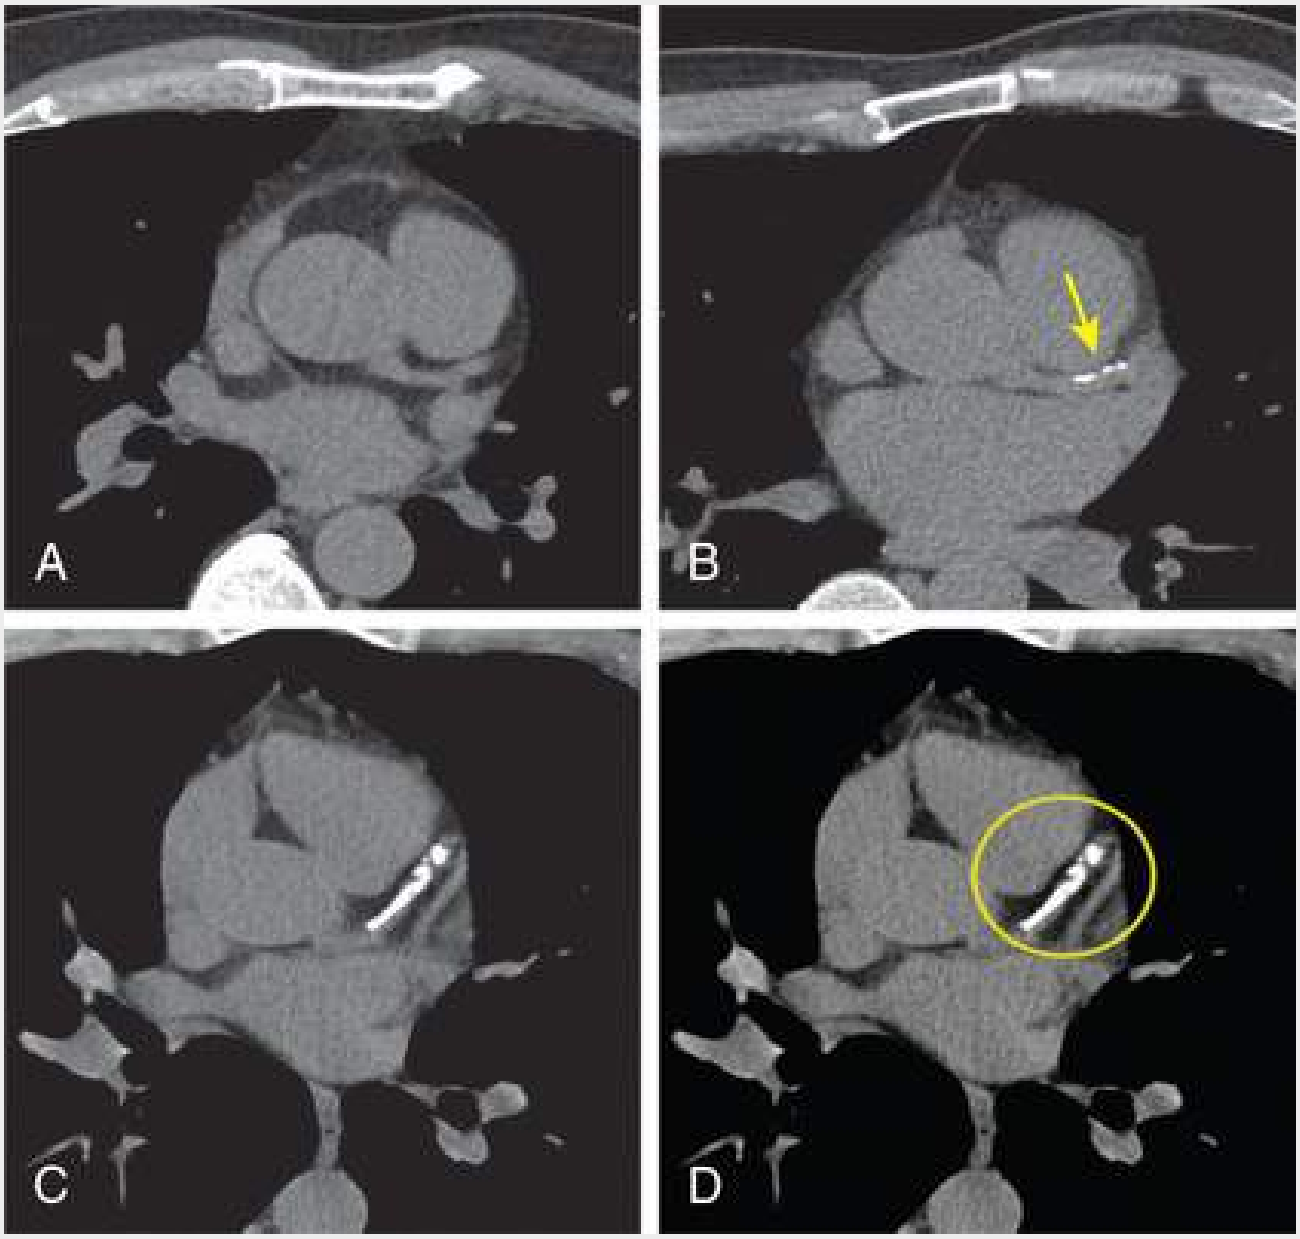

FIGURE 18.4 Examples of coronary artery calcium (CAC) imaging. Representative axial slices of a CAC CT scan demonstrate **A,** no evident calcium; **B,** mild coronary calcium; and **C,** severe coronary calcium. **D,** Method of quantification of the Agatston CAC score, in which the surface area of the coronary calcium is multiplied by the Hounsfield unit (HU) density conversion factor: a value of 1 = 139 to 199 HU, 2 = 200 to 299 HU, 3 = 300 to 399 HUs, and 4 = >400 HU.

Prognostic Implications

The prognostic value of CAC has been demonstrated consistently across many cohorts worldwide, most notably in the Multi-Ethnic Study of Atherosclerosis (MESA), a population-based prospective cohort study of asymptomatic U.S. adults. Risk of incident adverse events for individuals with a CAC score of 0 was very low, with a major adverse cardiovascular event (MACE) rate of 0.5% over 4 years. However, higher levels of CAC showed a correspondingly higher risk of MACE; patients with a CAC score of 400 or higher experienced events more than 10% of the time, a rate exceeding the traditional definitions of a "coronary heart disease equivalent."[13] This prognostic value of CAC is incremental to clinical CAD risk factors, increasing the discrimination of future adverse clinical events (area under the receiver operating characteristic [ROC] curve 0.77 versus 0.82; $P < 0.001$).[14] The MESA study demonstrated higher CAC in Caucasians and Hispanics, male sex, and advancing age and also importantly provided population-based reference standards by which individual scores may be compared.[15] A CAC score greater than the 75th

percentile for age, sex, and ethnicity may be considered “high risk,” irrespective of the absolute score; however, the prognostic value of the absolute CAC score demonstrates uniformity across ethnic groups and by sex, and thus it has been suggested that absolute CAC rather than CAC percentiles be used for prediction of events.[13,16] The Heinz-Nixdorf Recall study similarly showed in an older population-based cohort that the upper quartile of CAC had an event rate 11.1 times that of the lowest quartile in men and 3.2 times that of the lowest quartile in women ($P < 0.01$ for both).[17]

In evaluating individuals without evident CAC, a long-term “warranty period” appears to be present. In a single-center study, 422 individuals with a baseline CAC score of 0 underwent annual CAC for 5 consecutive years and were compared to a matched cohort of 621 individuals with a baseline CAC greater than 0. In those without CAC, conversion to CAC greater than 0 occurred in 25% at an average of 4 years, suggesting no need for repeat imaging until at least this point. Evaluation of the matched cohort with CAC at baseline demonstrated CAC greater than 0 to be the strongest predictor of CAC progression (hazard ratio [HR] >12).[18] The slow conversion of 0 score to a CAC greater than 0 appears to translate to predictability of clinical outcomes. In a large study of 4864 participants with a baseline CAC of 0, the warranty period, defined by less than 1% mortality per year, extended to 15 years for individuals at low and intermediate risk for CAD events, as defined by the National Cholesterol Education Program and Adult Treatment Panel III (NCEP/ATP IIII) risk categories, regardless of age or sex. For individuals considered at high clinical risk, the warranty period extended only to 5 years and was 14 years for individuals older than 60[19] (**Fig. 18.5**).

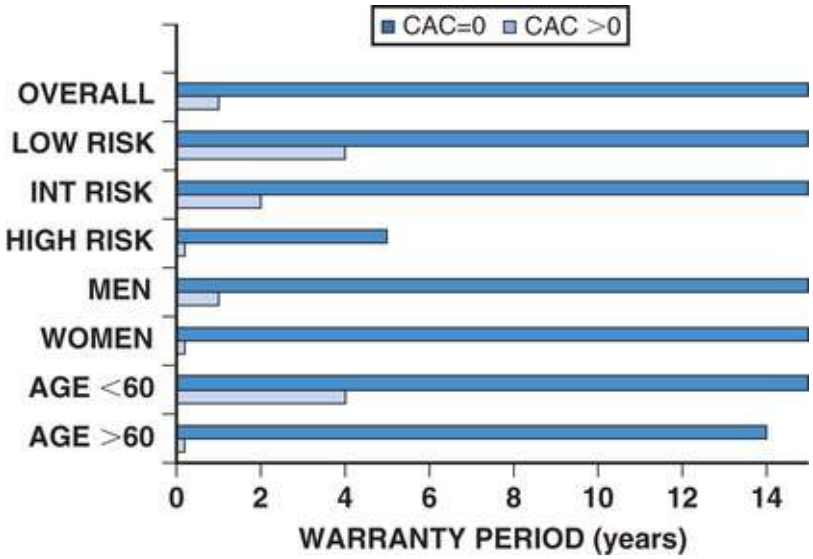

FIGURE 18.5 “Warranty” period of normal coronary artery calcium (CAC) study. Comparison of warranty period of individuals with (*dark blue*) versus without (*light blue*) CAC, as defined by a <1% annual mortality rate in 9715 individuals undergoing CAC scoring. *INT,* Intermediate. (Modified from Valenti V, O'Hartaigh B, Heo R, et al. A15-year warranty period for asymptomatic individuals without coronary artery calcium: a prospective follow-up of 9,715 individuals. JACC Cardiovasc Imaging 2015;8:900-9.)

In addition to improving prognostication and discrimination of risk, as evaluated by ROC curves, CAC improves accurate risk reclassification beyond risk scoring alone, either with older risk scores such as the Framingham Risk Score (FRS) or newer ones such as the American College of Cardiology and American Heart Association (ACC/AHA) 2013 Guideline Pooled Cohorts Equation.[14,20] Most notably, in the intermediate-risk population, CAC correctly reclassifies risk estimates from 52% to 66%, with less impact on the high- and low-risk groups.[17] Compared with other risk markers, such as brachial flow–mediated dilation, carotid intimal-media thickness, high-sensitivity C-reactive protein (CRP), and family

history, CAC provides superior discrimination and risk classification for CAD events.[21]

Notably, CAC is a measure of not only coronary atherosclerotic burden but also overall vascular atherosclerotic burden. In this regard, CAC is useful to predict cerebrovascular disease events. In the MESA study, among participants followed for almost 10 years, CAC was an independent predictor of cerebrovascular risk, even after accounting for traditional cerebrovascular disease events, and improved discrimination as well.[22] CAC is also associated with other adverse future clinical events, including atrial fibrillation, cancer, stroke, and congestive heart failure.[22-26]

One notable finding of CAC is the relationship of CAC density and incident risk. In a MESA analysis of 3398 patients followed for almost 8 years, the log-normalized CAC volume score was highly predictive for incident CAD events. However, higher CAC density demonstrated a protective influence, with CAC density scores associated with lower CAD risk. These contemporary data suggest that the integrated metric of the surface area and density of calcium, as is the case for the Agatston CAC score and for which higher density results in higher CAC scores, may require reexamination in prognostic studies.[27]

Although the negative predictive value of a CAC score of 0 has been consistently demonstrated with an event rate in asymptomatic patients, with an annualized event rate of 0.5% over 5 years in recent meta-analyses, it should not be considered similarly in symptomatic patients.[28] Recent data from the multinational CONFIRM registry showed that 4% of symptomatic patients with CAC of 0 had obstructive CAD of 50% stenosis or more, and CAC offered no incremental discriminatory utility above CCTA. Similarly, in the ROMICAT study, a CAC of 0 in acute chest pain patients did not adequately exclude acute coronary syndrome.[29,30]

The role of serial imaging of CAC is not well defined. Although progression of CAC is associated with an increased risk for future CAD events, prior studies have revealed no effect on CAC by statin treatment, thus raising the question of what information a follow-up CAC scan will offer[31] (see Classic References, Callister). In addition, the proper therapeutic course of action remains to be definitively determined for CAC visualized on noncardiac CT scans. CAC is frequently observed on myocardial perfusion imaging (MPI) as part of the attenuation correction scan (**see Chapter 16**). Although the likelihood of ischemic MPI is more than 2% with CAC less than 100, risk for future adverse events increases with higher CAC scores, and more than one third of patients with CAC greater than 400 have an abnormal MPI.[32,33] Similarly, CAC visualized on screening CT images for lung cancer also portend adverse prognosis, although no study to date has evaluated the effect of treatment of this CAC.

Clinical Trials and Professional Guidelines

To date, no adequately powered randomized clinical trial has been performed to assess the effects of a CAC-guided strategy compared to a clinical risk factor–guided strategy for event-free survival. Two prospective randomized trials provide new information on the potential effects of CAC treatment. In the St. Francis Heart Study, 1005 patients with CAC greater than 80th percentile were randomized to atorvastatin (20 mg), vitamin C (1 g), and vitamin E (1000 units) daily and compared to those receiving placebo.[34] At a 4.3-year follow-up, no differences were observed in the composite cardiovascular disease (CVD) endpoint (6.9% versus 9.9%; $P = 0.08$). Notably, for patients with a baseline CAC score greater than 400, there was a significantly lower event rate (8.7% versus 15.0%; $P = 0.046$). These study results, in the context of the new 2013 ACC/AHA cholesterol and risk guidelines, require updating with the more contemporary approaches to treatment.

In the single-center Early Identification of Subclinical Atherosclerosis by Noninvasive Imaging

Research (EISNER) study of 2137 volunteers randomized to CAC scoring versus no CAC scoring, those receiving CAC scoring experienced near-complete cessation of FRS progression compared to those not receiving CAC scoring (**Fig. 18.6**). This cessation of FRS progression resulted from achieving lower systolic blood pressure, low-density lipoprotein (LDL) levels, abdominal girth, and weight. In an economic analysis, the CAC group experienced similar costs and medical testing as those not undergoing CAC scanning.[35,36]

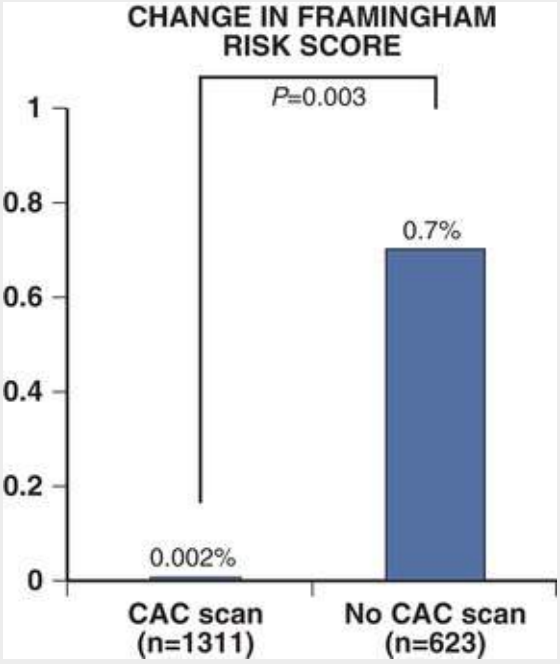

FIGURE 18.6 Primary outcome of randomized open-label EISNER trial of individuals who underwent coronary artery calcium (CAC) scanning versus those who did not. Framingham risk scores for individuals undergoing CAC scans (*left*) were unchanged over the 4-year follow-up period, whereas individuals who did not undergo CAC scan (*right*) experienced progression of Framingham risk scores. CAC scans were associated with improvement in systolic and diastolic blood pressure ($P < 0.001$), low-density lipoprotein level ($P < 0.001$), and reduced body weight ($P < 0.001$). (From Rozanski A, Gransar H, Shaw LJ, et al. Impact of coronary artery calcium scanning on coronary risk factors and downstream testing the EISNER (Early Identification of Subclinical Atherosclerosis by Noninvasive Imaging Research) prospective randomized trial. J Am Coll Cardiol 2011;57:1622-32.)

The 2013 ACC/AHA cholesterol and risk guidelines utilizing the new pooled cohort equations dramatically increased the number of people recommended to receive statins[37] (**see Chapter 45**). CAC evaluation is a class IIB recommendation for performance that is reserved for adults age 40 to 75 with no atherosclerotic cardiovascular disease, LDL of 70 to 189 mg/dL, and 10-year cardiovascular disease risk less than 7.5%. Among this population, CAC of 300 or more or 75th or greater percentile for age, sex, and ethnicity may be considered with other high-risk markers for determining the need for statins.[38] In the 2013 ACC multimodality imaging appropriate use criteria (AUC; see end of chapter), CAC scoring is considered inappropriate for performance in asymptomatic patients with low global CAD risk and may be appropriate in those with intermediate to high global CAD risk.[39] Application of these criteria to population-based CAC cohorts reveals that among intermediate-risk patients who would be considered appropriate for CAC scanning in the MESA study, 57% had a CAC of 0, with an atherosclerotic CVD event rate of 1.5 per 1000 person-years. However, among statin-recommended patients who would not have been considered appropriate for CAC evaluation by guidelines, 41% had CAC of 0, with only 5.2 CVD events per 1000 person-years, far below their risk estimate by the pooled cohort equations.[24] Among adults with CVD risk less than 7.5%, the number needed for screening to identify a statin-eligible

candidate was 14.7, superior to other high-risk measures (e.g., high-sensitivity CRP and ankle-brachial index).[40] Similarly, among statin-eligible patients in the Framingham Heart Study, a CAC = 0 identifies one-third of them as low-risk patients with a CVD rate of 1.6% over 9.4 years.[41]

Randomized controlled trials (RCTs) using CAC, informed by current guidelines and the AUC, will be needed to determine the appropriate patient population and follow-up treatment strategy that may benefit from CAC screening.

Coronary Computed Tomographic Angiography

Diagnostic Accuracy

Since its introduction, the primary interest in the clinical use of coronary CT angiography (CCTA) has been as a noninvasive alternative to coronary angiography (**Fig. 18.7**). An array of single-center studies and three prospective multicenter studies evaluated the diagnostic performance of CCTA, primarily compared to an invasive coronary angiography (ICA) reference standard (**Table 18.2**). Of the three multicenter studies, with a CAD prevalence of 25% to 68%, the Assessment by Coronary Computed Tomographic Angiography of Individuals Undergoing Invasive Coronary Angiography (ACCURACY) trial[42] and the study by Meijboom and colleagues[43] enrolled only patients without known CAD, observing a sensitivity of 95% and 99% and specificity of 83% and 64%, respectively. In contrast, the Coronary Artery Evaluation Using 64-Row Multidetector Computed Tomography Angiography (CORE64) study enrolled a heterogeneous group of patients with and without known CAD with a CAC score less than 600, noting the sensitivity and specificity to be 85% and 90%, respectively.[44] Based on these results, it is usually noted that CCTA is an excellent imaging modality for the exclusion of CAD. Further, its specificity for detection of coronary artery stenosis is similar or superior to more traditional stress testing methods, with or without imaging (**see Chapters 13, 14, and 16**).

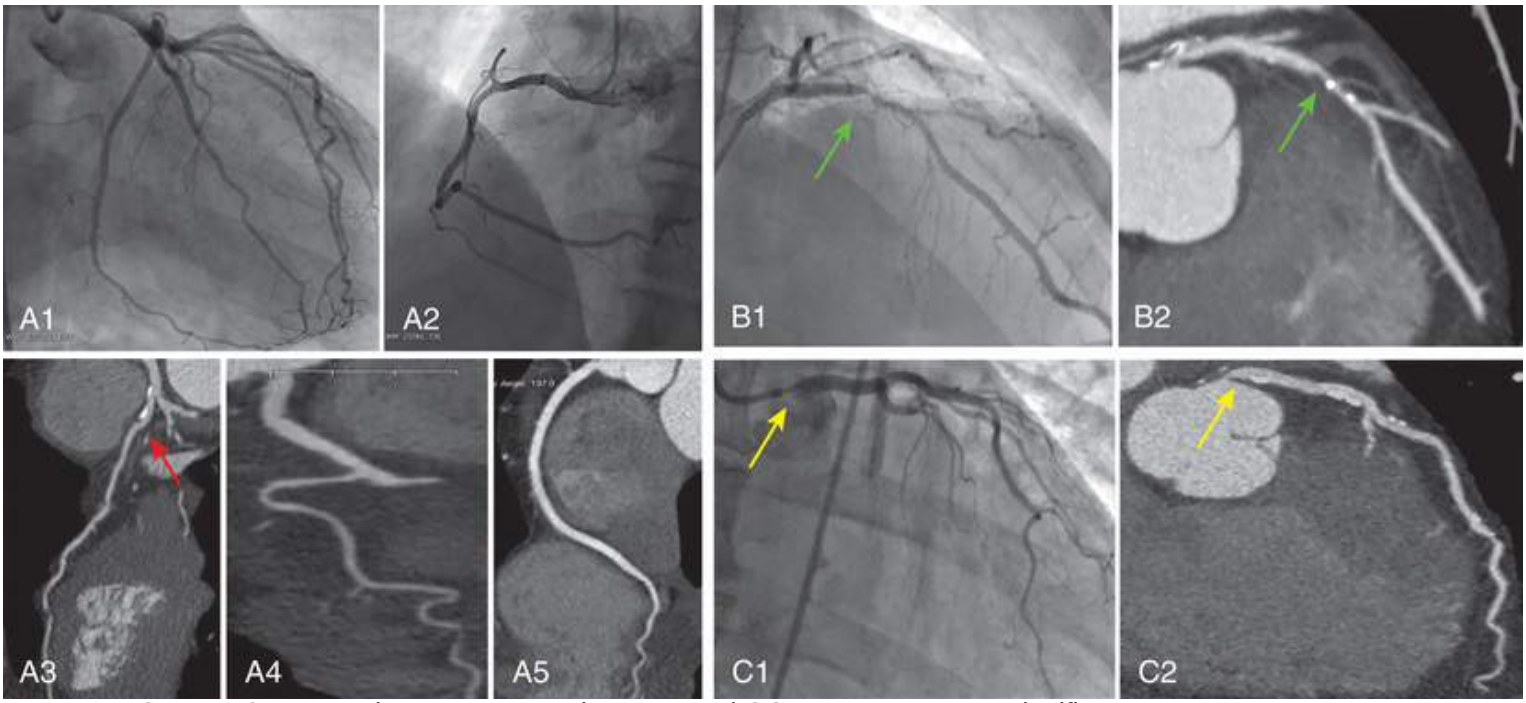

FIGURE 18.7 Invasive coronary angiograms and CCTAs: **A1** to **A5,** no significant coronary artery stenoses; **B1** and **B2,** moderate coronary artery stenosis; and **C1** and **C2,** severe coronary artery stenosis. **A1, A2,** Left and right invasive coronary angiograms demonstrate no significant stenosis. CCTA demonstrates mild, nonobstructive calcified plaque in the left anterior descending artery (LAD) **(A3)** (*red arrow*) and no stenosis in the left circumflex artery **(A4)** or right coronary artery **(A5).** Invasive angiogram of the LAD **(B1)** demonstrates moderate coronary stenosis in the midportion of the vessel, which is similar to the CCTA (*green arrows*) **(B2).** Left main artery angiogram reveals very-high-grade stenosis of the ostium **(C1),** which is identified also by the CCTA **(C2)** (*yellow arrows*).

With each improvement of CT technology, diagnostic performance of CCTA has been evaluated in smaller single-center studies of 30 to 160 patients. The sensitivity and specificity of CCTA versus ICA—both a per-patient and a per-vessel basis—have generally been observed to be higher than those using conventional 64–detector row CCTA, with both values generally above 90% (**Table 18.3**).

Studies directly comparing CCTA to traditional stress testing methods are less common but have been evaluated in a single, large-scale multicenter trial. Contemporary evidence to date suggests a value to CCTA over other imaging methods for the diagnosis of high-grade coronary stenoses. In the prospective multicenter Evaluation of Integrated Cardiac Imaging in Ischemic Heart Disease (EVINCI) study of 475 patients across several European centers, patients underwent CCTA, MPI by single-photon emission computed tomography (SPECT), or positron emission tomography (PET) and left ventricular wall motion analysis by stress echocardiography (SE) or cardiac magnetic resonance (CMR) imaging.[45] Significant CAD, as defined by greater than 70% luminal stenosis, was observed in 29% of patients. Among all the imaging modalities, CCTA demonstrated the highest diagnostic accuracy, with a sensitivity and specificity of 91% and 92%, respectively, and an area under ROC curve of 0.91. In contrast, MPI was observed to have a sensitivity and specificity of 74% and 73%, respectively, and area under ROC curve of 0.74. Wall motion analysis by SE or CMR demonstrated a higher specificity but lower sensitivity at 92% and 49%, respectively.

To date, no prospective multicenter study has been performed to evaluate the diagnostic performance of CCTA for in-stent restenosis (ISR) imaging, which may differ from native coronary artery examination due to the blooming artifacts of metallic stents that may preclude the ability to accurately assess the presence or absence of ISR (**Fig. 18.8**). It is commonly believed that stent size is the only factor that influences the visualization of stents by CCTA, but CT scan parameters and stent alloy type also play a significant role. Comparatively, current-generation drug-eluting stents are better visualized than older stents with different metallic makeup. Several meta-analyses report high diagnostic performance for stent imaging by CCTA, with sensitivity and specificity of 82% to 91% and 91% to 93%, respectively.[46-49] Notably, improvements in coronary stent technology may enhance the evolution of CCTA. Bioabsorbable drug-eluting vascular scaffolds comprised of poly-L-lactide and poly-D,L-lactide particularly accommodate CCTA visualization with little to no blooming artifacts. These revascularization methods, if

proven effective, may allow for more routine assessment of patency by CCTA.

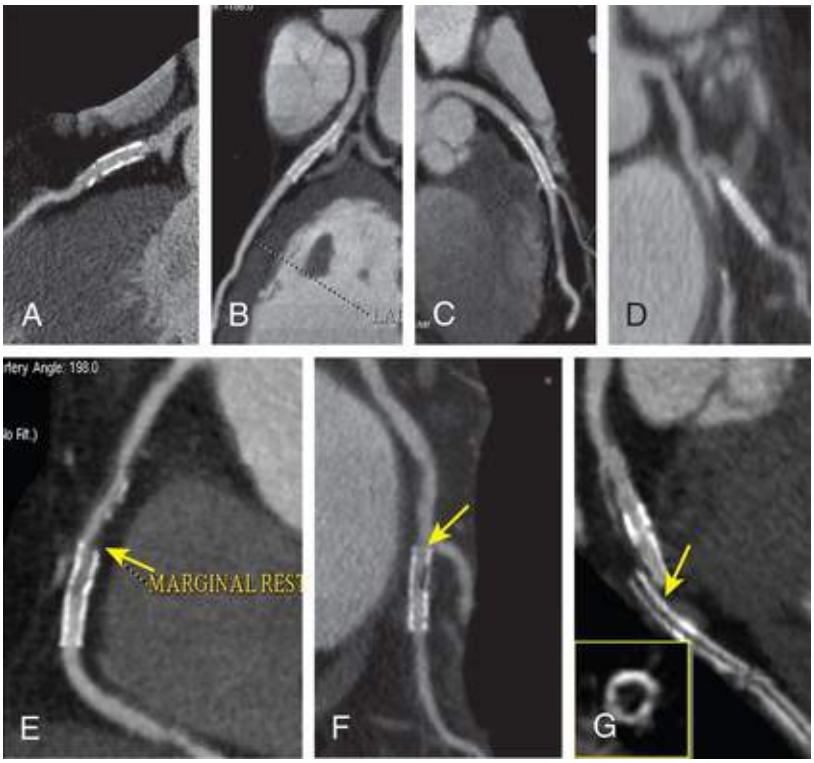

FIGURE 18.8 CCTA imaging of intracoronary stents: **A,** 4.0 mm; **B,** 3.5 mm; **C,** 3.0 mm; **D,** 2.25 mm. Note the smaller diameter of the 2.25-mm stent **(D)** exhibits "blooming" artifact that renders it difficult to visualize the coronary lumen within the stent. **E,** Mild; **F,** moderate; and **G,** severe in-stent restenosis (*yellow arrows*). In **G** there is malapposition of two stents, with a 100% occlusion of the stent (*yellow arrow, inset*).

Similarly, no large-scale trial has ever been conducted to examine the diagnostic performance of CCTA for evaluation CABG patency (**Fig. 18.9**). Contemporary studies evaluating CCTA have reported very high diagnostic accuracy for both stenosis and occlusion in CABGs. In a meta-analysis that combined the assessment of CABGs with stenosis and occlusion, sensitivity and specificity of CCTA was 96.1% and 96.3%, respectively.[50] In another study that separately categorized the two, CCTA demonstrated a sensitivity and specificity of 99% and 99%, respectively, for occlusion, and 98% and 98% for stenosis. Despite its high performance to identify and exclude CABG disease, such patients often have extensive native CAD. No study to date has evaluated the accuracy of CCTA for those undergoing CABG on a per-patient basis, in which the accuracy is evaluated for both CABG and native coronary arteries.

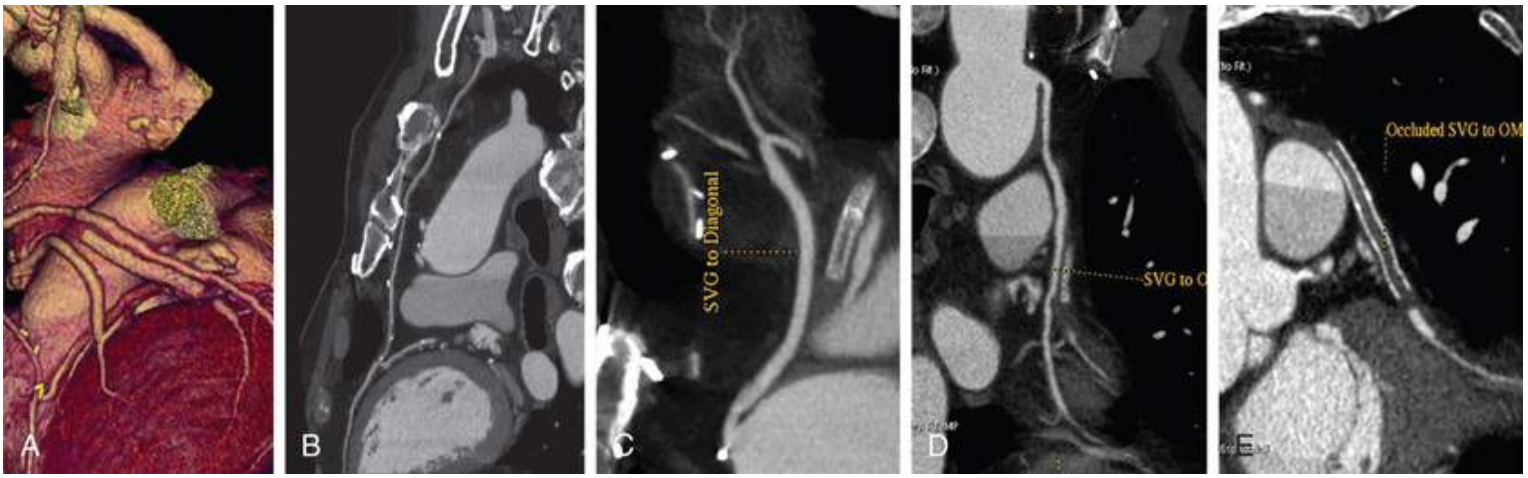

FIGURE 18.9 Patient with multiple coronary artery bypass grafts. **A,** The topology of the grafts can be appreciated well in a volume-rendered view. Curved reformat views demonstrate **B,** patency of left internal mammary artery graft to left anterior descending artery (LAD); **C,** patency of saphenous vein graft (SVG) to first diagonal branch of LAD; and **D,** patency of SVG to second obtuse marginal graft of left circumflex artery. **E,** Total occlusion of SVG to first obtuse marginal graft can be seen in the native graft as well as the portion of the graft containing a stent.

Prognostic Implications

Numerous potential coronary artery and cardiac characteristics observable by CCTA beyond luminal stenosis severity offer prognostic utility for risk stratification of patients with suspected CAD. These features include extent, severity, and location of CAD, as well as atherosclerosis measures of plaque composition, plaque burden, high-risk plaque features, and arterial remodeling.

To date, the largest study evaluating the prognostic value of these CAD findings is the Coronary CT Angiography Evaluation for Clinical Outcomes: an International Multicenter Registry (CONFIRM) study[51] (**eTable 18.1**). At its inception, this dynamic observational cohort study comprised 27,125 stable patients with suspected CAD who underwent CCTA and were followed for all-cause mortality, nonfatal myocardial infarction (MI), and other MACE events. The first published study from CONFIRM examined differences in all-cause mortality rates based on CCTA CAD findings, as stratified by single-, double-, and triple-vessel CAD.[52] In a 2.3-year follow-up, a 2.6-fold increased risk of death was observed for patients with any stenosis greater than 70%, as well as a 1.6-fold increased risk of death for those with milder stenoses (<50%). Increasing risk of mortality was observed for patients with greater numbers of coronary artery distribution involved for one-vessel (hazard ratio [HR] 2.00), two-vessel (HR 2.92), and three-vessel or left main CAD (HR 3.7) ($P < 0.01$ for all). A gender-CAD relationship was observed, with women experiencing greater risk of mortality than men for three-vessel CAD (HR 4.21 versus 3.27). Importantly, incident rates of all-cause death were very low in the absence of CAD by CCTA, with an annualized rate of 0.28%. Subsequent studies have validated this very low rate of events and suggest a warranty period of CCTA to extend beyond 5 years for patients with no evident stenosis or atherosclerosis by CCTA. These prognostic findings of CCTA have been subsequently evaluated within the CONFIRM study in many clinically important subgroups for both all-cause mortality and MACE, including for women and men, elderly patients, patients with a CAC score of 0, asymptomatic patients, diabetic patients, obese patients, patients of different ethnicities, individuals with no modifiable CAD risk factors, patients with impaired renal function, patients with low and high lifetime CAD risk, asymptomatic diabetic patients, patients with impaired left ventricular systolic function, smokers, patients with left coronary dominance, and patients with metabolic syndrome.[53-70] Beyond traditional statistical

techniques that employ logistic or linear regression methods, machine learning has now been employed to improve the prognostic ability of CCTA findings in CONFIRM.[71] Among 10,030 patients followed after CCTA for 5 years, boosting method–based machine learning proved superior to clinical- or clinical/image-based evaluation alone, demonstrating a higher area under the ROC curve of 0.61 and 0.64 and 0.79, respectively.

ETABLE 18.1

Prognostic Value of CAD Severity Assessed by CCTA in Various Population (CONFIRM Registry)

STUDY	POPULATION	SAMPLE SIZE (*n*)	CLINICAL OUTCOME	FOLLOW-UP PERIOD	STUDY OBJECTIVE	HAZARD RATIO (HR) BY CATEGORY	CLINICAL EVENT RATE	PRINCIPAL FINDING
Villines[53]	Symptomatic with no prior CAD	10,037	ACM, nonfatal MI and late revascularization	Median 2.1 years	Impact of CAD severity in patients with zero CACS	In patients with zero CACS Nonobstructive CAD: 1 Obstructive CAD: 5.7 (2.5-13.1)	Overall with zero CAC: 0.9% No CAD: 0.6% Nonobstructive CAD: 2.0% Obstructive CAD: 3.9%	In symptomatic patients with CACS zero, severity of CAD is associated with increased cardiovascular events
Chow[151]	No prior CAD, enable to assess FRS	14,064	ACM	Median 2.0 years	Impact of LVEF and CAD severity over FRS	No CAD: 1 Nonobstructive CAD: 2.8 (1.9-4.0) Obstructive CAD with nonhigh FRS: 3.3 (2.2-5.0) Obstructive CAD with high FRS: 4.9 LVEF<50%: 2.7 (2.1-3.5)	No CAD: 0.7% Nonobstructive CAD: 2.0% Obstructive CAD with nonhigh FRS: 3.0% Obstructive CAD with high FRS: 5.2% LVEF <50% : 4.8%	CCTA measures of CAD severity and LVEF have independent prognostic value
Min[51]	No prior CAD	24,775	ACM	Median 2.1 years	CAD severity by age and sex	No CAD: 1 Male vs. female 3-VD/LM: 3.27 (1.9-5.5) for male; 4.21 (2.5-7.2) for female: <65 vs. ≥65 3-VD/LM: 6.19 (3.4-11.2) for age <65 3.10 (1.9-4.9) for age ≥65	N/A	CAD severity by CCTA are associated with higher mortality rates, with risk profiles differing for age and sex
Rana[54]	Patients with and without diabetes	3370 vs. 6740 matched DM vs. non-DM	ACM	Median 2.2 years	CAD severity in DM patient	No CAD in non-DM: 1 In DM patients No CAD: 3.63 (1.7-7.9) Nonobstructive CAD: 5.25 (2.6-10.8) 1-VD: 6.39 (2.9-13.7) 2-VD: 12.33 (5.6-27.1) 3-VD: 13.25 (6.2-28.6)	DM patients: 3.2%, Non-DM patients: 1.7%	DM individuals experience higher risk of mortality compared with non-DM individuals
Cho[54]	Asymptomatic with no prior CAD	7590	ACM, nonfatal MI	Median 2 years	CAD severity in asymptomatic patients	No CAD: 1 Nonobstructive CAD: 1.7 1-VD: 2.1 2-VD: 5.9 3-VD or LM: 7.1	Overall rate: 2.2% No or nonobstructive CAD: 1.6% Obstructive CAD: 4.6%	Prognosis for asymptomatic individuals is stratified by CAD severity by CCTA
Labounty[59]	No prior CAD, enable to assess risk factors and BMI collected	16,291	ACM, nonfatal MI	Mean 2.4 years	ACM and MI event across 5 BMI categories (<20.0, 20.0-24.9, 25.0-29.9, 30.0-34.9, and ≥35 kg/m^2)	N/A	Annualized mortality event rate: <20.0: 1.2%; 20.0-24.9: 0.4%; 25.0-29.9: 0.4%; 30.0-34.9: 0.4%; ≥35: 0.4% Annualized mortality and MI rate: <20.0: 0.3%; 20.0-24.9: 0.3%;	A higher BMI is independently associated with increased risk of myocardial infarction

							25.0-29.9: 0.5%; 30.0-34.9: 0.7%; ≥35: 1.2%	
Min[55]	No prior CAD, enable to assess ICA or revascularization information	15,223	ACM	Median 2.1 years	ACM between medical therapy vs. coronary revascularization	Revascularization vs. medical therapy: In high-risk CAD: 0.4 (0.2-0.8) In low risk CAD: 3.2 (0.8-13.9)	In low risk of CAD: 0.97% for medical therapy, 2.06% for revascularization In high risk of CAD: 5.34% for medical therapy, 2.28% for revascularization	Coronary revascularization is associated with survival benefit in patients with high-risk CAD by CCTA, with no apparent benefit of revascularization in patients with low-risk CAD
Dwivedi[57]	Enable to assess creatinine value, LVEF assessment	5864	ACM	Median 1.6 years	ACM according to renal function	Impaired renal function: HR 2.3 (1.7-3.2) Obstructive CAD: HR 1.8 (1.3-2.5) Abnormal LVEF: 4.2 (2.5-7.1)	No CAD: 0.33% Nonobstructive disease: 1.82% Obstructive disease: 2.43%	CAD severity and LVEF by CCTA provide effective risk stratification across renal function
Hadamitzky[58]	Enable to assess plaque characteristics and risk factors	17,793	ACM	Median 2.3 year	Prognostic value of plaque composition and plaque location	Number of segment with any plaque: 1.2 (1.03-1.4) Number of segment with stenosis >50%: 1.2 (1.1-1.3) Number of segment with stenosis >70%: 1.3 (1.1-1.5) Number of proximal segment with calcified or mixed plaque: 1.4 (1.1-1.7) Number of proximal segment with stenosis: 1.5 (1.2-1.9)	N/A	Both plaque burden and stenosis, particularly in proximal segments, carry incremental prognostic value
Otaki[61]	Young patients (men age <55 and women age <65)	6308	ACM, nonfatal MI	Mean 2 years	ACM and MI event by family history in young patients	Without family history of CAD: 1 With family history of CAD: 2.6 (1.4-4.8)	Annual rate of MI Without family history of CAD: 0.2% With family history of CAD: 0.5%	Positive family history in young patients is strong clinical predictor of MI
Leipsic[60]	Exclude patients with modifiable risk factor	5262	ACM, nonfatal MI and late revascularization	Mean 2.3 years	CAD severity in patients with no medically modifiable risk factors	No CAD In symptomatic patients Obstructive CAD: 11.9 (4.8-29.6) In asymptomatic patients Obstructive CAD: 6.3 (2.4-16.7)	Overall without modifiable risk factor No CAD: 0.48% Nonobstructive CAD: 0.53% Obstructive CAD: 8.0%	Among individuals suspected of having CAD but without modifiable risk factors, CAD is significantly increased hazard for MACE and mortality
Hulten[152]	Patients with ethnicity data	16,451	ACM, nonfatal MI	Median 2.0 years	Impact of obstructive CAD for MACE according to ethnicity	Nonobstructive CAD: 1 Obstructive CAD: Caucasian: 2.8 (1.7-4.4) Africans: 6.3 (1.1-35.0) East Asians: 4.8 (2.2-10.9)	Annualized incidence of MACE Nonobstructive CAD Caucasian/Africans/East Asians: 0.7%/1.1%/0.1% Obstructive CAD Caucasian/Africans/East Asians: 2.2%/4.8%/0.8%	Presence and severity of CAD visualized by CCTA predict death or MI across 3 large ethnicities
Leipsic[64]	No prior CAD history, nonobstructive CAD	11,462	ACM, nonfatal MI	Mean 2.3 years	Gender difference MACE rate	No CAD: 1 Nonobstructive CAD Men: 1.8 (1.1-2.9) Women: 2.0 (1.2-3.3)	Annualized MI and death event rate MI rate: men, 0.2%; women, 0.2% ACM rate: men, 0.6%; women, 0.6%	Women and men experience comparable rates of incident mortality and MI in age, risk factor matched
Hulten[63]	Asymptomatic patients age 20-60 without diabetes or prior CAD	1863	ACM, nonfatal MI and late revascularization	Median 2.0 years	MACE by FRS and lifetime risk	N/A	Patients with low FRS Low lifetime risk: 0.32% High lifetime risk: 0.28%	Prognosis of MACE did not differ between low lifetime risk vs. high lifetime risk due to low number of

								events
Nakazato[66]	No prior CAD, enable to assess per-segment data	15,178	ACM, nonfatal MI and late revascularization	Median 2.1 years	CAD severity for MACE by age (<65 and ≥65)	<65 vs. ≥65 years No CAD in <65 years: 1 Nonobstructive CAD: 2.7 (1.8-4.0) vs. 6.2 (4.2-9.1) 1-VD: 11.4 (7.7-16.9) vs. 19.9 (13.6-29.1) 2-VD: 17.4 (10.9-27.9) vs. 36.1 (23.7-54.8) 3-VD or LM: 47.6 (28.5-79.7) vs. 48.1 (30.1-76.8)	N/A	Nonobstructive, and obstructive CAD are associated with higher MACE rates, with different risk profiles based on age
Min[65]	Asymptomatic diabetes with no prior CAD	400	ACM, nonfatal MI and late revascularization	Mean 2.4 years	CAD severity in asymptomatic DM patient	Per-patient maximal stenosis per grade: 1.8 (1.2-2.8) Number of obstructive vessels: 1.9 (1.3-2.7) Segment stenosis score: 1.1 (1.05-1.2)	33 MACE occurred (13 deaths, 8 MI, 12 revascularization) in asymptomatic DM patients: 8.25%, annualized rate 3.4%	CAD severity by CCTA associated with high MACE rate in asymptomatic DM patients
Arsanjani[62]	No prior CAD, enable to assess LVEF	7758	ACM	Mean 2.0 years	Impact of gradation measurement of LVEF	Normal LVEF: 1 45% ≤LVEF <55%: 1.4 (0.9-2.1) 35% ≤LVEF<45%: 3.14 (2.0-4.9) LVEF<35%: 5.2 (3.4-7.9)	Normal LVEF: 1.8% 45% ≤LVEF <55%: 2.9% 35% ≤LVEF <45%: 7.5% LVEF <35%: 12.8%	LV dysfunction and volumes measured with cardiac CT angiography augment risk prediction
Chow[68]	Nonobstructive CAD and no prior CAD and enable to assess medication history	10,418	ACM	Median 27months	Statin treatment and mortality event	Baseline statin treatment: Overall: 0.4 (0.3-0.7) Nonobstructive CAD: 0.3 (0.2-0.6) No CAD: 0.7 (0.3-1.4)	Nonobstructive CAD: Statin treatment: 1.0% Nonstatin treatment: 2.2% No CAD: Statin treatment: 0.6% Nonstatin treatment: 0.8%	Baseline statin therapy was associated with a significant reduction in mortality for individuals with nonobstructive CAD but not for individuals without CAD
Schulman-Marcus[153]	Patients with obstructive CAD by CCTA	1637	ACM, nonfatal MI	3 years	Effects of cardiac medication in patients with obstructive CAD	Cardiac medications Statin: 0.6 (0.4-0.9) Aspirin: 0.7 (0.5-1.1) Beta-blocker: 1.1 (0.7-1.6) ACE inhibitor: 1.4 (0.9-2.1)	N/A	In patients with obstructive CAD by CCTA, baseline use of statins was associated with improved clinical outcomes
Gebhard[69]	No prior CAD and enable to assess coronary dominance information	6382	ACM, nonfatal MI, and late revascularization	Median 2.1 years	Impact of coronary dominance for prognosis	Left dominance: 1 Right dominance: No CAD: 1.04 (0.7-1.6) Nonobstructive CAD: 1.0 (0.4-2.2) Obstructive CAD: 0.5 (0.2-1.3)	Cumulative event rate: Left dominant: 18.8% Right dominant: 19.1%	MACE did not differ significantly between patients with left or right coronary dominance.
Ahmadi[67]	Patients with metabolic syndrome	690	ACM, nonfatal MI and late revascularization	Median 2.5 years	Prognosis of CCTA in metabolic syndrome	Mortality event: 2.4 (1.2-4.7) MI: 0.8 (0.2-4.0) MACE 2.2 (1.3-3.7)	Metabolic syndrome: 1.9% No metabolic syndrome: 0.8%	Metabolic syndrome was associated with high incidence of MACE
Nakanishi[70]	No prior CAD with enable to assess smoking status	9456	ACM, nonfatal MI	Mean 2.8 years	Impact of current/past smoking for cardiac event	Never smoker: 1 Past smoker: 1.2 (0.8-1.6) Current smoker: 1.9 (1.4-2.6)	Never smoker: 2.8% Past smoker: 2.9% Current smoker: 4.8%	Compared with never smokers, higher MACE risk was observed only in current smokers, not past smokers
Cherubu[73]	Exclude patients with modifiable	1184	ACM, nonfatal MI and late	Mean 5.6 years	Long-term prognosis of CAD	No CAD: 1 Nonobstructive	No CAD: 5.6% Nonobstructive CAD:	CAD severity by CCTA provide long-

	risk factor		revascularization		severity in patients with no modifiable risk factors	CAD: 2.2 (1.3-3.7) Obstructive CAD: 6.6 (3.9-11.3)	13.2% Obstructive CAD: 36.3%	term (5-year) prognostic information in patients with no modifiable risk factors
Schulman-Marcus[154]	No prior CAD, enable to assess plaque severity information	5632	ACM, nonfatal MI	5 years	Sex difference in MACE risk and CAD severity	No CAD: 1 Nonobstructive CAD Men: 2.6 (1.6-4.0) Women: 2.2 (1.4-3.3) 1-VD Men: 2.7 (1.7-4.3) Women: 3.7 (2.4-5.8) 2-VD Men: 3.6 (2.2-5.8) Women: 3.9 (2.2-6.9) 3-VD/LM Men: 4.4 (2.7-7.2) Women: 5.9 (3.5-10.2)	N/A	There is no sex interaction for association between MACE risk and increased per-vessel extent of obstructive CAD
Blanke[155]	Patients with DM with no prior CAD	1823	ACM, nonfatal MI, and late revascularization	Mean 5.5 years	Long-term prognosis of CAD severity in DM patients	No CAD: 1 Nonobstructive CAD: 5.1 (2.9-8.9) 1-VD: 8.2 (4.6-14.5) 2-VD: 9.0 (4.8-17.1) 3-VD/LM: 24.8 (13.5-45.5)	Annualized MACE rate Overall DM patients: 6.8% No CAD: 1.3%	Among patients with DM, nonobstructive and obstructive CAD according to CCTA were associated with higher rates of MACE at 5 years

CCTA, Coronary CT angiography; *CAD,* coronary artery disease; *DM,* diabetes mellitus; *ACM,* all-cause mortality; *MI,* myocardial infarction; *MACE,* major adverse cardiovascular event; *LVEF,* left ventricular ejection fraction; *N/A,* nonapplicable; *VD,* vessel disease.

One potential benefit of CCTA imaging is its ability to discern nonobstructive CAD stenoses that can be present even in the setting of high overall atherosclerotic plaque burden. Prior studies have demonstrated that the majority of individuals experiencing their first unheralded MI do not in fact possess obstructive CAD stenosis. This was demonstrated first in a two-center prospective CCTA study of 2583 patients with suspected CAD.[72] At a 3.1-year follow-up, this population, limited only to those with maximum per-patient stenoses less than 50%, demonstrated differential outcomes based on the number of epicardial coronary artery distributions with any nonobstructive atherosclerosis, which were associated with a nearly twofold increased risk of mortality. A nearly fivefold increased risk of mortality was observed for individuals with nonobstructive CAD in all three epicardial vessel distributions.

One potential utility of CCTA is to identify at-risk individuals who do not meet conventional definitions as such by clinical risk scoring. In a 2.3-year follow-up study of 5262 patients without known CAD who were free from any modifiable CAD risk factor (e.g., smoking, hypertension, dyslipidemia, diabetes), the presence of any stenosis of 50% or more was associated with a 6.64-fold increase in the risk of MACE events, a finding independent of symptomatic state.[60] These findings persisted to almost 6 years, with increased mortality rates observed for individuals with one- or two-vessel obstructive CAD (HR 1.70) and three-vessel of left main CAD (HR 2.87).[73] Importantly, the presence of nonobstructive CAD alone was associated with increased risk of death in a manner similar to obstructive one- or two-vessel CAD (HR 1.73). Even among symptomatic individuals with a CAC score of 0, CCTA appears to offer incremental prognostic value for future mortality, nonfatal MI, or late coronary revascularization

more than 90 days after CCTA performance.[63] Among 8907 symptomatic patients undergoing both CCTA and CAC scoring, those with a CAC of 0 but a noncalcified plaque causing a 50% or greater stenosis experienced a more than fivefold increase in the rates of the composite endpoint.

Early reports of atherosclerosis findings were limited to classifications of noncalcified, calcified, and "mixed" plaques. In general, a cutoff point of 130 HU has been historically defined as calcified plaque, with values below this threshold interpreted as noncalcified plaque. Categorizations of noncalcified plaque can represent an admixture of fibrous, fibrofatty, and fatty plaques that, because of their significant overlap in HU by CCTA, are generally combined into a single group. Atherosclerotic plaques exhibiting a lower HU density (e.g., <70 HU) tend toward more lipoid plaques, with fibrous plaques manifesting higher HU densities (e.g., 70 to 130 HU). Recent studies have elicited some important imaging markers of atherosclerosis by CCTA based on HU densities that are associated with adverse clinical events and coronary ischemia.[74] More specifically, an atherosclerotic plaque with HU density less than 30 has been highly correlative on invasive ultrasound to plaques with lipid-laden necrotic cores found in "vulnerable" plaques.

In addition to atherosclerotic plaque composition, measures of arterial wall remodeling are quantifiable by CCTA. Similar to studies with intravascular ultrasound and histopathology, in which vulnerable plaques exhibit high rates of positive arterial remodeling, in an extreme compensatory response to CAD, the external elastic membrane area at the site of a coronary plaque is greater than that at an adjacent reference site (**see Chapter 44**). This ratio, when greater than 1.10, is generally considered positive remodeling. An additional atherosclerotic plaque feature on CCTA examined for its prognostic value is "spotty calcifications," defined as distinct calcifications 3 mm or less in length and circumscribing a 90-degree or less arc in cross section. This term, taken from the histopathology literature, is considered as the *microcalcifications* often present in a ruptured coronary artery. However, current-generation CT scanners do not have the spatial resolution to image these atherosclerotic characteristics, and thus the spotty calcifications on CT are actually *macrocalcifications*, and extrapolation of their findings to pathology-confirmed microcalcifications should be done with caution.

In the initial large-scale study evaluating the prognostic utility of atherosclerotic plaque characteristics, low-attenuation plaques with HU less than 30 and positive arterial remodeling were assessed for their ability to risk-stratify 1059 stable patients who underwent CCTA and were followed for acute coronary syndrome (ACS) occurrence to 27-month follow-up[75] (**Fig. 18.10**). Atherosclerotic plaques were categorized as having no high-risk features, one-feature positive, or two-feature positive plaques. Compared to patients with no high-risk features, significantly higher rates of ACS occurred in patients with one- and two-feature positive plaques (0.49% versus 3.7% versus 22.2%, respectively; $P < 0.001$). In a follow-up study of 3158 patients, CCTA-defined high-risk plaque was an independent predictor of future ACS incremental to high-grade stenosis.[76] In this study, for the 449 patients who underwent serial CCTA imaging, atherosclerotic plaque progression was also strongly associated with future ACS. These findings supporting the additive value of atherosclerotic plaque burden and plaque composition are also seen in patients presenting with non–ST-segment elevation MI (NSTEMI). In an evaluation of 312 patients presenting with NSTEMI or stable angina, lesions responsible for events demonstrated lower attenuation patterns by CCTA in those with NSTEMI.

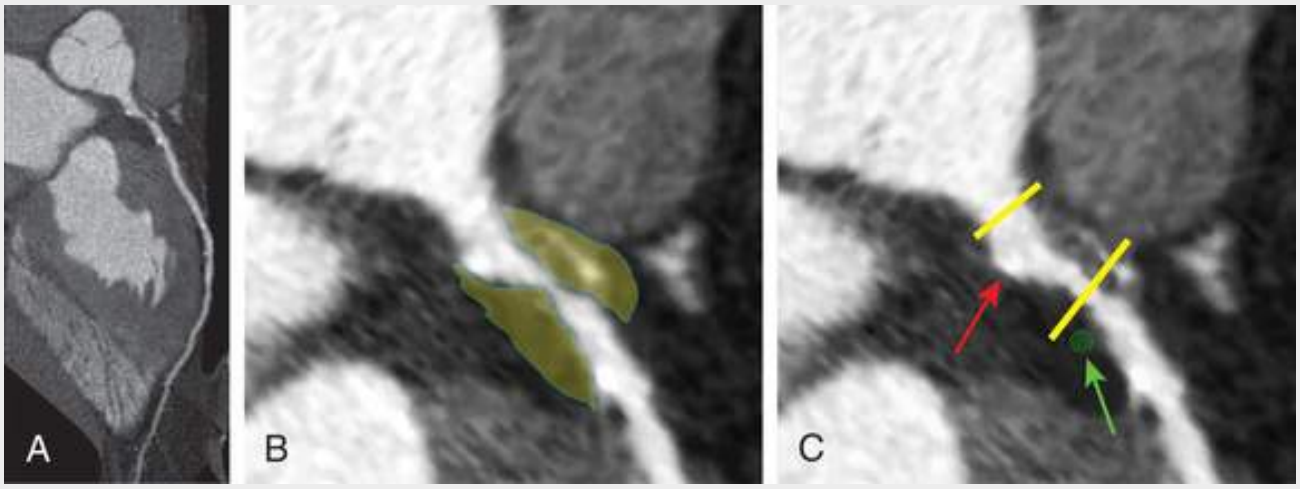

FIGURE 18.10 Atherosclerotic plaque that exhibits adverse plaque characteristics. **A,** Curved multiplanar reformat view demonstrates high-grade plaque in proximal portion of left anterior descending (LAD) artery, with smaller plaques in midportion of LAD. **B,** Close-up view reveals a stenosis with high atherosclerotic plaque burden. **C,** Three adverse plaque characteristics, including positive arterial remodeling *(yellow lines),* spotty calcifications *(red arrow),* and low attenuation plaque <30 Hounsfield units *(green arrow and circle)*. In this case the *remodeling index,* or the ratio between the external elastic membrane at the site of the greatest diameter within the stenosis to the external elastic membrane at the proximal reference vessel, is 1.14. A ratio >1.10 is considered positive arterial remodeling.

One potentially important clinical question arising from a normal CCTA without evidence of stenosis or atherosclerosis is its relatively benign nature. Prior studies have observed a very low risk of future mortality or MACE in individuals with normal CCTA. Annualized event rates have been reported at 0.01% to 0.24%.[77] These data emphasize the importance of the negative predictive value of CCTA not only to exclude the presence of CAD, but also to effectively rule out the risk of future events. At present, a normal CCTA appears to confer at least a 5-year warranty period. Given these propitious findings, prior studies have evaluated whether CCTA as a screening test offers incremental prognostic role over CAC in asymptomatic individuals. In a study of 7590 patients without chest pain syndrome who were followed for 24 months, CCTA added no prognostic value for future death or MACE (C-statistic, 0.75 versus 0.77), with no significant net reclassification of patients to higher or lower risk groups.[54] As such, routine performance of CCTA in asymptomatic individuals appears to have no tangible clinical benefit and, as per contemporary ACC multimodality imaging appropriate use criteria, should be avoided.[39]

In addition to native coronary artery findings, CCTA has also been evaluated for other cardiovascular findings that may offer incremental prognostic utility and that can be visualized on CCTA. Factors proven useful in this regard include determination of left ventricular systolic function and wall motion abnormalities, epicardial and pericardial adipose tissue, aortic calcifications, and nonalcoholic steatohepatitis.[62,78] Further, coronary findings include measures of plaque for prediction of no flow at the time of percutaneous intervention,[79] as well as future adverse event rates following CABG surgery.[80]

Relationship of Findings to Ischemia

A common question is to what degree CCTA findings coincide with coronary or myocardial ischemia. Traditional image-based decisions about coronary revascularization have relied heavily on “physiologic” measures of ischemia and blood flow, with prior studies suggesting that anatomic-based revascularization strategies do not affect event-free survival. CCTA has been compared to a host of physiologic stress tests, including SPECT, PET, and fractional flow reserve (FFR) for the correlation of anatomic stenoses to myocardial perfusion deficits (**see Chapters 16, 57, 61, and 62**). These studies have been generally small in sample size, 42 to 110 patients.[81-83] In the largest study comparing CCTA findings to rubidium-82

PET, CCTA was associated with myocardial perfusion defects, but only to a moderate degree. With worsening coronary stenosis on CCTA, as defined by less than 50%, 50% to 70%, and more than 70% stenosis, the positive predictive value (PPV) was only 29%, 44%, and 77%, respectively, at the per-patient level (**Fig. 18.11**). Conversely, the negative predictive value (NPV) to exclude myocardial ischemia was remarkably high, at 92%, 91%, and 88%, respectively. Similarly, using FFR in 79 patients with stable symptomatic CAD, CCTA showing 50% or more stenosis identified less than half of lesions that demonstrated coronary pressure differences.[84] The findings are generally consistent across studies and have raised the concern that CCTA findings will provoke higher rates of ICA and ad hoc coronary revascularization.

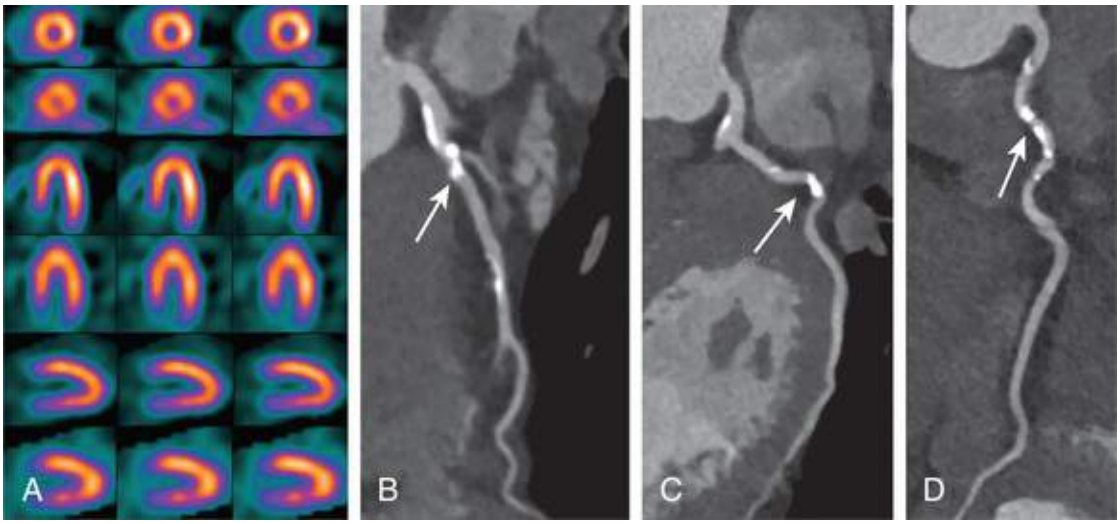

FIGURE 18.11 Example of discordance between physiologic and anatomic testing. **A,** Stress-rest single-photon emission computed tomography (SPECT) study of 66-year-old diabetic man with atypical chest pain shows no myocardial perfusion defect. During the stress test, patient exercised for 8 minutes and 30 seconds on Bruce treadmill protocol. CCTA demonstrates severe calcified plaque that precludes visualization of **B,** left anterior descending artery; **C,** left circumflex artery; and **D,** right coronary artery (*arrows*).

To offset the potential for increased rates of ICA, some have advocated for a hybrid approach in which CCTA is combined with SPECT, PET, or CT perfusion testing for improvements in identification of hemodynamically significant coronary artery stenoses.[85] One such method is the acquisition of CAC during SPECT or PET using information derived from the CT attenuation correction scans (**see Chapter 16**). This has proved useful in improving the sensitivity of SPECT (76% versus 86%) for identification of coronary stenoses, but had minimal effect on specificity (91% versus 86%).[86] Another hybrid method is simply to combine CCTA with SPECT.[82] This method has proved generally superior to the CAC approach whereby a hybrid approach was superior to SPECT for measures of specificity (53% versus 75%), with no decrement in sensitivity (95% versus 95%). Concerns remain for the routine use of the hybrid imaging approach that these procedures may increase radiation exposure to patients as well as potentially result in increased diagnostic workup costs.

Beyond simply luminal diameter stenosis, CCTA has also been evaluated for other measures of CAD to identify hemodynamically-significant CAD. In the Functional Imaging Criteria for Guiding Review of Invasive Coronary Angiography, Intravascular Ultrasound, and Coronary Computed Tomographic Angiography (FIGURE-OUT) study of 181 lesions of intermediate stenosis severity, minimum luminal area appeared to be superior to percent-diameter stenosis for identifying FFR-verified coronary ischemia (area under ROC curve, 0.712 versus 0.657).[87] Further, a recent prospective multicenter study of 252

patients from 17 centers evaluated the role of atherosclerotic plaque characteristics (APCs), including positive arterial remodeling (PR), low-attenuation plaque (LAP), and spotty calcifications (SC), for identification of ischemia-causing coronary artery lesions[88] (**Fig. 18.12**). A dose-response relationship was noted for increasing numbers of APCs and ischemia, with two or more APCs associated with a 12-fold increase in the rate of ischemia. This improvement for identification of ischemia existed only for PR (odds ratio [OR] 5.3) and LAP (OR 2.1), with no improvement noted for SC. Importantly, arteries exhibiting PR were useful for diagnosis of lesion-specific ischemia for stenoses of 50% or greater as well as 50% or less, the latter being present in almost 17% of ischemic lesions. One additional APC available by CCTA imaging is the percent aggregate plaque volume (%APV), which is the sum of the entire plaque volume within a vessel divided by the sum of the vessel volume from the artery ostium to the distal end of the coronary lesion. In a study of 58 lesions, %APV demonstrated high discriminatory capacity to identify vessel ischemia beyond traditional diameter stenosis alone (0.85 versus 0.68), with %APV enabling significant net reclassification over stenosis alone (net reclassification index [NRI] 0.77)[89] (**Fig. 18.13**).

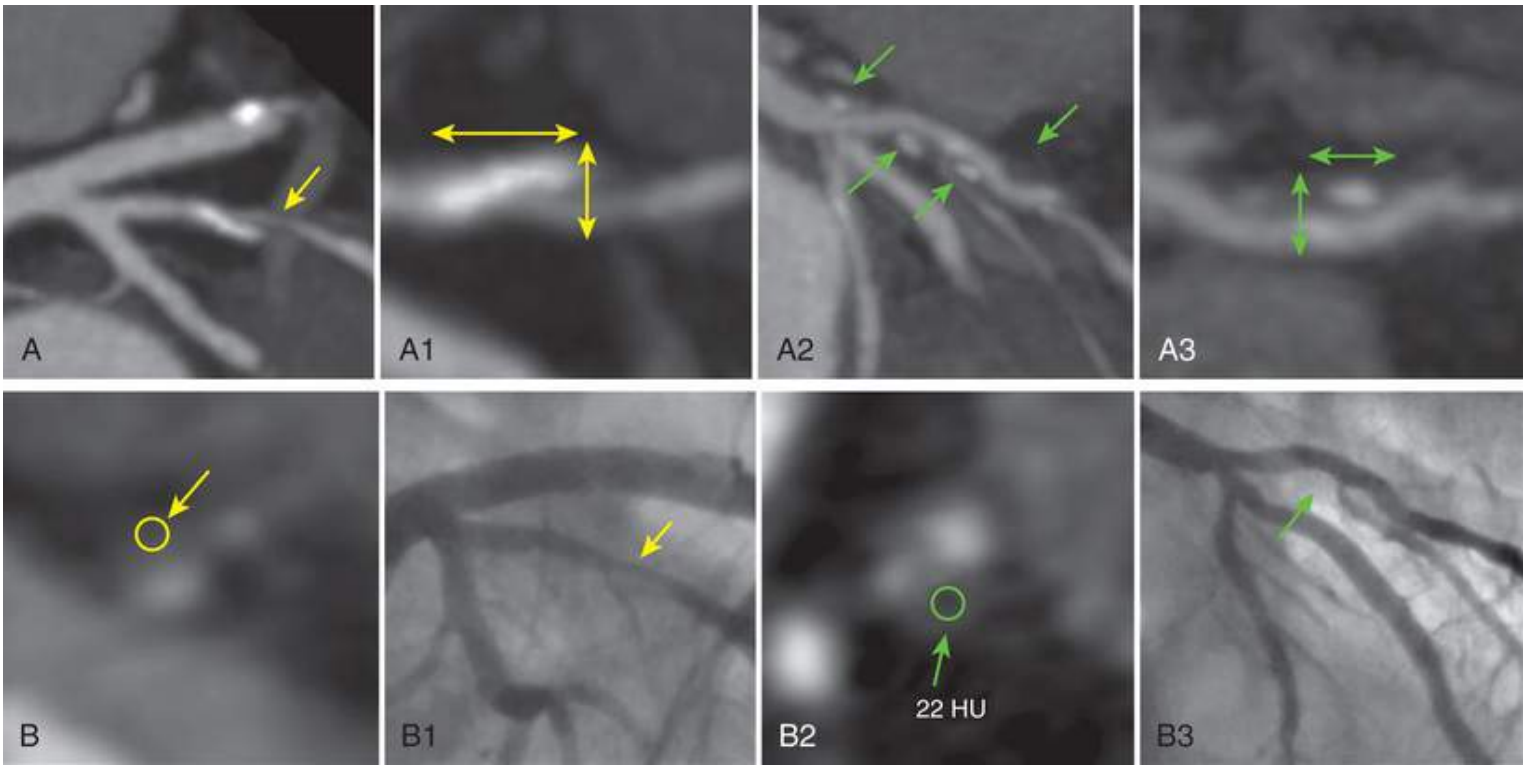

FIGURE 18.12 Relationship of atherosclerotic plaque characteristics (APCs) and coronary ischemia in two patients **(A, B)** undergoing CCTA, invasive coronary angiography (ICA), and atherosclerotic plaque evaluation. Patient **A** has high-grade stenosis from a single calcified plaque **(A1),** with no positive arterial remodeling **(A2)** and no low-attenuation plaque (Hounsfield unit [HU] density >30) **(A3).** Despite the severity of the stenosis confirmed by ICA, fractional flow reserve (FFR) demonstrates no ischemia with a value >0.80. In contrast, patient **B** demonstrates no significant stenosis but numerous atherosclerotic plaques with spotty calcifications **(B1)** that display positive arterial remodeling **(B2),** and low attenuation (HU <30) **(B3).** ICA confirms the absence of high-grade coronary stenoses. Despite this, coronary ischemia is present by an invasive FFR value of 0.76. (Modified from Park HB, Heo R, O'Hartaigh B et al. Atherosclerotic plaque characteristics by CT angiography identify coronary lesions that cause ischemia: a direct comparison to fractional flow reserve. JACC Cardiovasc Imaging 2015;8:1-10.)

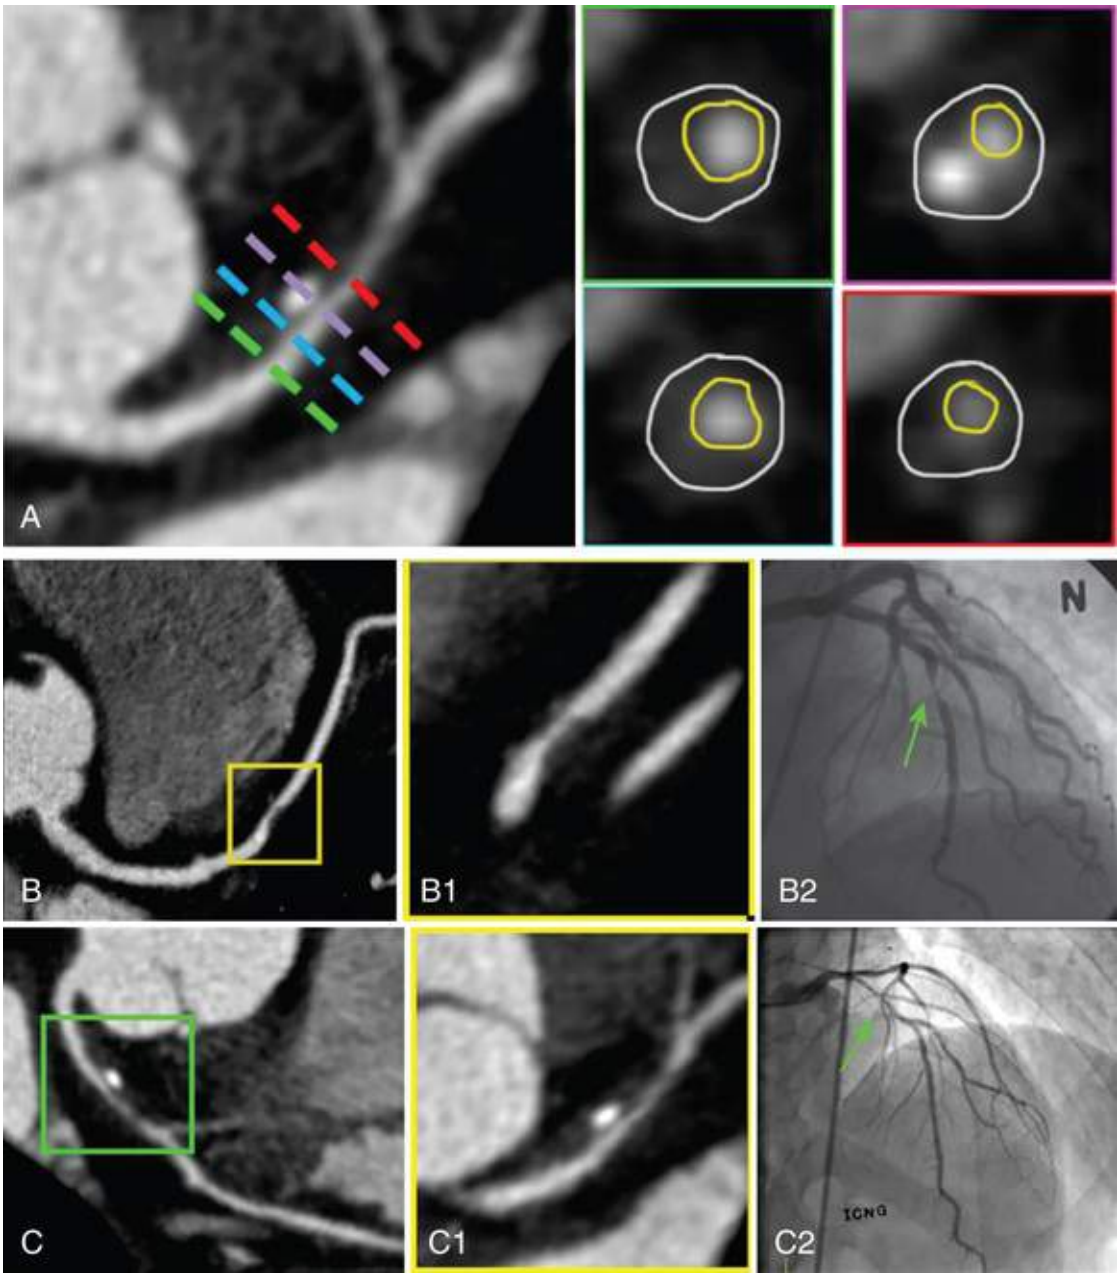

FIGURE 18.13 Relationship of aggregate plaque volume and coronary artery ischemia. **A,** Aggregate plaque volume percent (%APV) can be calculated by the ratio of the plaque area over the vessel area to the length of a coronary vessel; 1-mm cross-sectional areas are traced for vessel, lumen, and plaque areas. **B,** High-grade stenoses (*yellow box*) that are associated with low %APV **(B1)** are less likely to cause ischemia **(B2). C,** In contrast, stenoses (*green box*) that are associated with high %APV **(C1)** are more likely to produce ischemia **(C2)**. (Modified from Nakazato R, Shalev A, Doh JH, et al. Aggregate plaque volume by coronary computed tomography angiography is superior and incremental to luminal narrowing for diagnosis of ischemic lesions of intermediate stenosis severity. J Am Coll Cardiol 2013;62:460-7.)

Use in Patients with Acute Chest Pain

Each year, in the United States alone, almost 8 million patients present to the emergency department (ED) with complaints consistent with possible ACS, representing the second most common cause of ED visit.[90] This accounts for up to $15 billion of health care costs, although less than 1% of these patients are ultimately diagnosed with ACS. Workup patterns used at different medical centers include observational "chest pain" units, in-patient admission to exclude ACS by troponin markers, stress tests to diagnose hemodynamically significant CAD, and, most recently, CCTA to identify or exclude high-grade coronary stenoses.

A recent meta-analysis examined the relative diagnostic performance of CCTA versus other diagnostic

methods, including stress echocardiography and SPECT, when using ICA or ACS as a reference standard. In this analysis, CCTA demonstrated favorable diagnostic performance that was superior to stress echocardiography and SPECT (CT sensitivity/specificity, 95%/99%; stress echocardiography, 84%/94%; SPECT, 85%/86%).[91] Based on these favorable diagnostic findings, several observational cohort studies —both from research initiatives as well as site-specific clinical care—have attempted to determine the natural clinical outcomes of patients with low to intermediate acute chest pain (as defined primarily by the Thrombolysis in Myocardial Ischemia [TIMI] risk score) who present with suspected ACS.[90] In the largest observational study to date, the Rule-Out Myocardial Infarction Using Computed Assisted Tomography (ROMICAT), 368 patients with negative initial myocardial necrosis biomarkers and a nondynamic ECG underwent CCTA for diagnosis and exclusion of ACS.[92] In this population of individuals undergoing evaluation, 31 patients (8.4%) were diagnosed with ACS. CCTA identified approximately half these individuals as having no stenosis or atherosclerosis and 20% who had high-grade coronary stenosis. On discharge, none of those individuals without stenosis or atherosclerosis experienced ACS. Similarly, patients with nonobstructive CAD enjoyed a 98% NPV for ACS. In contrast, the PPV of CCTA for those with CCTA-identified obstructive coronary stenosis was only 35%, suggesting an overdiagnosis phenomenon in which CCTA may identify stenoses that are ultimately not the cause of the acute chest pain syndrome. In a low-risk population of 600 patients presenting with acute chest pain, more than four of five patients could be effectively discharged with a 30-day ACS rate of 0%.

Both these studies have raised concerns that the rates of ACS are low, and it remains unstudied whether less costly methods can be substituted for CCTA to achieve similar clinical outcomes. To assess this, several prospective randomized trials sought to determine the differential clinical and economic outcomes of a CCTA-based ACS evaluation versus the standard of care (**Table 18.4**). These trials differed in their inclusion criteria as well as mode of evaluation in the standard-of-care arms. In the ROMICAT II and CT Coronary Angiography Compared to Exercise ECG (CT-COMPARE) studies, low- to intermediate-risk patients were enrolled, whereas the American College of Radiology Imaging Network (ACRIN-PA) and Coronary Computed Tomographic Angiography for Systematic Triage of Acute Chest Pain Patients to Treatment (CT-STAT) studies enrolled low-risk patients.[93-96] Uniform to these trials was a high NPV for ACS that was safe (i.e., with few reported adverse cardiovascular outcomes in a follow-up of 30 days to 6 months). Other important clinical, workflow, and resource utilization parameters were evaluated, including time to diagnosis, length of stay, rates of ED discharge, total and ED costs, and rates of downstream ICA. In both ACRIN-PA and ROMICAT II trials, a CCTA-based strategy resulted in immediate discharge of approximately half of patients, which was approximately two to four times the rate of standard-of-care practice. Among these large-scale trials, only ROMICAT II observed no ED cost-savings, whereas the other studies observed a 15% to 38% reduction. These cost-savings were in part the result of shorter lengths of stay but were offset by higher rates of ICA and coronary revascularization. Consistently, the latter is observed and evokes unease about the potential for CCTA findings to provoke unnecessary procedures in these low-risk or low- to intermediate-risk individuals.

ECG, Electrocardiogram; *MPI,* stress myocardial perfusion imaging; *CCTA,* coronary computed tomographic angiography; *IQR,* interquartile range; *ED,* emergency department; *USD,* United States Dollars; *ACS,* acute coronary syndrome; *ICA,* invasive coronary angiography; *MACE,* major adverse cardiac events.

MACE definitions:

CT-STAT: ACS, cardiac death or revascularization 6 months in patients who had normal or near-normal index testing.

ROMICAT-II: death, myocardial infarction, unstable angina, or urgent coronary revascularization within 28 days.

ACRIN/PA: cardiac death or myocardial infarction within 30 days.

PROSPECT: all-cause death, myocardial infarction, cardiac arrest and cerebrovascular accident.

The Cardiac CT in the Treatment of Acute Chest Pain (CATCH) trial aimed to determine the prognostic utility of CCTA compared to the standard of care in 299 patients presenting with acute chest pain and normal ECG and blood biomarkers.[97] For a primary composite MACE endpoint, there was a 19-month reduction in the CCTA group versus the standard-of-care group (HR 0.62; $P = 0.04$), with no modest differences when events were limited only to those experiencing cardiac death of nonfatal MI ($P = 0.06$). These results are consistent with a recent meta-analysis of four randomized trials and three case-control studies totaling more than 3300 patients. CCTA-based care resulted in a 74% reduction in downstream events and a 42% reduction in repeat ED visits.[98]

The most contemporary RCT, the Better Evaluation of Acute Chest Pain with Computed Tomography Angiography (BEACON), evaluated the use of a CCTA-based strategy versus the standard of care at seven sites where high-sensitivity troponins were used for early diagnosis of ACS.[99] The 500 patients were evaluated for a primary endpoint of coronary revascularization within 30 days following the index ED visits, for which there was no difference between strategies. Although a CCTA-based strategy did not increase ED discharge rates or change lengths of stay, CCTA patients did incur lower medical costs and less outpatient testing after ED discharge.

CCTA versus MPI stress testing was evaluated in the Study Comparing CT Scan and Stress Test in Diagnosing Coronary Artery Disease in Patients Hospitalized for Chest Pain (PROSPECT) trial.[100] The

400 patients represented an ethnically diverse population of more than 50% Hispanic and 37% African American patients of low socioeconomic status and were stratified to either CCTA or MPI testing at the index ED visit. The primary outcome—the rate of ICA without revascularization within 1 year—was no different between testing groups. At a median average follow-up of 40 months, no differences were observed for MACE in this underpowered study, although radiation exposure was lower for patients undergoing CCTA over MPI, and CCTA was regarded with higher patient satisfaction.

Some have advocated for a "triple rule out" (TRO) in which a long *z*-axis scan length is used to acquire images of the entire chest cavity to exclude the presence of CAD, pulmonary embolism, and aortic dissection (**see Chapters 63 and 84**). In a study of 12,834 patients from the Advanced Cardiovascular Imaging Consortium, patients undergoing TRO CT were compared to those undergoing CCTA alone.[101] The rates of diagnosis of significant disease pathology were similar for both TRO and CCTA (17.4% and 18.3%), with pulmonary embolism and aortic dissection more often observed in the TRO group (1.1% versus 0.4% and 1.7% versus 1.1%). However, nondiagnostic CT images were observed at a significantly higher rate with TRO than CCTA (9.4% versus 6.5%), which somewhat negates the uniform performance of TRO in patients with acute chest symptoms.

Use in Patients with Stable Suspected Coronary Artery Disease

At present, almost 10 million CAD imaging tests are performed each year in the United States, which annually represents 25% of the total number of individuals diagnosed with CVD.[102] The vast majority of these tests are stress tests with imaging, typically by SPECT MPI. Given the relatively recent introduction of CCTA, there is an intense interest to determine whether anatomic imaging by CCTA versus physiologic imaging by stress MPI offers any relative advantage in the care of stable patients with CAD. To this end, numerous large-scale observational cohort registries and randomized trials have been performed to determine the efficacy of each of these modes of workup (**Table 18.5**).

*Functional testing included exercise electrocardiogram, nuclear stress testing, or stress echocardiography.

†Hazard ratios were adjusted for age, sex, CAD risk equivalent (i.e., history of diabetes, peripheral arterial disease, or cerebrovascular disease), and the prespecification of the intended functional test if patients were randomly assigned to the functional-testing group.

‡Hazard ratios were adjusted for study center and minimization variables, excluding baseline diagnosis.

**CAD death was defined as death due to myocardial infarction in all cases.

PROMISE, Prospective Multicenter Imaging Study for Evaluation of Chest Pain; SCOT-HEART, Scottish Computed Tomography of the HEART; *CAD,* coronary artery disease; *CCTA,* coronary computed tomography angiography; *HR,* hazard ratios; *CI,* confidence interval; *MI,* myocardial infarction; *PCI,* percutaneous coronary intervention; *CABG,* coronary artery bypass graft surgery.

In the large-scale Prospective Multicenter Imaging Study for Evaluation of Chest Pain (PROMISE) randomized trial, 10,003 patients underwent either CCTA or “functional” testing, which included not only SPECT MPI but also stress echocardiography and stress ECG testing without imaging.[103] At a median-follow-up of 25 months, the primary endpoint—defined as all-cause mortality, nonfatal MI, unstable angina hospitalization, or procedural complication—was no different for the CCTA group than for the functional testing group (HR 1.04). Median average radiation exposure was lower for CCTA patients than those in the functional assessment arm (10.0 versus 11.3 mSv). CCTA was associated with a higher rate of

ICA within the 90 days following the index test (12.2% versus 8.1%), although those undergoing ICA in the CCTA arm were observed to have a higher rate of high-grade coronary stenosis. Despite higher rates of ICA, 3-year costs for CCTA were similar to functional testing, with $254 higher costs for CCTA at 90 days and similar costs at 1 and 3 years of follow-up.[104] Similarly, quality-of-life measures, as determined by the Duke Activity Status Index and Seattle Angina Questionnaire, were consistently similar during the entire follow-up period.[105] These nonsignificant differences in quality-of-life and clinical outcomes occurred despite significantly higher rates of prescribed primary prevention medical therapies for patients undergoing CCTA over functional testing for aspirin (11.8% versus 7.8%) and statins (12.7% versus 6.2%).[106] Compared with patients undergoing functional testing, CCTA patients were more likely to adopt a heart-healthy diet and achieve weight loss. Prognostically, compared with functional testing, CCTA was associated with greater predictive abilities for future adverse clinical outcomes when an abnormal test was reported (HR 5.86 versus 2.27).

In contrast to the clinical outcomes-based endpoint of the PROMISE trial, the Scottish Computed Tomography of the Heart (SCOT-HEART) trial examined an endpoint of diagnostic certainty of angina caused by CAD at a 6-week endpoint.[107] "Diagnostic certainty" was defined by the caring physician and categorized by presence versus absence, as well as unlikely versus probable angina. Importantly, this study was not a direct comparison of anatomic versus functional testing, but rather a test of standard of care (SOC) plus CCTA versus SOC alone, which included clinical evaluation plus symptom-limited exercise testing if considered clinically necessary. For the primary endpoint, there was a significant increase in the diagnostic certainty (relative risk [RR] 3.76) among imaging physicians, associated with a lower frequency of angina diagnosis (RR 0.78). A similar pattern emerged for the attending clinician, whose certainty rose by 1.75-fold with negligible effects on frequency of diagnosis. Increases in diagnostic certainty resulted in significant changes in downstream planned diagnostic evaluations in the SOC plus CCTA group versus SOC alone (15% versus 1%). Contrary to the PROMISE trial, average median radiation doses of CCTA were significantly lower (4.1 mSv).

In the 6-week follow-up of patients in the SCOT-HEART study, marginal differences were observed for near-term death or MI (1.3% versus 2.0%; $P = 0.053$). At 20 months' follow-up, however, when prognostic evaluations began at initiation of preventive therapy, those undergoing CCTA experienced a 50% reduction in fatal and nonfatal MI compared to SOC alone.[108] These findings were associated with similar rates of ICA between CCTA and SOC groups, but higher rates of confirmation of obstructive CAD in CCTA patients as well as higher rates of preventive medical therapies (HR 4.03).

The precise reasons for the improvement in clinical outcomes after CCTA have yet to be proved in an RCT. Large-scale observational evidence suggests the clinical outcomes benefit following CCTA may result from efficacy of primary preventive medical therapies. In 10,418 patients from the CONFIRM registry followed for 27 months with no or nonobstructive CAD, defined by a maximal per-patient coronary stenoses between 1% and 50%, those with evident mild coronary stenoses experienced a 56% reduction in mortality.[68] Independent of NCEP/ATP III guidelines, statins conferred a clinical benefit only for patients with evident CAD on CCTA. A subsequent study from CONFIRM evaluated the effects of primary versus secondary medical therapy on outcomes in patients with obstructive CAD of 50% or greater stenosis on CCTA. In this cohort, statins were similarly associated with a 43% reduction in the risk of MACE, with no decrement in this risk for patients prescribed aspirin, beta blockers, and ACE inhibitors. A further analysis of 15,223 stable patients without known CAD followed for 2.1 years revealed significant clinical outcomes differences for patients undergoing medical therapy versus medical therapy plus coronary revascularization based on extent and severity of CAD on CCTA.[59] CAD was categorized as high risk versus non–high risk based on the Duke CAD index, a metric that integrates the

degree of stenosis severities with the location of the stenoses. Patients with high-risk CAD undergoing medical therapy alone fared worse than patients who underwent revascularization (5.34% versus 2.28% mortality), whereas patients with non–high risk CAD or no CAD experienced higher rates of death if they were treated with coronary revascularization over medical therapy alone (2.06% versus 0.97%). These findings were corroborated in a follow-up study of 15,207 intermediate-likelihood patients at 2.3 years. Revascularization for patients with obstructive CAD resulted in a reduced mortality risk (HR 0.61) and, conversely, a more than twofold increase in mortality risk for patients without obstructive CAD.[109]

Given the potential increase in health care costs associated with CCTA, the recent Comprehensive Cardiac CT versus Exercise Testing in Suspected Coronary Artery Disease (CRESCENT) RCT examined the safety and efficacy of a tiered CT approach where the less costly CAC scan was performed as the initial test, followed by CCTA only if the CAC score was between 1 and 400.[110] These patients were randomized against a functional testing arm and followed for 1 year for clinical adverse events, angina symptoms, time to diagnosis, downstream testing rates, and health care costs. Compared with functional testing, patients undergoing CCTA experienced a higher rate of CAD event-free survival (96.7% versus 89.8%) with fewer angina symptoms. Time to diagnosis was more rapid with a CCTA approach compared with functional testing, a strategy associated with more than 50% lower rates of downstream testing and approximately 20% lower health care costs.

Physiologic Evaluation of Coronary Artery Disease

The sine qua non of CAD diagnostic imaging is the concomitant diagnosis of anatomic and physiologically significant CAD from a single test for identification and exclusion of actionable CAD that may benefit from revascularization. By invasive standards, FFR at the time of ICA has emerged as such an approach by pinpointing coronary stenoses that cause ischemia in a lesion-specific fashion (**see Chapters 57, 61, and 62**). Fractional flow reserve, defined as the ratio of pressure distal to a coronary stenosis to the pressure proximal to the coronary stenosis at maximum flow conditions, is considered both a diagnostic and a prognostic "gold standard."[111] To date, FFR represents the only method of ischemia evaluation that results in improved event-free survival over angiographic stenosis-guided revascularization or medical therapy alone.

FFR derived from CCTA (FFR_{CT}) is a method for deriving three-vessel FFR values using typically acquired CCTA (**Fig. 18.14**). In this regard, FFR_{CT} requires no additional testing or radiation and no medications, but can be performed on any acquired CCTA. As with invasive FFR, FFR_{CT} enables precise localization of ischemia-causing coronary stenoses. The concept of lesion-specific ischemia is new for the field of noninvasive imaging, which has previously relied on myocardial perfusion evaluation as an indirect measure of flow-limiting CAD. These stress testing methods have significant limitations for guiding decisions of referral to ICA and/or revascularization, given the almost two thirds of ICAs that reveal nonobstructive CAD at angiography.[112]

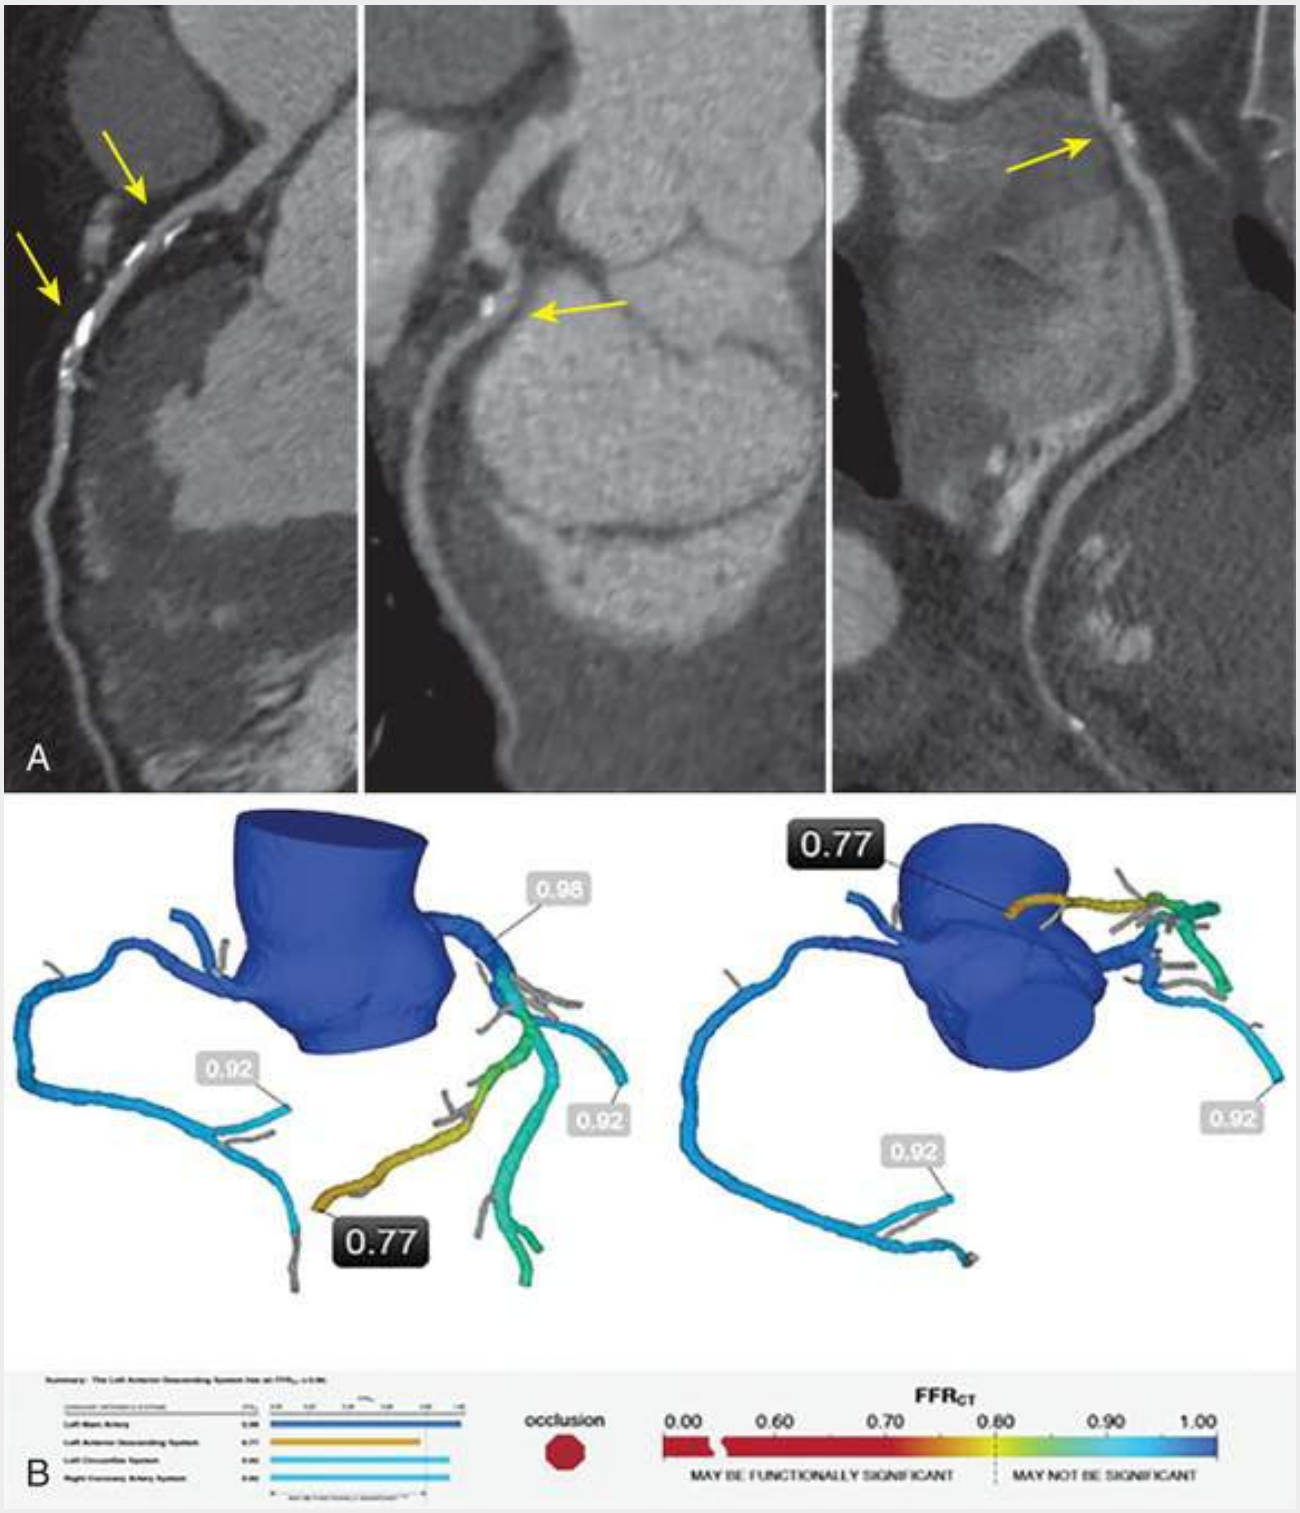

FIGURE 18.14 Fractional flow reserve derived from CCTA (FFR_{CT}). **A,** CCTA demonstrates moderate stenosis in proximal portion of left anterior descending artery (LAD). Midportion of LAD cannot be adequately visualized due to severe calcified plaque. Mild nonstenotic plaque is noted in left circumflex artery and moderate stenosis in midportion of right coronary artery. **B,** FFR_{CT} demonstrates significant ischemia in LAD (FFR_{CT} 0.77) that spares the diagonal branch (FFR_{CT} 0.92). Note that FFR_{CT} allows for interrogation of ischemia at all points in the coronary artery tree.

The advent of FFR_{CT} was coincident with the introduction of 64–detector row CCTA, because of the need for high-fidelity patient-specific coronary arterial geometry in its calculation.[113] At its core, FFR_{CT} calculations are based on the application of computational fluid dynamics (CFD) to CCTA to calculate coronary fluid pressure, velocity, and flow. Ubiquitous in nearly every field of engineering (e.g., automotive, aerospace), CFD principles rely on the laws of mass conservation and momentum balance. In the steps to calculate FFR_{CT}, coronary arteries and left ventricular myocardium are segmented with

subvoxel resolution. Based on form-function relationships, rest coronary flow for each artery is calculated as a function of the myocardial mass it subtends. To ensure correct FFR_{CT} values, allometric scaling laws are employed to calculate distal intramyocardial microcirculatory resistance. Hyperemia is then modeled using a response of coronary arteries to adenosine, the agent used in invasive FFR, and for which maximal reductions in coronary resistance occur at a predictable threshold. The final step in the calculation of FFR_{CT} is the distribution of several million tetrahedral meshes through each artery and its branch, then solving the fluid dynamic equations to obtain FFR values at every point in the coronary vascular bed.

The diagnostic performance of FFR_{CT} has been evaluated in three prospective multicenter trials: Diagnosis of Ischemia-Causing Stenoses Obtained Via Noninvasive Fractional Flow Reserve (DISCOVER-FLOW), Determination of Fractional Flow Reserve by Anatomic Computed Tomographic Angiography (DeFACTO), and Analysis of Coronary Blood Flow Using CT Angiography: Next Steps (NXT)[114-116] (**Table 18.6**). Each trial represented an improved generation over the last, with the NXT trial most recently reported. In this study of 254 patients referred for clinically indicated ICA, CCTA and FFR_{CT} were performed, with 484 vessels directly interrogated by invasive FFR. The primary endpoint of this study was the area under ROC curve for FFR_{CT}, 0.90 and 0.93 on a per-patient and per-vessel basis, respectively, which corresponded to an overall per-vessel diagnostic accuracy of 86%. These performance characteristics compared favorably to anatomic evaluation alone by ICA or CCTA, which revealed modest accuracies for diagnosis of invasive FFR-determined ischemia (77% versus 53%). A recent meta-analysis of diagnostic imaging modalities evaluated the comparative diagnostic performance of FFR_{CT} to SPECT, SE, CMR, and ICA. For invasive FFR-verified ischemia, highest sensitivities of testing modalities were observed for CCTA (90%), CMR (90%), and FFR_{CT} (90%), with more moderate specificities observed for FFR_{CT} (71%).

FFR_{CT}, Fractional flow reserve computed tomography; *PPV,* positive predictive value; *NPV,* negative predictive value; *AUC,* area under the receiver operating characteristic (ROC) curve.

The combination of FFR_{CT} findings with APCs, including PR, LAP, and SC, for the diagnosis of lesion-specific ischemia as referenced by invasive FFR has been studied in 252 patients enrolled in the DeFACTO trial. In this study of 407 vessels directly interrogated by invasive FFR, only PR added incremental discriminatory value to FFR_{CT} alone for diagnosis of ischemia-causing coronary lesions

(area under ROC curve, 0.87 versus 0.83). In a subsequent study of the NXT population, coronary artery atherosclerotic plaque volumes were studied for their ability to provide incremental diagnostic value to FFR_{CT}. Overall plaque volumes were separated into noncalcified, low-density noncalcified, and calcified plaque. Aggregate plaque volumes were inversely correlated with ischemia in a manner independent of high-grade stenosis severity, with low-density noncalcified plaque plus FFR_{CT} yielding an area under the ROC curve of 0.90 for discrimination of lesion-specific ischemia.[117]

FFR_{CT} has been assessed for its ability to alter the clinical management of patients undergoing noninvasive and invasive testing. In the crossover-design Prospective Longitudinal Trial of FFR_{CT} Outcome and Resource Impacts (PLATFORM), 584 symptomatic patients with suspected CAD were assigned to either usual care or a CCTA-FFR_{CT}–based evaluation, to determine the rates of no obstructive CAD of 50% or greater stenosis at ICA.[118] Two separate cohorts were studied, referred for invasive assessment and for noninvasive stress testing. Compared with a CCTA-FFR_{CT}–based approach, usual care resulted in a significantly lower rate of obstructive CAD at ICA (12% versus 73%) and also resulted in 61% of ICAs being canceled after CCTA-FFR_{CT} findings were known. These cancellations were associated with 32% lower costs and similar quality-of-life measures by a CCTA-FFR_{CT} algorithm compared to usual care, a finding that extended to the 1-year follow-up. In contrast, among patients referred to noninvasive imaging, the rates of nonobstructive CAD at ICA were not statistically different (13% versus 6%). For these patients undergoing noninvasive imaging, quality-of-life measures were higher with a CCTA-FFR_{CT}–based strategy than with usual care, although with higher costs ($2766 versus $2137).[119]

Early investigations of the potential of FFR_{CT} to guide clinical decisions of coronary revascularization have been recently studied.[120] In a pilot study of 44 patients, CFD was applied to calculate FFR_{CT} values with subsequent computational modeling of coronary stenting for ischemia-causing lesions. Before and after "virtual stenting" FFR_{CT} moderately correlated with the invasive FFR at a mean difference of 0.006 and 0.024, respectively, and a diagnostic sensitivity and specificity of 85% and 57%.

CCTA is advocated by the ACC Multimodality Appropriate Use Criteria for the Detection and Risk Assessment of Stable Ischemic Heart Disease as appropriate for several clinical indications that are largely classified on the basis of symptoms suggestive of CAD or prior test results[39] (see end chapter, **Tables 18G.1** and **18G.2**). Appropriate symptom-based indications include those with intermediate pretest probability of CAD with an uninterpretable ECG or who are unable to exercise, new or worsening symptoms after a normal exercise ECG test, or newly diagnosed systolic heart failure. Prior testing within 90 days for abnormal or uncertain results after exercise ECG or stress imaging is considered appropriate for performance, with no appropriate indications for asymptomatic individuals.

Assessment of Cardiovascular Structure and Function

Beyond coronary artery stenosis and atherosclerosis, ECG-gated CT allows for comprehensive assessment of cardiac structure and function. Because cardiac function evaluation requires retrospective ECG helical gating, with significantly greater amounts of radiation exposure, cardiac CT functional evaluation is less frequently performed. In specific cases, however, it may be useful, and techniques to acquire optimal image acquisition and measurements should be known.

Left ventricular (LV) assessment can be determined by continuous image acquisition throughout the cardiac cycle in an array of patient subsets[121] (**Table 18.7**). In most cases, image reconstruction is performed at every 5% or 10% increment of the R-R interval, which enables cardiac motion assessment. Although 4D cardiac function evaluation at 5% increments appears "smoother" in motion than 10% increments, it is important to note that these images do not differ with respect to temporal resolution, which is fixed by the model of the CT scanner. Techniques to acquire these measurements vary and have historically been aimed to replicate echocardiography and SPECT planes, including short-axis and two-, three-, and four-chamber views, and are useful for correct sizing of cardiac chambers. However, current software algorithms allow for semiautomated segmentation with manual correction of LV cavities, which offers ease of volumetric measurement. LV volumes have been reported using prospectively triggered axial CT scans, which are acquired at variable points in mid-diastole. Because this phase of the cardiac cycle is not typically acquired by other imaging methods, care should be taken not to compare these CT findings to normal values, which have been detailed in normal individuals free of cardiovascular pathology.

EDV, End-systolic volume; *ESV,* end-diastolic volume; *LVEF,* left ventricular ejection fraction; *ECC,* echocardiography; *CAD,* coronary artery disease; *IHD,* ischemic heart disease.

Despite current CT temporal resolution being significantly poorer than other imaging modalities, CT has generally demonstrated high correlation with other methods. Using a CMR gold standard, cardiac CT quantification demonstrated *r* values for comparison of LV ejection fraction (EF), end-systolic volume, and end-diastolic volume and mass: 0.93, 0.95, 0.93, and 0.86, respectively.[122] Partly because of these findings, cardiac CT is considered appropriate for use by recent multimodality AUC to be useful to differentiate etiologies of congestive heart failure (CHF). Regional wall motion assessment can be determined with high specificity and, when coupled with coronary angiographic findings, may help determine ischemia as a cause for impaired function and wall motion. Additional information can be gleaned by quantitation of attenuation patterns in myocardial tissue, with low attenuation suggestive of resting perfusion deficits that are sequelae of prior MI. Repeat contrast injection after initial performance of cardiac CT, typically 10 minutes later, may be useful for identification of areas of delayed hyperattenuation suggestive of nonviable myocardial scar.[123] For patients with preexisting chronic kidney disease, a CAC score of 0 can exclude high-risk CAD and may be considered as an alternative to CCTA.

Other specific etiologies of CHF are elicited through interpretation of cardiac CT.[121,124] These include

hypertrophic cardiomyopathy through measurements of LV wall thickness, systolic anterior motion of the mitral leaflets, and myocardial hyperattenuation pattern inconsistent with the angiographic CAD (**see Chapter 78**). Similarly, diagnosis of infiltrative cardiomyopathies such as sarcoidosis can be augmented by visualization of noncardiac structures such as mediastinal lymphadenopathy. LV myocarditis, noncompaction, arrhythmogenic right ventricular cardiomyopathy, constrictive pericarditis, and amyloidosis have also been reported as being diagnosable by cardiac CT (**see Chapters 77 and 83**). Other important pathologies, such as LV apical thrombus, ventricular aneurysms, and pseudoaneurysms, are easily diagnosed and serve as an added diagnostic benefit of cardiac CT.

With limitations, valvular assessment can be performed by cardiac CT.[125] Given current contrast protocols that aim to selectively opacify the LV cavity over the right, the general focus for valvular evaluation by cardiac CT has been on left-sided valves. Aortic stenosis is generally accurately diagnosed by cardiac CT (**see Chapter 68**). Double-oblique localization of the aortic valve at the level of the leaflet insertions can be easily performed by initial start planes in the left sagittal oblique and left coronary oblique axes, which allows visualization of the phasic motion of the valve throughout the cardiac cycle. Although some have suggested cardiac phases of 10% to 30% of the R-R interval as the optimal time for evaluation of the aortic valve area (AVA), this is variable among individuals and should instead be measured at the largest valve orifice area irrespective of the phase. Meta-analytic data from 14 studies suggest an overestimation of AVA by cardiac CT compared to transthoracic echocardiography (TTE), with better correlation to transesophageal echocardiography (TEE). One potential caveat is in AVA assessment in the case of low-flow, low-gradient aortic stenosis, where the lack of augmentation of LV contractile function may significantly reduce the perceived anatomic AVA by cardiac CT. Numerous other aortic valvular conditions are easily visualized by cardiac CT, including congenital bicuspid or quadricuspid aortic stenosis and extent and severity of aortic valve calcium.

In contrast to aortic stenosis, which relies on retrospective gating, aortic regurgitation (AR) can be assessed with moderate accuracy during prospective triggered cardiac CT. Among 53 patients with AR, compared to 29 patients without AR, undergoing cardiac CT and TTE, cardiac CT demonstrated a sensitivity and specificity of 98% and 98% to grade AR severity.[126] The utility of cardiac CT for AR evaluation is for moderate to severe cases, since cardiac CT misses more than one fourth of mildly regurgitant valves. Aortic regurgitant volume can be quantified when cardiac CT is performed by retrospective helical gating methods. Calculation of LV and right ventricular (RV) end-systolic and end-diastolic volumes enables calculation of their respective stroke volumes. RV stroke volumes subtracted from LV stroke volumes represent the aortic regurgitant volume.

Mitral valve (MV) evaluation can be more challenging than for the aortic valve because of its complex anatomic structure and highly mobile valvular apparatus[127] (**see Chapter 69**). MV scallops and chordae tendineae are very thin structures, and high-intensity opacification of the left ventricle and atrium with iodinated contrast can often obfuscate their visualization. Improved visualization of the MV and its related structures may occur with postprocessing techniques using a MinIP, which will enhance the relatively hypoattenuated valve tissue over the contrast-filled cavities.

Cardiac CT may also be useful for diagnosis of mitral stenosis when the MV is visualized by double-oblique short-axis methods.[125] Although prospective axial triggering methods allow for diastolic evaluation at 75% of the R-R interval, inspection of each diastolic phase should be carefully performed for the greatest MV area if retrospective helical gating is performed. At its greatest area, short-axis planimetry will offer measurements of the anatomic regurgitant orifice in a manner highly correlative to TTE for the diagnosis of moderate or severe mitral stenosis. Comparisons to TEE reveal a general overestimation of the MV area by cardiac CT.

Mitral regurgitation on cardiac CT can be quantified by two methods: calculation of the regurgitant volume and measurement of the anatomic regurgitant orifice area (ROA). Measurement of mitral regurgitant volume by differences in LV and RV stroke volumes shows high correlation to TTE (r = 0.95) with no significant biases.[128] Importantly, planimetry of the MV by cardiac CT provides only the *anatomic* ROA, which may differ from the hemodynamically dependent *effective* ROA. Numerous other MV pathologies can be readily interpreted on cardiac CT scans and may offer assistance in diagnosis of mitral regurgitation, including prolapse, flail leaflet, paravalvular abscess, endocarditis, or in the case of prosthetic valves, thrombus formation or dehiscence.

Structural Heart Disease Interventions

Given the anatomic and physiologic data afforded by cardiac CT, coupled with recent advances in complex percutaneous therapies for structural heart disease, CT has evolved to become an important imaging modality for preprocedural guidance and postprocedural follow-up for many of these interventions. These include imaging for transcatheter heart valve replacement, left atrial appendage occlusion, and arrhythmia ablation (**Chapter 38**).

Since its demonstrated superiority over conservative therapy and similar outcomes to surgical therapy in high-risk patients with severe aortic stenosis, transcatheter aortic valve replacement (TAVR) is finding expanding clinical utility in patients with less severe aortic valvular disease[129-131] (**see Chapter 72**). Almost coincident with this has been the examination of the potential of cardiac CT findings to provide information that may improve procedural TAVR outcomes or prevent unnecessary complications.[132] Specific to TAVR, cardiac and vascular CT scans are routinely performed and provide information related to (1) aortic annular size and calcifications, (2) prediction of TAVR deployment angles, (3) coronary ostial heights, (4) aorto-iliac size and atherosclerotic burden, and (5) postprocedural evaluation of TAVR devices for evidence of leaflet thickening suggestive of thrombosis (**Fig. 18.15**).

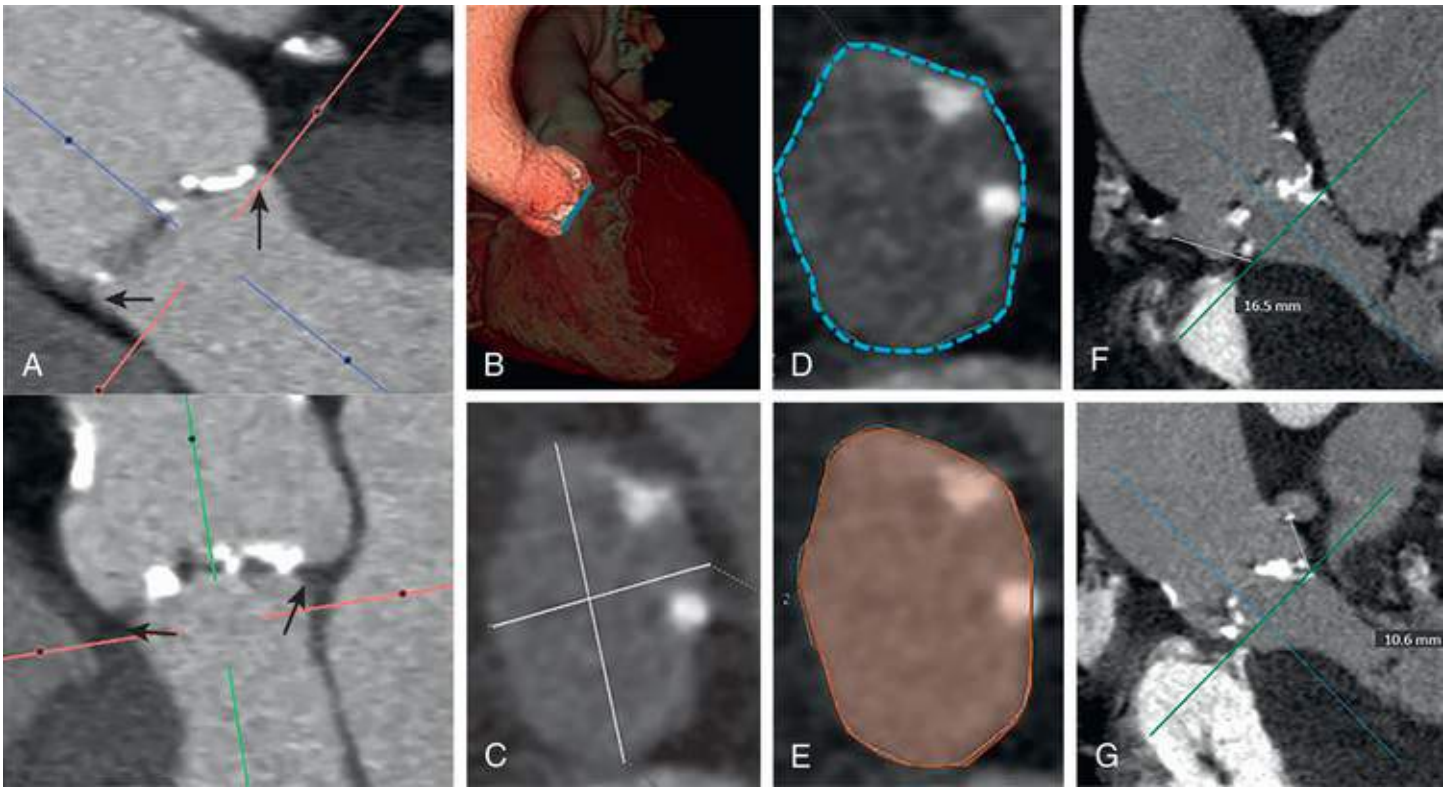

FIGURE 18.15 Cardiovascular CT for preprocedural planning of transcatheter aortic valve replacement (TAVR). **A,** Double-oblique approach to identifying aortic annular plane before TAVR (*black arrows*). Aortic annuli should be measured at the leaflet insertions rather than in the valve plane. **B,** Volume-rendered imaging of the aorta, aortic annulus, and aortic valve. *Blue line* indicates the plane of the aortic annulus. When all points in the aortic annular plane are aligned (as indicated by *blue line*), these CT projection angles can be helpful to proceduralists as a guide to which angles may be useful at the time of the TAVR procedure. Diameter **(C)**, area **(D)**, and, perimeter **(E)** measurements of the aortic annulus for proper sizing of the TAVR prostheses. Measurement of the right coronary ostial height **(F)**, and left coronary ostial height **(G)**, to ensure that the TAVR will not occlude the coronary ostia.

Cardiac CT scanning for TAVR is largely performed with retrospective helical gating. Patients undergoing TAVR are generally elderly, and the need for dynamic assessment of the aortic annulus often outweighs the risk of radiation from a cardiac CT. On CT the aortic annulus is localized by a double-oblique method that aligns the plane of insertion of the left, right, and noncoronary cusp leaflets. This plane is generally asymmetric to the plane of the left ventricular outflow tract (LVOT) and proximal ascending aorta, with the right coronary cusp leaflet generally inserting more inferior than its counterparts. The left-right, craniocaudal angles that define the aortic annular plane can aid in the determination of the fluoroscopic angles for coaxial deployment of TAVR at the time of the procedure. CT assessment of the aortic annulus reveals a structure that is elliptoid in shape, is often calcified, and exhibits dynamism throughout the cardiac cycle. Rather than report the uneven diameters of the elliptical aortic annulus, area measurements are preferred because they can be better applied to correctly size the circular-shaped TAVR devices. Given the larger annular area at the end of systole, it is during this phase of the cardiac cycle that aortic annular measurements should be reported. Proper TAVR sizing by CT reduces rates of postprocedural paravalvular aortic regurgitation (PAR), whose incidence increases with greater TAVR device diameter (or area) minus CT annular diameter (or area), respectively.[133] Appropriate device sizing is also important to prevent oversizing compared to aortic annular measurements, which can lead to aortic rupture. The calcifications of the aortic annulus, valve, and proximal aorta are important to note. Severity of aortic valve calcification at the level of the aortic wall, valve edge, or valve commissures by CT increases risk of PAR as well as rupture.

Several additional pre-TAVR CT findings are noteworthy. Given the generally high-profile TAVR stent

devices, it is important to measure the distance between the aortic annular plane and the coronary ostia. Catastrophic cases have occurred where TAVR deployment resulted in acute coronary occlusion and sudden death. Measurements of the coronary height should be done from the aortic leaflet insertions to the inferior portion of the left and right coronary ostia. This is generally an oblique plane and should not be substituted for a measurement perpendicular to the annular plane, which may underestimate the coronary height. Further, in candidates of TAVR, aortoiliac angiography is often simultaneously performed to assess the dimensions of the vasculature for planned transfemoral approaches. Several important imaging features can predict periprocedural complications, including minimum aortoiliac artery diameter less than diameter of external sheath, severe calcifications in femoral and superficial femoral arteries, “horseshoe” calcifications, and severe aortic atheromatous plaque. Patients undergoing TAVR who have underlying renal insufficiency may undergo low-dose iodinated contrast protocols, which have included use of monochromatic DECT imaging and selective aortoiliac angiography.

In the emerging field of transcatheter mitral valve replacement (TMVR), cardiac CT will likely play a similarly important role[127] (**see Chapter 72**). As with TAVR procedures, double-oblique methods of CT image reconstruction can be useful to assess the MV anatomy, which is a complex D-shaped structure with a saddle-shaped morphology. CT can be useful to quantify the mitral annular size, extent and location of calcifications, and 3D geometry. Similar to TAVR, CT will allow for depiction of fluoroscopic angles coplanar to the mitral annulus to help guide device deployment. Because TMVR prosthesis deployment will often extend into the LVOT, it will create a “neo-LVOT” after the procedure. Coupled with information related to the type and size of the TMVR device, CT allows for determination of the degree of LVOT obstruction that may result from TMVR.

For patients with atrial fibrillation (AF) being considered for pulmonary vein isolation (**see Chapter 38**), cardiac CT can be useful for detailed morphologic characterization of the left atrium, left atrial appendage (LAA), and pulmonary veins (PVs).[134] Left atrial measurements by CT are generally reported volumetrically and at end-systole, with values consistent with those derived by CMR. LAAs are easily appreciated on cardiac CT, which has been used to exclude LAA thrombus in patients with AF. Thrombus in the LAA will appear as an area of hypoattenuation with a generally distinct border. This contrasts with “thrombus in formation” (or very low LAA velocities), which possesses a hazier appearance. For individuals with suspected LAA thrombus on CT, a follow-up noncontrast study approximately 45 to 60 seconds after the contrast-enhanced CT is helpful. Loss of the hypoattenuation signal within the LAA at this second CT will exclude the diagnosis of LAA thrombus, whereas its persistence will establish the diagnosis (**Table 18.8**).

TABLE 18.8

PPV, Positive predictive value; *NPV,* negative predictive value.

The interindividual variations of LAA shape and size are considerable, but attempts have been made to

categorize LAA types into morphologies that represent a cactus, a chicken wing, a windsock, and a cauliflower. For AF patients who cannot tolerate anticoagulation, these findings may contribute to the determination of their suitability for percutaneous LAA occlusion.[135] LAA morphologies may have prognostic utility; a chicken-wing LAA shape may be associated with a lower risk of thromboembolic events for patients undergoing catheter ablation for AF. Given their high anatomic variability, the left atrium and PVs are often reconstructed by CT postprocessing methods and co-registered with left atrial electrical information obtained at the PV isolation procedure. This integrated electroanatomic map can offer improved localization of arrhythmogenic foci, as well as reduce complications such as PV stenosis or atrio-esophageal fistulas. 2D-3D image co-registration techniques also exist to fuse cardiac CT image data with x-ray fluoroscopy data for improved spatial orientation during the procedure.

Appropriate Use Criteria

Multimodality Imaging in Stable Ischemic Heart Disease and Heart Failure

James E. Udelson, Vasken Dilsizian, and Robert O. Bonow

Beginning in 2005, the America College of Cardiology (ACC) along with other professional societies published appropriate use criteria (AUC), a set of recommendations for the use of diagnostic and therapeutic procedures keyed to clinical situations. With respect to diagnostic imaging, since the initial document on single-photon emission tomography (SPECT) imaging in 2005, each AUC document considered an individual imaging test or procedure (e.g., SPECT, echocardiography), across numerous clinical indications. The AUC recommendations are meant to inform clinical decision making for the optimal use of cardiac imaging.

The most recent AUC documents provide recommendations for the appropriate use of imaging in clinical syndromes rather than focusing on one specific imaging modality alone. The documents encompass patients with stable ischemic heart disease, that is, those with suspected or known coronary artery disease[1] (**Table 18G.1**) and patients with heart failure[2] (**Table 18G.2**). The documents recommend criteria for the use of numerous testing modalities within each of those clinical syndromes, including exercise electrocardiography and all widely used imaging modalities, such as SPECT perfusion imaging, echocardiography, coronary computed tomographic angiography (CCTA) and calcium imaging, and cardiac magnetic resonance imaging (CMR). Testing is rated based on the published literature as well as expert opinion, in a well-defined process. Tests are rated using the current nomenclature as "appropriate," "may be appropriate," or "rarely appropriate."[3]

Section 4. Determine Exercise Level Prior to Initiation of Exercise Prescription or Cardiac Rehabilitation								
4.1. Exercise Prescription								
78.	No prior revascularization	A	R	R	R	R	R	R

Appropriate Use Key: A = Appropriate; M = May Be Appropriate; R = Rarely Appropriate.

CABG, Coronary artery bypass graft; *CAD,* coronary artery disease; *CCT,* coronary computed tomography; *CCTA,* coronary computed tomography angiography; *CHD,* coronary heart disease; *CMR,* cardiac magnetic resonance imaging; *ECG,* electrocardiogram; *Echo,* echocardiography; *LBBB,* left bundle branch block; *LV,* left ventricular; *METs,* metabolic equivalents; *PCI,* percutaneous coronary intervention; *PVC,* premature ventricular complex; *RNI,* radionuclide imaging; *VT,* ventricular tachycardia.

TABLE 18G.2

Appropriate Use of Cardiovascular Imaging in Heart Failure

	Indication	REST ONLY					REST + STRESS				CCT	Cath
		Echo	RNV	SPECT	PET	CMR	Echo	SPECT	PET	CMR		
1. Initial Evaluation of Cardiac Structure and Function for Newly Suspected or Potential Heart Failure												
Newly Suspected or Potential Heart Failure												
1.	Symptoms of heart failure Shortness of breath OR Decreased exercise tolerance OR Symptoms of fluid retention AND Findings of heart failure Abnormal chest radiograph (e.g., enlarged silhouette, pulmonary venous congestion) OR Abnormal biomarker(s) (e.g., BNP, pro-BNP) OR Signs of heart failure Evidence of impaired perfusion OR Evidence of volume overload	A	A	M	R	A	R	R	R	R	M	R
2.	Malignancy Current or planned cardiotoxic therapy AND No prior imaging evaluation	A	A	R	R	A	R	R	R	R	R	R
3.	Familial or genetic dilated cardiomyopathy in first-degree relative	A	M	R	R	A	R	R	R	R	R	R
4.	Known adult congenital heart disease	A	M	R	R	A	R	R	R	R	M	M
5.	Acute myocardial infarction Evaluation of LV function during initial hospitalization	A	M	M	R	A	M	M	R	R	R	A
2. Evaluation for Ischemic Etiology												
6.	Angina/ischemic equivalent syndrome	M	R	R	M	M	A	A	A	A	A	A
7.	WITHOUT angina/ischemic equivalent syndrome	M	R	R	M	M	A	A	A	A	M	A
3. Viability Evaluation (After Ischemic Etiology Determined) Known to Be Amenable to Revascularization With or Without Angina												
8.	Severely reduced ventricular function (EF <30)	M	R	A*	A	A	A	A	A	A	M	R
9.	Moderately reduced LV function (EF 30%-39%)	M	R	M*	A	A	A	A	M	A	M	R
10.	Mildly reduced LV function (EF 40%-49%)	M	R	M*	M	A	A	A	A	A	M	R
4. Consideration and Follow-Up for Implantable Cardioverter-Defibrillator (ICD)/Cardiac Resynchronization Therapy (CRT)												
Implantable Cardioverter-Defibrillator Therapy												
11.	Evaluation determine patient candidacy Meets published clinical standards for device eligibility Candidacy requires assessment of EF and/or other structural information	A	A	M	R	A	R	R	R	R	M	R
12.	Routine follow-up after placement No deterioration in clinical status AND No change in arrhythmia status	R	R	R	R	R	R	R	R	R	R	R
13.	Follow-up after placement Change in arrhythmia status Appropriate ICD discharge (e.g., VT/VF)	A	R	M	R	R	R	R	R	R	M	R
14.	Follow-up after placement Change in arrhythmia status Inappropriate ICD discharge (e.g. rapid AFib)	A	R	M	R	R	R	R	R	R	R	R
Cardiac Resynchronization Device Therapy												
15.	Initial evaluation to determine patient candidacy Meets published clinical standards for device eligibility Candidacy requires assessment of EF	A	A	M	R	A	R	R	R	R	M	R
16.	Procedure planning: considerations Patient meets all published clinical standards for device Evaluation of myocardial fibrosis/scarring, coronary vein variations, and intracavitary thrombus (for dyssynchrony evaluation)	A	R	R	R	A	R	R	R	R	A	R
17.	Follow-up early (<6 months) after implantation No improvement in symptoms OR No improvement functional capacity	A	M	M	R	R	R	R	R	R	M	R
18.	Follow-up late (>6 months) after implantation Improved symptoms (i.e., from class III, IV to class I, II) OR Improved functional capacity	M	R	R	R	R	R	R	R	R	R	R
5. Repeat Evaluation of Heart Failure												
19.	New angina or ischemic equivalent syndrome	A	M	M	M	M	A	A	M	M	M	A
20.	New or increasing heart failure symptoms (e.g., shortness of breath, exertional dyspnea) AND Adherent to medical therapy	A	M	M	R	M	A	A	M	M	M	M
21.	No new symptoms AND No other change in clinical status <1 year since prior imaging	R	R	R	R	R	R	R	R	R	R	R
22.	No new symptoms AND No other change in clinical status ≥1 year since prior imaging	M	R	R	R	R	R	R	R	R	R	R

*SPECT rest/redistribution.

Appropriate Use Key: A = Appropriate; M = May Be Appropriate; R = Rarely Appropriate.

AFib, Atrial fibrillation; *BNP,* brain natriuretic peptide; *Cath,* catheterization; *CCT,* coronary computed tomography; *CMR,* cardiac magnetic resonance; *Echo,* echocardiography; *EF,* ejection fraction; *LV,* left ventricular; *PET,* positron emission tomography;

RNV, radionuclide ventriculography; *SPECT,* single-photon emission tomography; *VT/VF,* ventricular tachycardia/ventricular fibrillation.

The recommendations in these newer documents supersede those in prior AUC documents on each of the individual modalities. Moreover, a strength of these multimodality documents is that the writing panels had as one of its goals to "identify any and all tests that are considered reasonable for a given clinical indication."[1] The panel did not attempt to define which test might be "best" for each indication, but rather identified the range of testing that could be appropriate (or not) for a given clinical indications within the specific clinical syndrome. Importantly, it is acknowledged that local expertise and quality of testing are additional critical factors in determining test selection.

The AUC documents have been important in identifying for imaging laboratories and hospital systems that approximately 15% of tests that are ordered appear to fall into the category "rarely appropriate," providing clinicians with a guide to optimize case selection for testing, as well as test selection. The multimodality imaging AUC documents comprehensively compile the recommendations for all imaging modalities and are important guides to clinical practice.

Cardiac Catheterization

Joerg Herrmann

Cardiac catheterization refers to all forms of direct invasive and catheter-based assessments of the heart. In clinical practice, a distinction is often made between coronary angiography (**see Chapter 20**) and hemodynamic (right ± left) heart catheterization, given the different aspects of these procedures. This chapter focuses on cardiac catheterization in general and hemodynamic catheterization in particular.

The first cardiac catheterization has been accredited to Reverend Stephen Hales, who used brass pipes inserted into the venous and arterial systems of a horse to perform a biventricular catheterization in 1711.[1] (See also Classic References, Mueller.) Animal catheterization procedures became common practice thereafter, and its inapplicability to humans a common assumption for two centuries. In 1929, however, German surgery resident Werner Forssmann, aiming to find better approaches for delivering drugs directly into the heart, advanced a well-oiled 4 French (4F) ureteral catheter via the left cubital vein for a total length of 65 cm into his own heart, walked the stairs to the radiology department, and documented a right atrial catheter position by a chest x-ray film.[2] The American physician-physiologists André Cournand and Dickinson Richards redesigned Forssmann's catheter and advanced the technique in the 1940s. This allowed for a safer procedure, longer indwell times, and easy, repeated collection of true mixed venous blood and thus the calculation of cardiac output by the use of the direct Fick principle for the first time in humans.[1] All three physicians were awarded the Nobel Prize in Physiology and Medicine in 1956. Cardiac catheterization has continued to evolve in many aspects, and currently more than 80% of all U.S. hospitals offer this service.[3]

Cardiac catheterization is not to be understood in isolation but rather as part of the continuum of the evaluation of patients with various cardiac conditions. It is to be pursued with the knowledge of noninvasive test results, and appropriately so, when these do not suffice to direct management decisions. The invasive examination therefore is to provide definitive guidance and needs to be adapted to the presentation and disease processes of the individual patient. **Fig. 19.1** provides an overview of the main indications, illustrating the scope of cardiac catheterization and its appropriate use criteria (AUC).[4] Performing the right procedure on the right patient for the right reason in the right way for the right outcome is becoming increasingly important, especially in a changing health care environment. **eTable 19.1** lists clinical scenarios in which cardiac catheterization is rarely appropriate.

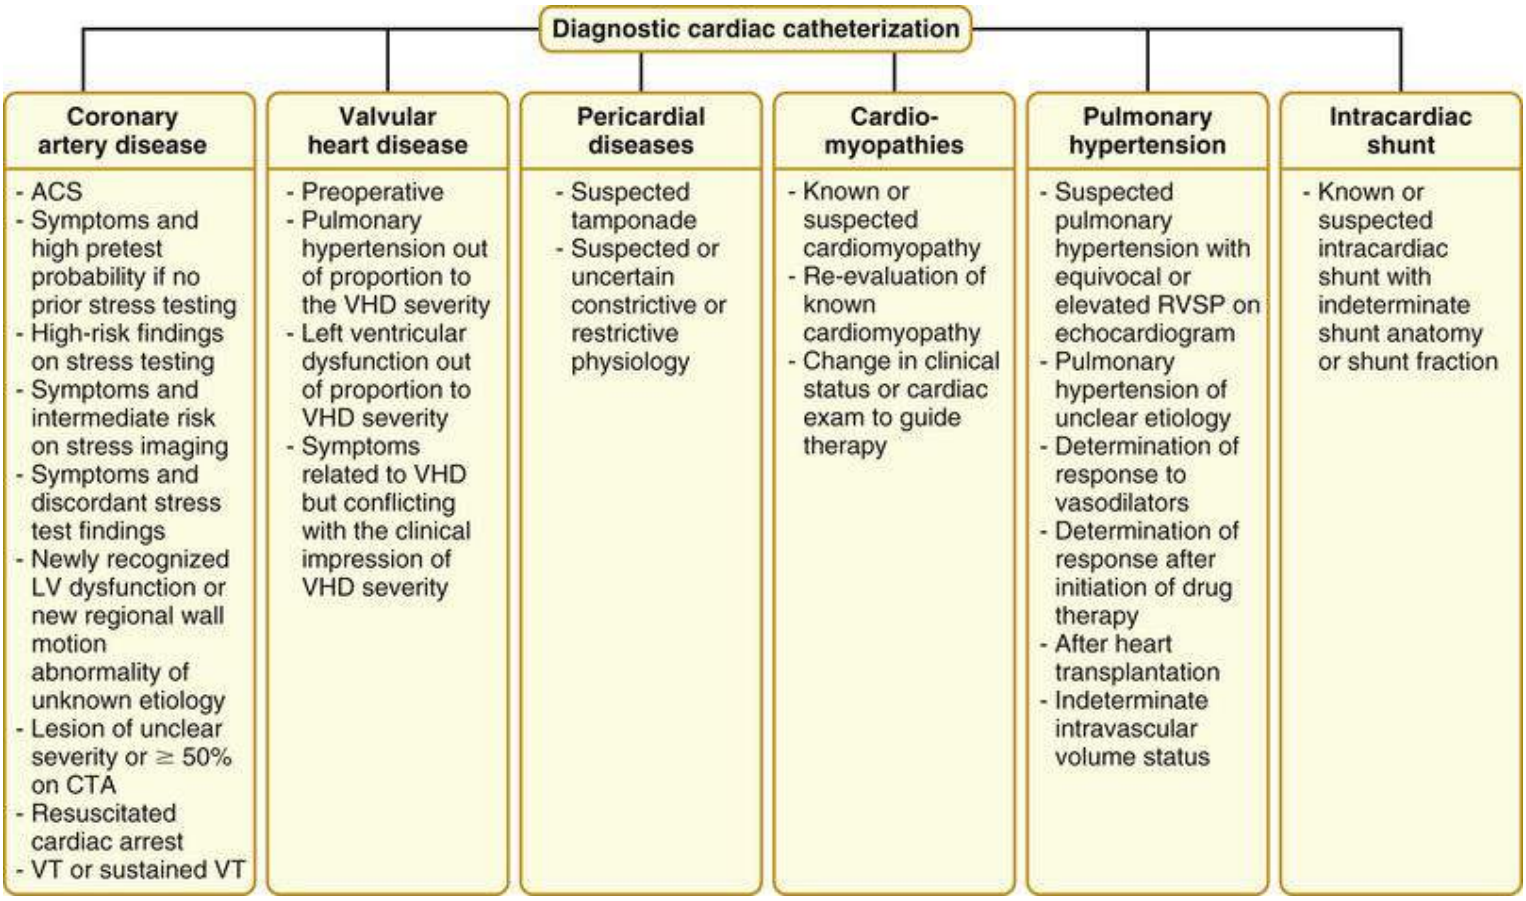

FIGURE 19.1 Overview of the main appropriate use indications for cardiac catheterization. *ACS,* Acute coronary syndrome; *CTA,* computed tomographic angiography; *LV,* left ventricular; *RVSP,* right ventricular systolic pressure; *VT,* ventricular tachycardia.

ETABLE 19.1

Overview of Clinical Scenarios Considered Rarely Appropriate for Cardiac Catheterization

Suspected Coronary Artery Disease (CAD)
No Prior Noninvasive Stress Imaging (No Prior PCI, CABG, or Angiogram Showing ≥50% Angiographic Stenosis)
Low global CAD risk, asymptomatic
Intermediate global CAD risk, asymptomatic
Low pretest probability, symptomatic
Prior Noninvasive Testing (No Prior PCI, CABG, or Angiogram Showing ≥50% Angiographic Stenosis)
Low-risk findings (e.g., Duke treadmill score ≥5), asymptomatic
Low-risk findings (e.g., <5% ischemic myocardium on stress SPECT MPI or stress PET, no stress-induced wall motion abnormalities on stress echo or stress CMR), asymptomatic
Coronary Calcium Score
Any calcium score, asymptomatic
Coronary Computed Coronary Angiography
Lesion <50% non–left main, asymptomatic
Cardiac Magnetic Resonance Imaging (CMR)
Area of delayed gadolinium myocardial enhancement of unknown etiology, asymptomatic
Patients with Known Obstructive CAD (e.g., Prior MI, PCI, or CABG, or Obstructive Disease on Invasive Angiography)
Medically Managed Patients
Low-risk noninvasive findings, asymptomatic/controlled symptoms or unchanged findings
Postrevascularization (PCI or CABG)
Asymptomatic or stable symptoms
Arrhythmias and No Prior Noninvasive Assessment of Ischemia with Normal Systolic Function
Syncope, low CHD risk
New-onset atrial fibrillation or flutter, low or intermediate CHD risk
Heart block (e.g., second-degree type II or third-degree AV block) OR symptomatic bradyarrhythmias, low or intermediate CHD risk
Preoperative Coronary Evaluation for Noncardiac Surgery in Stable Patients
Low-risk surgery, 4 METs functional capacity without symptoms
Intermediate-risk surgery, no risk or 1 to 2 risk factors
Vascular surgery, no risk factors
Chronic Native or Prosthetic Valvular Disease
Asymptomatic related to valvular disease and non-severe mitral stenosis, mitral regurgitation, aortic stenosis, or aortic regurgitation
Symptomatic related to valvular disease and noninvasive imaging for valvular disease concordant with clinical impression of severity

METs, Metabolic equivalents.

This chapter reviews cardiac catheterization within the framework of operational aspects (pre-, intra-, and postprocedural assessment), technical aspects and procedural performance, and clinical aspects and integration into patient care.

Operational Aspects of Cardiac Catheterization

Initial guidelines for the cardiac catheterization were published by the American College of Cardiology (ACC) and the American Heart Association (AHA) in 1991 (see Classic References, Pepine). These have since been supplemented by expert consensus statements on best practice standards for cardiac catheterization by the ACC and the Society for Cardiac Angiography and Interventions (SCAI) in 2001 with updates in 2012 and 2016.[3,5] These documents provide the necessary foundation for the operational aspects.

The Cardiac Catheterization Laboratory

There are four basic types of catheterization laboratories: hospital-based laboratories with full support services including cardiovascular surgery, hospital-based laboratories without cardiovascular surgical capability, freestanding laboratories, and mobile laboratories. To qualify for a full–support service facility, all the following on-site support services must be available: cardiovascular surgery, cardiovascular anesthesia, mechanical circulatory support services, vascular services, endovascular surgery/interventions, intensive care unit, nephrology consultative service and dialysis, neurology consultation services, hematologic consultative and blood bank services, and advanced imaging services (echocardiography with Doppler, computed tomography [CT], magnetic resonance imaging [MRI]; **see Chapters 14, 17, and 18**).[3] If offered, similar services should be available for pediatric patients. Even though cardiovascular surgery is the critical differentiating service, the catheterization laboratory requires all the listed services to provide catheterization services to the full spectrum of case complexities.

Approximately one fourth to one third of catheterization laboratories do not have cardiovascular surgery backup.[3] One may argue that almost all diagnostic procedures that do not involve additional risks could be performed safely without any surgical backup. Indeed, given the favorable safety and quality reports over time, the 2012 ACC/SCAI cardiac catheterization laboratory standards document lifted several (historic) restrictions. Accordingly, the only patient groups not recommended to undergo diagnostic cardiac catheterization without cardiovascular surgery backup are those with pulmonary edema caused by ischemia, those with class 4 symptoms from severe valvular dysfunction with reduced ejection fraction, those with complex congenital heart disease, those with acute coronary syndromes unless percutaneous coronary intervention (PCI; **see Chapter 62**) is possible, and patients at risk of vascular complications unless vascular services are available.[3] Even among non–high-risk patients, complications may arise that require surgical intervention. Moreover, some advanced diagnostic procedures should be performed only by experienced operators who are capable of managing any possible complications. This pertains to transseptal puncture, fractional flow reserve (FFR; **see Chapters 57, 61, and 62**), intravascular ultrasound or optical coherence tomography, and any PCI procedure. Minimum requirements for the performance of invasive cardiovascular procedures in a setting without on-site cardiovascular surgical services are outlined in a SCAI expert consensus, which pertains mainly to the pursuit of PCI.[6] Freestanding and mobile cardiac catheterization facilities fall into this category as well. For obvious reasons, this service is only for properly selected low-risk patients.

With the advanced structural heart interventions now available, especially transcatheter aortic valve replacement (TAVR; **see Chapter 72**), there has been increasing interest in hybrid cardiac catheterization laboratories.[7] These laboratories combine high-resolution imaging with the standards and capabilities of the operating room (OR). In practice, either catheterization laboratory imaging elements will be integrated into the OR or catheterization laboratories will be expanded to accommodate the OR requirements. Thus, these rooms are typically larger than usual and are operated by a team trained in and comfortable with both aspects.

Cardiac Catheterization Equipment

The key elements of the cardiac catheterization laboratory are the control room, the anesthesia cart and vital signs monitoring system, the imaging system, the data-processing/archiving system, and the data review and report station.

Imaging Equipment.

Imaging is an essential component of the catheterization procedure. Although not required for access, it is necessary for maneuvering the catheter. X-ray imaging remains the standard even though alternatives have

been tested, such as MRI, especially in children. The standard high-resolution x-ray imaging system operates in two modes: fluoroscopy and cine mode (cinefluorographic system). It consists of an x-ray tube that generates x-rays from electrical power under control of an x-ray generator, and a flat-panel x-ray detector, which produces a digital video image. This image is then processed, displayed, and stored. A feedback circuitry from the digital video processor to the x-ray generator enables adaptation of the x-ray output to imaging demands.[8] The frame rate and energy output are the corresponding determinates for radiation exposure and can be set by the operator. Furthermore, modern imaging systems allow for fluoroscopy storage, image processing, and road mapping as a standard tool to reduce exposure. Iodine-based contrast material serves as a positive contrast for x-ray imaging. It is injected either manually by a free syringe or manifold or in an automated manner. The volume of the individual contrast administration is usually limited to 10 mL based on the syringes typically used; however, 20-mL syringes have been used. For larger volumes (e.g., for filling of cardiac chambers), power injectors have been used.

Radiation Safety.

As low as reasonably achievable (ALARA) radiation has become the governing principle for the use of radiation to reduce both deterministic and stochastic effects. Even applying this principle, the radiation dose for cardiac catheterization is in the range of 1 to 10 millisieverts, typically 3 to 5 mSv, which is equivalent to 2 to 3 years of natural background radiation.

Deterministic effects are dose related, increasing in severity with increasing dose, typically once a threshold is exceeded. Cataracts and hair loss are examples, but skin injury is the most common deterministic effect, ranging from skin erythema, which can develop in hours, to desquamation and skin necrosis, developing over days to weeks. A reference point for the dose at the patient's skin level has thus been defined, termed the *interventional reference point,* when isocentric interventional equipment is used, and is located 15 cm (6 inches) from the x-ray tube on the central axis of the x-ray beam.[8]

Stochastic effects such as neoplasms and genetic defects are related to probability and not dose, although the likelihood increases with increasing exposure. An approximation of the total x-ray energy delivered to the patient therefore serves as a measure of the risk for stochastic effects. This is expressed as the *dose-area product*, which is the absorbed dose to air (air kerma) multiplied by the cross-sectional area of the x-ray beam at the point of measurement.[8]

Best practices to minimize radiation exposure include minimization of fluoroscopic beam time, use of beam collimation, application of the least magnification possible, and optimal positioning of the x-ray tube-image receiver unit with avoidance of extreme angles and rotation of the radiographic projection during long procedures. The estimated patient dose is continuously recorded, and warnings can be issued when certain levels are reached. State regulations vary but may state that procedures with an air kerma of 6000 milligray (mGy) or higher require reporting to an institutional radiation safety committee with documented patient follow-up.[9]

Similarly, all laboratory personnel exposed to radiation are required to record their exposure. It is recommended that at least two film badges be worn: one on the outside of the apron at the neck and the other under the apron at the waist. The latter monitors the effectiveness of the lead apron. The maximum allowable whole-body radiation dose per year for those working with radiation is 5 roentgen-equivalents-man (rem = 50 mSv), or a maximum of 50 rem in a lifetime.[8] Exposure reduction is accomplished by maximizing the distance from the x-ray source and scatter using appropriate shielding, lead aprons, thyroid collars, lead eyeglasses, and movable leaded barriers. Avoiding severely angulated views decreases radiation exposure to the operator as well by reducing scatter. The highest-risk angulation in this regard is the left anterior oblique (LAO) projection.

Physiologic Monitors.
All patients are adequately prepared for continuous monitoring of vital signs, including cardiovascular and respiratory status. Respiratory rate and oxygen saturation are tracked continuously by peripheral pulse oximetry. Cardiac rhythm is likewise continuously monitored with a surface electrocardiogram (ECG), mostly the three Einthoven leads. Systemic blood pressure is measured in regular intervals of only a few minutes by an automated system using an upper arm cuff. Once access is obtained, blood pressure measurement is supplemented by the use of fluid-filled catheter-tubing system connected to strain gauge pressure transducers and transmitted to a monitor. Catheterization laboratories performing hemodynamic evaluations furthermore need analyzers to measure arterial blood gases (ABGs) and the coagulation status by activated clotting time (ACT).

Accreditation

To gain proficiency in catheterization, the Accreditation Council for Graduate Medical Education set the requirements for level 1 at a minimum of 100 procedures over 4 months and for level 2 at 200 procedures over 8 months. For level 3, interventional catheterization, a total of 250 procedures over 20 months is required.

Thereafter, for proficiency to be maintained, cardiac catheterization laboratories for adults should perform a minimum of 300 procedures per year. The minimum volume for practicing physicians, however, has not been established. This is in distinction from PCI, even though a shift in focus has occurred toward quality. Regular quality assessments are recommended, and publically available outcome reports are now available. The laboratory director should have at least 5 years of catheterization experience and should be board-certified in interventional cardiology if PCIs are performed. The director is responsible for credentialing of physicians; review of laboratory, physician, and ancillary personnel performance; and provision of necessary training.

Catheterization Laboratory Protocol

Preprocedural Preparation of Patient

Every cardiac catheterization procedure needs to be properly planned. It begins with the referring physician, who should consider identifying the right patient for the right procedure, which is to be performed in the right manner for the right outcome.[4] AUC are in place to guide this process, and in general, the lower the level of appropriateness rating, the more documentation needs to be provided justifying the procedure. The benefits of the procedure relative to its risks need to be clearly explained. This equation varies by type of procedure and clinical status of the patient. In general, the risk of major complications and mortality related to cardiac catheterization is less than 0.5% and 0.08%, respectively (**Table 19.1**). For this reason, it is thought that the procedure can be performed with a relatively low risk even in the most critically ill patient. Most contraindications are currently viewed as “relative” (**Table 19.2**), except for inadequate equipment or catheterization facility. As outlined in the 1999 ACC/AHA coronary angiography guidelines, it is also a contraindication to perform a catheterization in patients who would not want further actions to be taken or in patients in whom nothing is to be gained in terms of management decisions, quality of life, or life expectancy. Accordingly, it is important to outline not only the potential risks and complications but also the potential benefits. Patients are ready to dismiss misconceptions once the correct information is provided with important implications for their choice of modes of therapy.[10] Shared decision making has thus been emphasized in the most current guidelines for

the management of patients with stable ischemic heart disease and remains an important principle in general.[11] Informed consent needs to be documented, as does code status and potential advance directives.

TABLE 19.1

Diagnostic Catheterization-Related Complications in Patients Without ST-Elevation Myocardial Infarction*

COMPLICATION	%
Any adverse event	1.35
Cardiogenic shock	0.24
Heart failure	0.38
Pericardial tamponade	0.03
Stroke (% of total hemorrhagic)	0.17 (9.16)
New requirement for dialysis	0.14
Non–risk adjusted in-hospital mortality	0.72
Non–risk adjusted in-hospital mortality, excluding CABG patients	0.60
CABG performed during admission	7.47
Salvage/emergency CABG	0.01/0.27
Urgent/elective CABG	5.27/1.92
Any bleeding event within 72 hours of the procedure	0.49
Any other vascular complication requiring treatment	0.15

*N = 1,091,557.

CABG, Coronary artery bypass graft surgery.

TABLE 19.2

Relative Contraindications to Diagnostic Cardiac Catheterization

- Acute gastrointestinal bleeding
- Severe hypokalemia
- Uncorrected digoxin toxicity
- Anticoagulation with INR >1.8 or severe coagulopathy
- Previous anaphylactoid reaction to contrast media
- Acute stroke
- Acute renal failure or severe chronic non–dialysis-dependent kidney disease
- Unexplained fever or untreated active infection
- Severe anemia
- Recent cerebrovascular event (<1 month)
- Uncooperative patient
- Pregnancy

From Davidson CJ, Bonow RO. Cardiac catheterization. In Mann DL et al, editors. Braunwald's Heart Disease: A Textbook of Cardiovascular Medicine. 10th ed. Philadelphia: Elsevier; 2012.

Once an appropriate shared decision has been made, the preprocedural evaluation should confirm or dismiss any relative contraindications and prepare the patient and the team. Vital elements are history of present illness (chief complaint/health issue to be addressed in the current care session of the patient) and past medical history, with particular emphasis of prior cardiac and vascular events and procedures. Comorbidities such as diabetes mellitus, chronic kidney disease, liver disease, hematologic diseases (e.g., heparin-induced thrombocytopenia), and infectious diseases (e.g., HIV, hepatitis) need to be recorded as well as the related medications. Any prior allergic reactions to drugs, latex, or contrast material need to be reviewed, as well as any prior problems with anesthesia. The physical examination should document heart, lung, and vascular access status as well as the volume and neurologic status. Laboratory tests should include complete blood count with platelets, serum electrolyte determinations with creatinine, and estimated glomerular filtration rate (eGFR). A time frame of 2 to 4 weeks of the procedure is sufficient unless a change in clinical status has occurred. Prothrombin time (PT) with

international normalized ratio (INR) is now recommended only for patients receiving warfarin or with hepatic or hematologic disease, and a partial thromboplastin time (PTT) for those receiving heparin. Women of childbearing age should have a pregnancy test. A 12-lead ECG is recommended.

Patients in atrial fibrillation receiving anticoagulation need to be advised to discontinue warfarin approximately 3 days before the procedure. The INR should be less than 1.8 for a femoral approach and less than 2.2 for a radial approach to minimize risk for bleeding.[3] The direct thrombin inhibitor dabigatran should be discontinued 24 hours before catheterization in those with eGFR of 80 mL/min or greater, 36 hours if eGFR is 50 to 79 L/min, and 48 hours if 30 to 49 mL/min. If PCI is likely to be performed (in addition to diagnostic catheterization), these timelines should be extended by a factor of 2. Direct Xa inhibitors (rivaroxaban, apixaban, or edoxaban) should be discontinued 24 hours before the procedure if the eGFR is 30 mL/min or higher, otherwise at least 36 hours. In case PCI is a possibility, the timeline for discontinuation is at least 48 hours. Aspirin and other oral antiplatelet agents are continued before the procedure. Patients taking metformin should hold the medication the morning of the procedure and not resume until renal function is stable for at least 48 hours after the procedure.[3]

All patients but especially those with diabetes and chronic kidney disease (CKD) should receive periprocedural hydration to reduce the risk of contrast-induced nephropathy (CIN). It is a class I indication to estimate the risk of CIN in patients who may undergo PCI, and validated risk calculators are available.[12] Diabetes mellitus and baseline renal function impairment are the strongest patient-related risk factors (**see Chapters 51 and 98**). No intervention other than fluid volume has been shown to be effective, but the definite amount depends on baseline fluid status and cardiac function. If tolerated, a total of 1 liter of normal saline should be administered from start to completion of the procedure. It is also important to perform biplane angiography and to limit the amount of contrast material (as a general rule, <3.7 times eGFR).[3]

Patients with a history of anaphylactoid reaction to contrast (angioedema, flushing, pruritus, urticaria, bronchospasm, arrhythmia, shock) or atopic conditions are at highest risk for acute hypersensitivity reactions to contrast and should be adequately prepared to avoid this complication, even though this is less common with arterial than with venous contrast administration.[3] The most common premedication regimens are 60 mg of prednisone the night before and the morning of the procedure; 50 mg of prednisone 12 hours, 7 hours, and 1 hour before the procedure; 100 mg of hydrocortisone 12 hours and immediately before the procedure; or 200 mg of hydrocortisone 2 hours before the procedure. Cimetidine (300 mg by intravenous push or by mouth), a nonselective histamine antagonist, and diphenhydramine (25 to 50 mg by IV push) may also be given just before the procedure. Patients with medication and food allergies might have a predisposition, but they are usually not premedicated, and no special preparation is required for those with a shellfish allergy. In addition to acute reactions, it is important to be aware of possible delayed hypersensitivity reactions, presenting with fever and rash up to 48 hours after the procedure. Acute hemodynamic and electrophysiologic complications during the catheterization are less common with the current use of low- and iso-osmolar contrast material.

Although some institutions have opted away from a strict fasting policy, it is still recommendable to have patients fast before the procedure: no liquids up to 2 hours before and no solid food up to 6 hours before the procedure.[3] The fasting status and vital status are assessed in the cath lab preparation area along with a number of other parameters. IV access for hydration and drug administration is placed as well as ECG telemetry and pulse oximetry.

In contrast to its early beginnings, cardiac catheterization is no longer tied to hospitalization, and the vast majority of cases are performed as (hospital-based) outpatient practice. Patient groups that may benefit from preprocedural hospitalization for preparation for diagnostic catheterization include those

with severe congestive heart failure, those with stage 4 CKD requiring additional preprocedural hydration, and those receiving oral anticoagulation who need to but cannot be bridged by low-molecular-weight heparin (e.g., mechanical heart valve patients).

Intraprocedural Care

Only patients who are fully ready should be transferred to the catheterization laboratory; **eFig. 19.1** provides a sequence algorithm.[13] Once all monitoring is in place, the patient is draped in a sterile manner, and with all team members present, a procedural briefing should be performed. This should include the patient's name and medical record number, the procedure to be performed, the need and availability of necessary equipment, patient's allergies and premedications, renal and anticoagulation status, antiplatelet therapy status if intervention might become a consideration, and signed informed consent. Some institutions have also started to document the AUC preprocedurally. Comprehensive preprocedural checklists have also been used and are recommendable to maintain a uniform standard.[5]

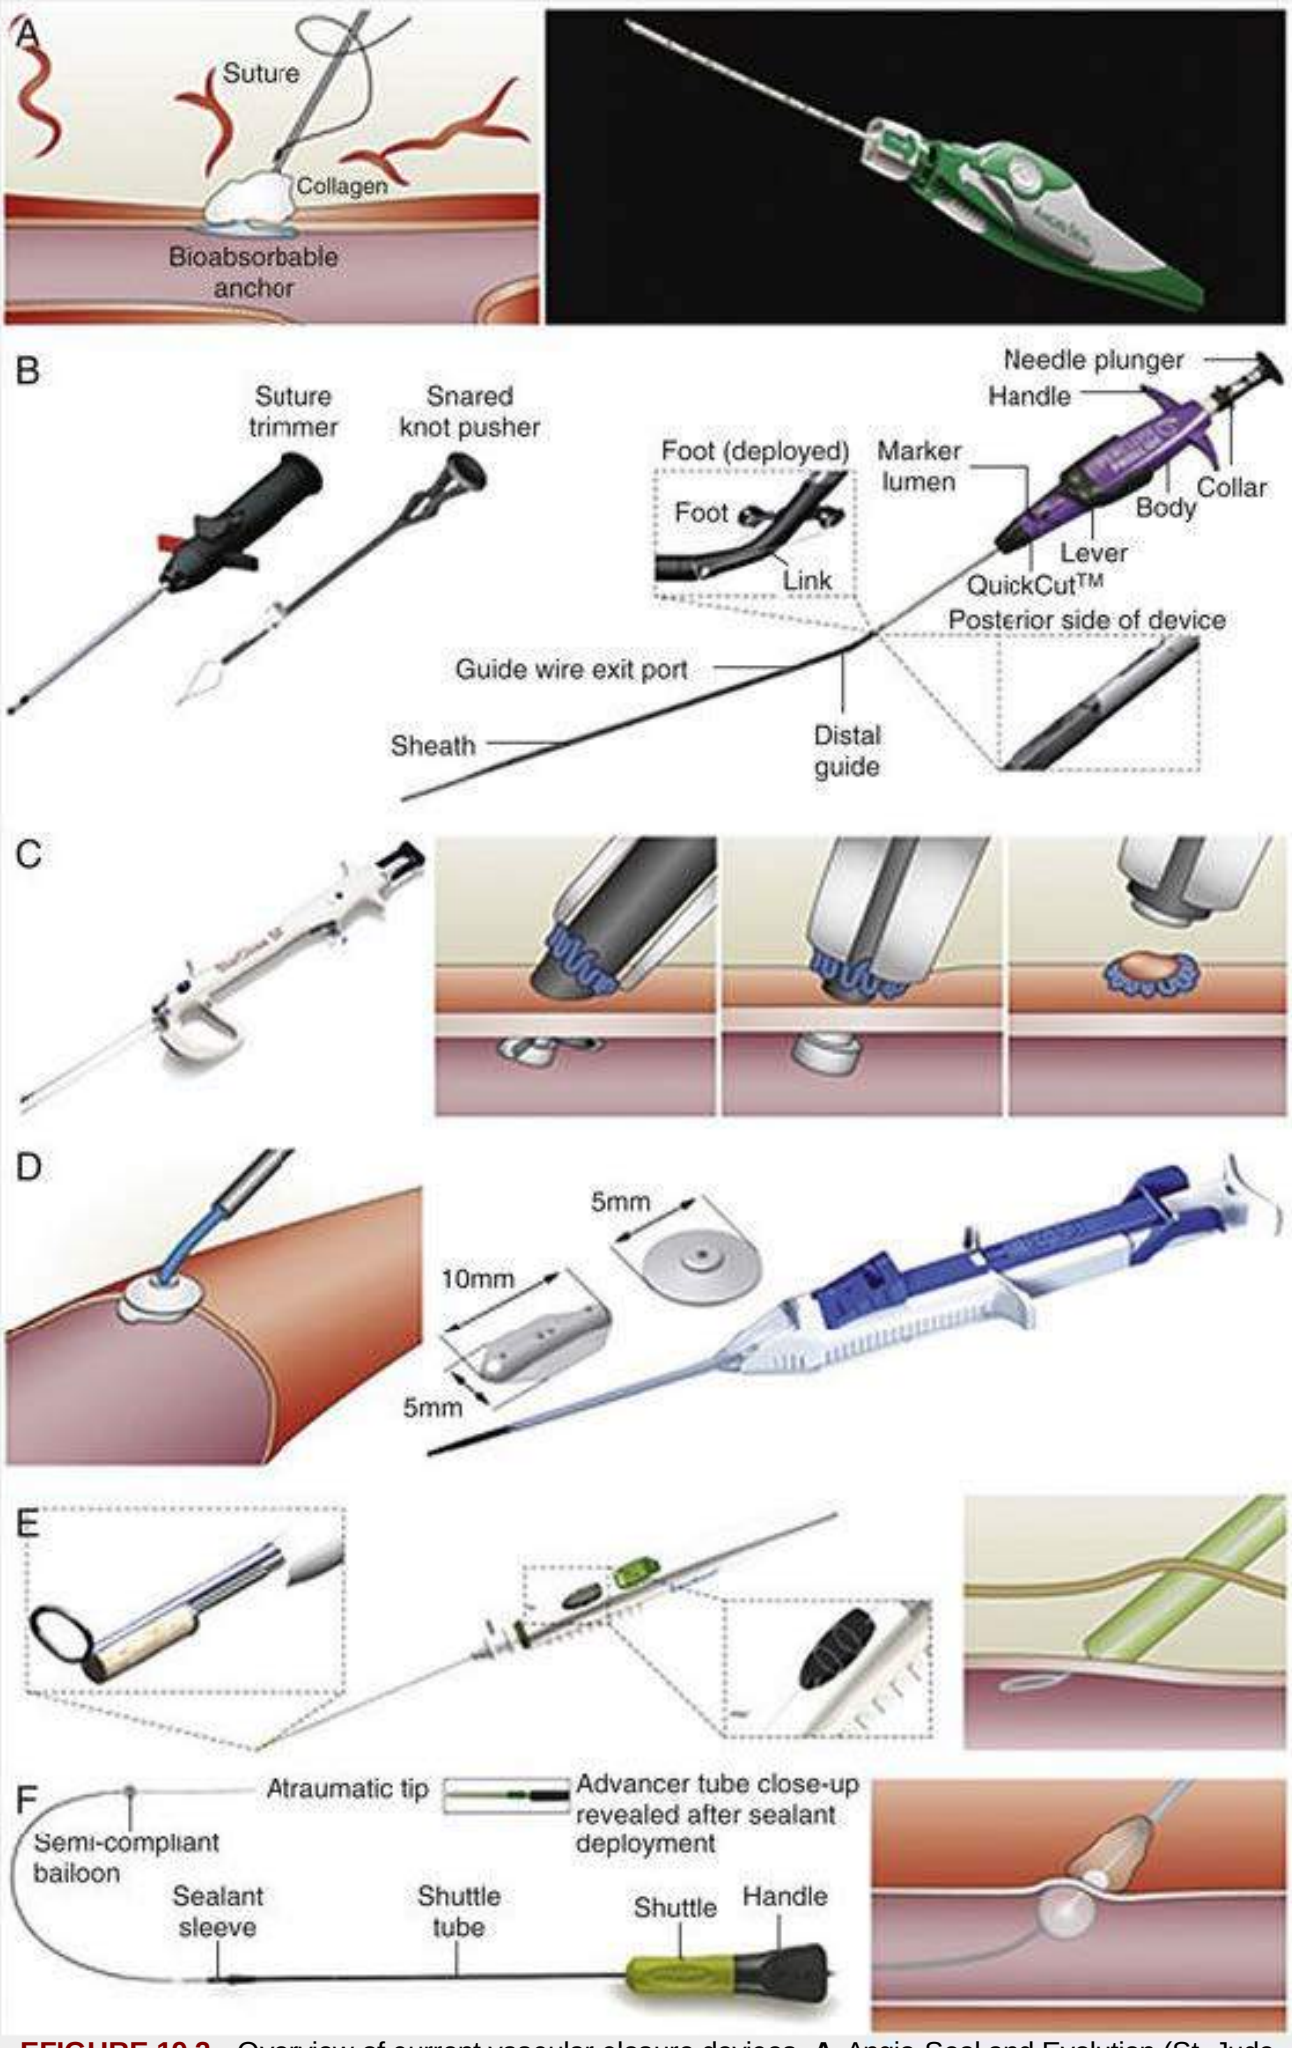
(From ACC/AHA/SCAI 2014 health policy statement on structured reporting for the cardiac catheterization laboratory: a report of the American College of Cardiology Clinical Quality Committee. J Am Coll Cardiol 2014;63:2591.)

If a hemodynamic catheterization is requested, this should be done before any contrast exposure, which could otherwise influence measurements given its vasoreactive properties. Similarly, one may obtain radial access but should avoid further manipulation and need for vasodilatory drugs until all hemodynamic measurements are complete. Leg elevation is another variable to consider, sometimes done to facilitate internal jugular venous access. Depending on the clinical presentation, the outlined sequence may change, as in patients with ST-segment elevation myocardial infarction (STEMI) or in cardiogenic shock; coronary angiography and intervention should be performed first, and any additional hemodynamic catheterization as needed thereafter.

Postprocedural Care

After completion of the procedure, the patient is transferred to a monitored bed and the postcare area. If only a diagnostic cardiac catheterization was performed, most patients can be discharged within 2 to 6 hours after the procedure unless some high-risk features are present, complications occurred, or supportive care is needed such as hydration or anticoagulation. In some instances, patients may also transfer directly to hospital services, such as those with heart failure and Swan-Ganz catheter placement for invasive monitoring. Any catheters other than those for hemodynamic monitoring are removed before the patient leaves the laboratory. The same applies to radial access sheaths, using an inflatable wristband for hemostasis and a deflation protocol thereafter. With femoral access, either a vascular closure device or manual compression is used. The latter is most often done in the postprocedural area. Firm pressure is applied approximately 2.5 to 5 cm (1 to 2 inches) above the skin incision point for 10 minutes, followed by bed rest for 2 hours in case of 4F-6F sheaths and 3 to 4 hours for sheaths greater than 6F. Venous sheaths are removed either in the catheterization laboratory or in the postprocedural area and require approximately 5 to 10 minutes of firm compression.

Vascular closure devices may be of benefit for patients who do not tolerate long periods of bed rest after femoral arterial access or those receiving anticoagulation (**eFig. 19.2**). These devices have not proved superior to manual compression in general, and may in fact be inferior in multiple vascular access attempts.[14] Vascular closure devices do play an important role in cases of large-bore access, which have become relatively common now in the era of TAVR with sheath sizes of 18F to 24F.



EFIGURE 19.2 Overview of current vascular closure devices. **A,** Angio-Seal and Evolution (St. Jude

Medical). **B,** Perclose Proglide (Abbot Vascular). **C,** Starclose (Abbot Vascular). **D,** FemoSeal (St. Jude Medical). **E,** Exoseal (Cordis EMEA). **F,** Mynx (AccessClosure). (From Byrne RA et al. Vascular access and closure in coronary angiography and percutaneous intervention. Nat Rev Cardiol 2013;10:27.)

Bleeding remains the most common complication and reason for postprocedural hospitalization. A distinction is made between access site and non–access site bleeds. The latter type can reflect underlying comorbidity unmasked by the anticoagulation and antiplatelet therapy of the procedure (e.g., peptic ulcer disease) or a complication of the procedure (e.g., pericardial bleed). Importantly, although often not as apparent initially, non–access site bleeds are often more relevant in terms of prognosis.[15] The anatomic location and severity of the bleed are important determinants of overall outcome. While more common after therapeutic than diagnostic catheterization, vigilance in terms of prevention, recognition, and management is still mandatory.

Access-site bleeds can present as minor oozing, more brisk bleeding, ecchymosis, or hematoma formation. The latter is considered a major vascular complication and is captured as a quality metric in registries such as the CathPCI registry of the ACC. Local hematoma larger than 5 cm, although likewise more common after PCI, are still noted in about 1 in 20 patients after diagnostic catheterization.[16,17] As a preventive effort, all sheaths should be removed as soon as possible, in case of anticoagulation with heparin once the activated clotting time is below 160 to 180 seconds and after 2 hours in case of bivalirudin and normal renal function. Protocols for sheath removal and after care should be in place, including distal extremity and blood pressure evaluation.

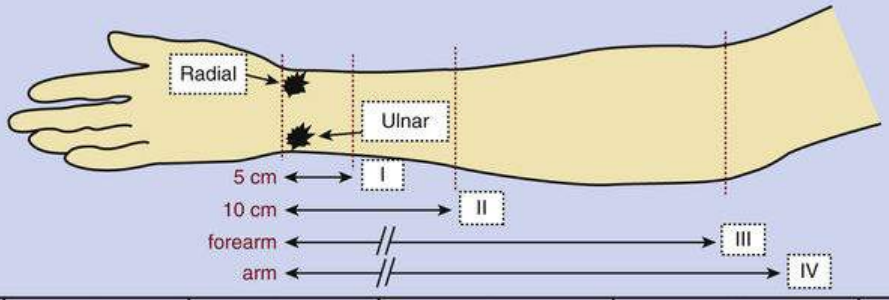
Other major vascular complications include retroperitoneal bleeding, pseudoaneurysm, arteriovenous fistula formation, and occlusion requiring arterial repair or thrombectomy, as well as infection. The incidence of major vascular complications combined is approximately 0.20% in the current era.[18] Related to the shift from the femoral to the radial access route, these complications have become less common with PCI but remain of concern with femoral access for structural cases. Historically, the rate of retroperitoneal hematoma was as high as 6%, whereas more recently it is 0.5%. Female gender, lower body mass index, and higher femoral arterial puncture site (above the upper third of femoral head) are the main risk factors. A retroperitoneal hematoma should be suspected in patients with unexplained hypotension and tachycardia, the latter being a distinguishing feature from vagal reactions, even though bradycardia may occur as well. In decreasing order, the most common presenting symptoms of retroperitoneal hematoma are hypotension (92%), diaphoresis (58%), groin pain (46%), abdominal pain (42%), back pain (23%), and bradycardia (31%). Some patients present with urinary or bowel urgency, peritoneal signs/irritation, and/or femoral neuropathy.[19] A hemoglobin drop on serial complete blood counts usually lags behind, and the interpretation may be confounded by the administration of fluid (and sometimes other blood losses) during the procedure. Thus, CT of the pelvis and abdomen should be performed as clinical suspicion demands. Thereafter, or even as a first step, an angiographic approach might be taken to visualize the vascular injury site and either aim to occlude it percutaneously or direct toward surgery. The risk of surgical repair is higher in patients of advanced age, with congestive heart failure, or a larger body surface area.

Ultrasound is the test of choice with concern for vascular complications more local to the access site, such as pseudoaneurysms. These communications between the artery and the overlying fibromuscular tissue result in a blood-filled cavity. They are classically seen with a low or lateral femoral artery puncture, excessive anticoagulation at the time of sheath removal, or inadequate compression of the puncture (access) site. The acceptable incidence is less than 0.2%, but studies have indicated an incidence as high as 3%.[20] The typical presentation is groin tenderness, a palpable pulsatile mass, and a systolic bruit. Sizes less than 2 cm represent a low likelihood of rupture and may be followed clinically

with serial ultrasound to document spontaneous thrombosis. For pseudoaneurysms larger than 2 cm in size, ultrasound-guided manual compression with or without thrombin or collagen injection is the treatment of choice. Covered stent placement or surgery are rarely required.

Arteriovenous (AV) fistulas have been reported to occur at an incidence of 0.25% to 1%, likewise more common with low femoral accesses (i.e., below the femoral head). Pain, swelling, and bruit are signs and symptoms similar to pseudoaneurysms, and ultrasound is again diagnostic. Most fistulas are very small and go undetected. Intervention is required only if significant shunting occurs (stent graft or vascular surgery).

After radial artery catheterization, vascular complication and access-related bleeding can be more subtle, and unnoticed and untreated hematoma can progress to the point of forearm compartment syndrome. Pain and paresthesia should serve as warning signs, and protocols for easy recognition and management have been developed (**eFig. 19.3**). Adequate hemostasis is important, but it is also critical to maintain patency of the radial artery, especially at sheath removal and shortly thereafter. Compression of the ipsilateral ulnar artery limited to this acute phase has sufficed to reduce radial artery occlusion.[21] Additional administration of vasodilators and adequate anticoagulation are important interventions. Otherwise, radial artery occlusion rates can be as high as 15% acutely and 3% to 5% chronically.



GRADE	I	II	III	IV	V
INCIDENCE	≤5%	<3%	<2%	≤0.1%	<0.01%
DEFINITION	Local hematoma, superficial	Hematoma with moderate muscular infiltration	Forearm hematoma and muscular infiltration, below the elbow	Hematoma and muscular infiltration extending above the elbow	Ischemic threat (compartment syndrome)
TREATMENT	Analgesia Additional bracelet Local ice	Analgesia Additional bracelet Local ice	Analgesia Additional bracelet Local ice Inflated BP cuff	Analgesia Additional bracelet, Local ice Inflated BP cuff	Consider surgery
NOTES		Inform physician	Inform physician	Inform physician	STAT call to physician
REMARKS	- Control blood pressure (BP) (importance of pain management) - Consider interruption of any anticoagulation and/or antiplatelet infusion - Follow forearm and arm diameters to evaluate requirement for additional bracelet and/or BP cuff inflation - Additional bracelet(s) can be placed alongside artery anatomy - Ice cubes in a plastic bag or washcloth are placed on the hematoma - Finger O_2 saturation can be monitored during inflated blood pressure cuff - To inflate blood pressure cuff, select a pressure of 20 mm Hg < systolic pressure and deflate every 15 minutes - After bracelet removal, use "Velpeau bandage" around forearm/arm for a few hours to maintain mild positive pressure				

EFIGURE 19.3 EASY trial hematoma grading scale with corresponding treatment strategies. (From Rao SV, Bernat I, Bertrand OF. Clinical update: remaining challenges and opportunities for improvement in percutaneous transradial coronary procedures. Eur Heart J 2012;33:2521-6.)

Overall, minor complications occur in approximately 1 in 25 patients undergoing routine cardiac catheterization, with the most common being transient hypotension and brief episodes of chest discomfort. The differential diagnostic considerations for hypotension, besides vasovagal reactions and severe (retroperitoneal) bleeds, should also include a contrast reaction, even though other manifestations should be present. Hives are less common with low-osmolar contrast agents and intra-arterial

administration; anaphylactoid reactions are very rare. IV corticosteroid and diphenhydramine are the main agents. Epinephrine is reserved for severe reactions, such as anaphylactic shock. Patients with severe allergic reactions and anaphylaxis should be observed at least overnight.

In patients with chest pain, the differential diagnosis is broad. If coronary angiography was performed, a dissection should be ruled out as well as embolization, especially if the aortic valve was crossed. The risk of myocardial infarction is 0.05%.[18,22]

If a right-heart catheterization was performed, the differential should include pulmonary embolism, pulmonary infarction, and pulmonary artery or right ventricular (RV) perforation. The most common complications of right-heart catheterization, however, are minor, nonsustained atrial or ventricular arrhythmias. Any patient with chest pain should have a 12-lead ECG, and those with significant changes, especially ST-segment elevation and after coronary angiography, should be taken back to the catheterization laboratory.

The risk of neurologic complications is 0.03% to 0.2%.[18,22] Those with severe aortic atherosclerosis and aortic stenosis are at higher embolic risk. After retrograde crossing of a stenotic aortic valve, neurologic deficits may be clinically apparent in as many as 3% of patients, and the incidence of focal acute cerebral embolic events may be as high as 22% by MRI.[23] Neurologic deficits can be noted at the time of or within a few hours after the procedure, and it is not clear whether the mechanisms differ by time of presentation.[24] The length of the procedure, volume of contrast material, urgent indications, and use of intra-aortic balloon pumps (IABPs) are known to increase the risk for stroke. Patient-related risk factors include diabetes mellitus, hypertension, previous stroke, and renal failure.[25] *Transient cortical blindness* needs to be distinguished from true stroke events. It is characterized by loss of perceived vision in conjunction with a normal neurologic examination occurring from minutes to 12 hours after angiography. Headaches, memory loss, and mental status changes can be present. Resolution begins within a few hours but it may take days to fully return to normal.[26] Furthermore, strokes should be distinguished from other conditions, including seizure, migraine, hypoglycemia, and encephalopathy. Standard stroke management with a multidisciplinary team is important to improve prognosis.

Death related to diagnostic cardiac catheterization is rare (0.08% to 0.75%) and mainly predicted by the clinical presentation. The strongest predictors are heart failure (especially advanced stages), hypotension and shock, acute coronary syndrome, severe aortic or mitral valve disease, renal failure, and moribund state. Patients with these conditions, especially in their complicated stage, are often referred to the cardiac catheterization laboratory as part of their hospital care. Other patient groups, such as those with critical coronary artery disease (e.g., severe left main stenosis), may need to be admitted to the hospital in response to the diagnostic findings for further management planning.

Technical Aspects and Procedural Performance

Arterial Access

Percutaneous Femoral Artery Technique

The standard access for many years has been the common femoral artery (CFA), also known as the Judkins technique. Familiarity with the anatomy is important, and the point of entry is 1 to 3 cm (1 to 2 fingerbreadths) below the inguinal ligament, in line with the palpable course of the CFA (**Fig. 19.2**). The inguinal crease can be misleading in obese as well as very thin individuals. In clinical practice the optimal point of skin entry over the inferior edge of the femoral head is therefore often identified under

fluoroscopy using a hemostatic clamp. Alternatively, ultrasound can be used to define the anatomy (**eFig. 19.4**). Ultrasound has been shown to improve first-pass success rates, reduce vascular complications in general, and might be useful particularly in patients with a diffuse pulse caused by scarring after multiple prior procedures.[27] The critical importance of the right location cannot be overemphasized, because too high of a location increases the risk of retroperitoneal hematoma, and too low increases the risk of pseudoaneurysm, AV fistula formation, and cannulation of the superficial femoral artery with sizes too small to accommodate any larger-sized sheaths or vascular closure devices. Further, a position off the femoral head does not leave an optimally firm backboard for hemostatic compression.

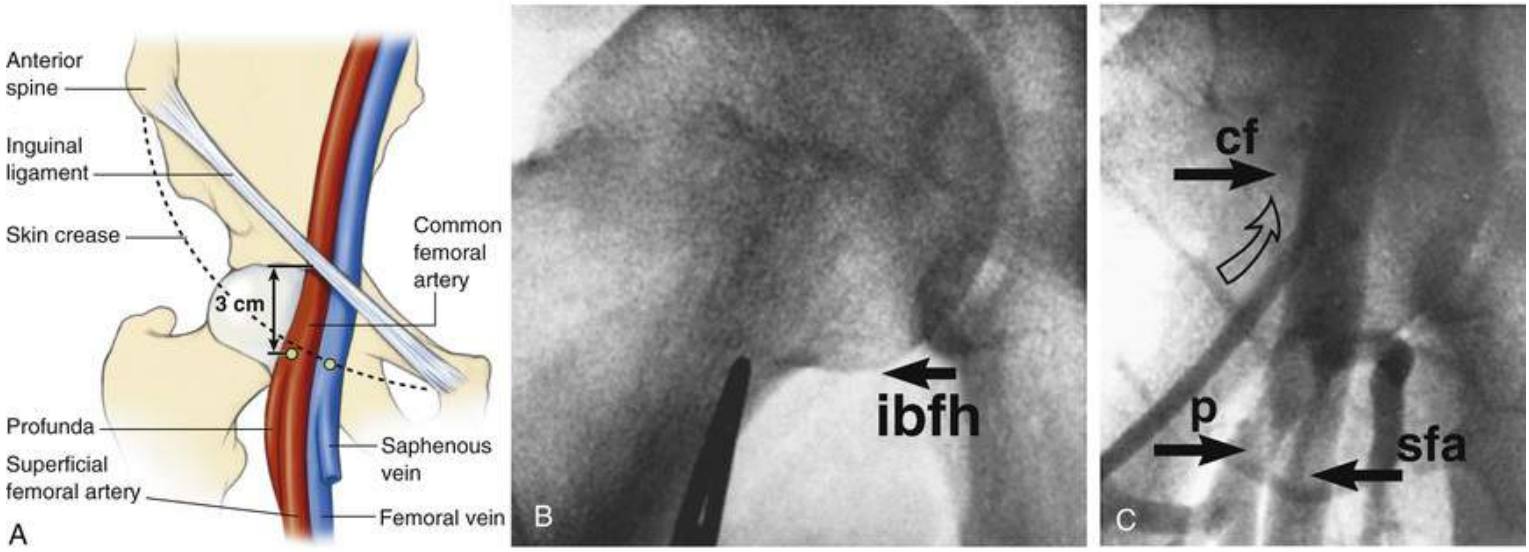


FIGURE 19.2 **A,** Schematic diagram showing the femoral artery and vein anatomy. The arterial skin nick should be placed approximately 3 cm below the inguinal ligament and directly over the femoral arterial pulsation; the venous skin nick should be placed at the same or lower level but approximately one fingerbreadth more medially. **B,** Localization of the skin nick by fluoroscopy and use of a hemostat, the top of which should point to the inferior border of the femoral head (*ibfh*). **C,** Catheter insertion (*open arrow*) into the common femoral artery (*cf*), above the bifurcation into the superficial femoral artery (*sfa*) and profunda (*p*) branches. (From Baim DS, Grossman W. Percutaneous approach, including transseptal and apical puncture. In Baim DS, Grossman W, editors. Cardiac Catheterization, Angiography, and Intervention. 7th ed. Philadelphia: Lea & Febiger; 2006, p 81.)

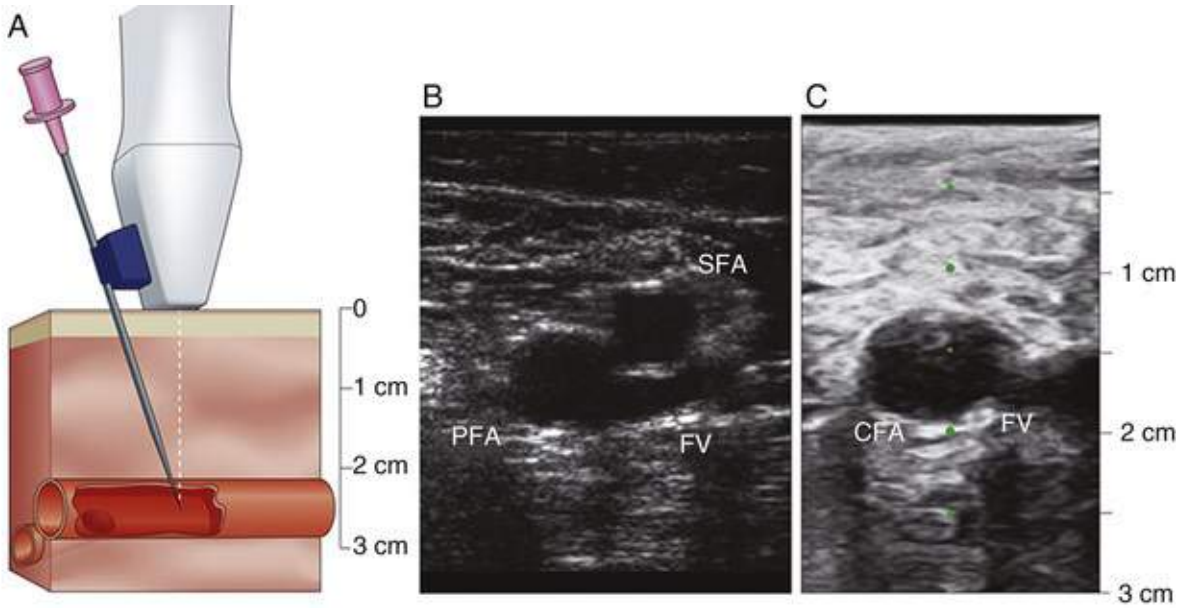

EFIGURE 19.4 Ultrasound-guided femoral artery access. **A,** The attached needle guide fixes the needle's angle of entry to intersect the vessel at the imaging plane 1.5 cm, 2.5 cm, or 3.5 cm below the skin, depending on the guide chosen. The vessel bifurcation is kept inferior to the probe at the time of insertion. **B,** The right femoral artery bifurcation is imaged in the axial plane, identifying the separation of the profunda femoral artery (*PFA*) and superficial femoral artery (SFA). Compression is used to differentiate arteries from the femoral vein (*FV*). **C,** The probe is moved superiorly until the common femoral artery (*CFA*) is visualized. During needle advancement, the anterior wall of the vessel is kept under the central target line, which indicates the path of the needle. (From Seto A et al. Real-time ultrasound guidance facilitates femoral arterial access and reduces vascular complications: FAUST (Femoral Artery Access with Ultrasound Trial). JACC Cardiovasc Interv 2010;3:751.)

Once conscious sedation and local anesthesia with 1% lidocaine (Xylocaine) are accomplished, a small transverse skin incision is made, and using the modified Seldinger technique (**Fig. 19.3**), an 18-gauge thin-walled needle is inserted at a 30- to 45-degree angle into the CFA. The backflow of blood should be solid and pulsatile; if not, one should suspect that the needle is either not freely or not at all in the lumen of the CFA. Once in the correct position, a 0.035- or 0.038-inch J-tip polytetrafluoroethylene (Teflon)–coated guidewire is advanced through the needle into the artery. The wire should pass freely, and if not, and particularly if the patient expresses any pain, the location of the wire needs to be defined carefully. Symptoms usually indicate vascular trauma such as dissections or perforations, which should be recognized immediately. Thus, while the advantages of the Judkins technique are the relative ease, speed, and reliability, experience and vigilance are still required to ensure quality and safety.

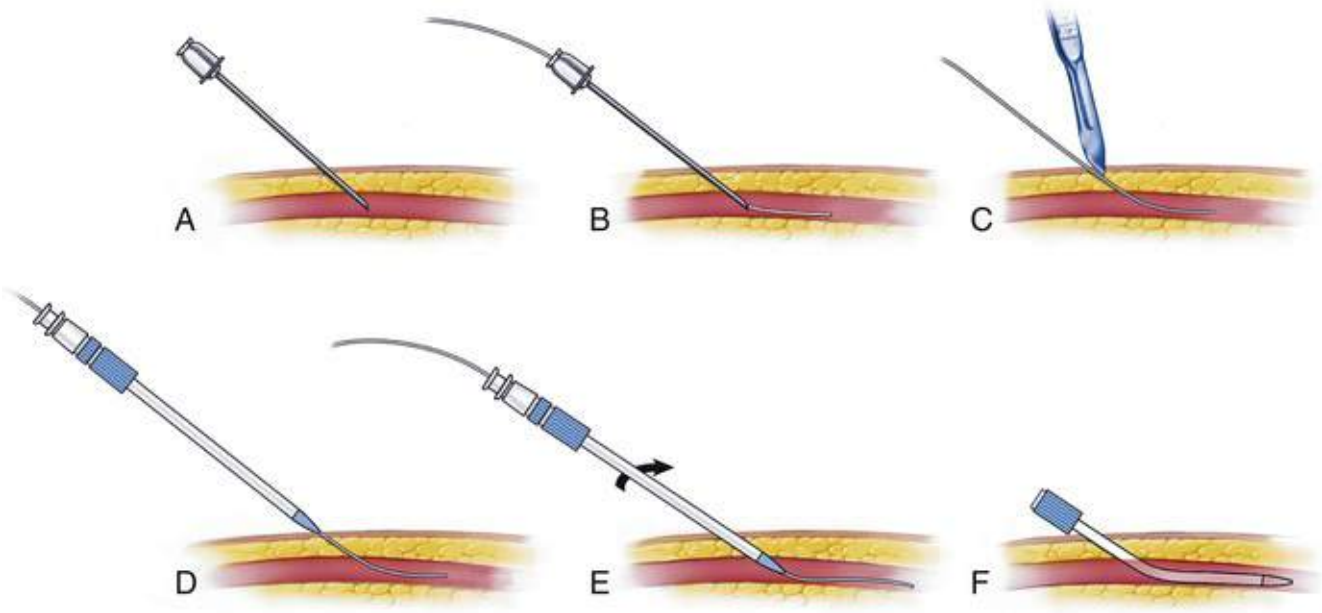

FIGURE 19.3 Modified Seldinger technique for percutaneous introduction of the catheter sheath. **A,** Vessel punctured by the needle. **B,** Flexible guidewire placed into the vessel through the needle. **C,** Needle removed, guidewire left in place, and hole in skin around wire enlarged with a scalpel. **D,** Sheath and dilator placed over guidewire. **E,** Sheath and dilator advanced over guidewire and into the vessel. **F,** Dilator and guidewire removed while sheath remains in the vessel. (From Hill JA, Lambert CR, Vlietstra RE, Pepine CJ. Review of general catheterization techniques. In Pepine CJ, Hill JA, Lambert CR, editors. Diagnostic and Therapeutic Cardiac Catheterization. 3rd ed. Baltimore: Williams & Wilkins; 1998, p 107.)

The femoral artery technique is disadvantageous for patients unable to endure long bed rest times, those with high bleeding risk, and those with peripheral artery disease (PAD). Patients with bleeding risk and PAD require careful assessment to ascertain that distal limb perfusion is adequate still during sheath placement and even once catheters are advanced, because some stenoses can be of a critical degree. Even if not of critical degree, iliofemoral stenoses may pose challenges to the retrograde passage of catheters, as does tortuosity. In fact, it might become necessary to opt early for a long sheath (>20 cm) to overcome tortuosity because it opposes catheter manipulation and can be of such a degree that the approach needs to be aborted as friction eliminates torquability, kinks compress the lumen, or length does not suffice. Any long sheath needs to be carefully placed under fluoroscopy. Similarly under careful fluoroscopic guidance, torquable floppy-tipped wires (e.g., Glidewire) may need to be used to advance to the aorta. A Judkins right or multipurpose catheter can be used to provide support, kept within short distance from the guidewire tip. On occasion, an extrastiff Amplatz-type guidewire is needed but may cause discomfort due to vessel folding and kinking. Long exchange-length wires are recommended in these difficult cases for any subsequent catheter exchanges. The dwell time of any wire should be kept to 2 to 3 minutes in consideration of the risk of thrombus formation (despite anticoagulation).

The sheath size should be at least equal to the catheter size used. Unfractionated heparin is no longer routinely given for diagnostic cardiac catheterization; however, for those with anticipated prolonged procedures, 2000 to 3000 units may be administered by IV push. In patients arriving on heparin, an ACT should be obtained after access and any further anticoagulation directed accordingly. Even though often mentioned, routine administration of protamine after the procedure to reverse the effect of heparin is not recommended. Hypotensive reactions can occur, especially in patients with diabetes and insulin use. Femoral sheaths should not be removed until the ACT is less than 160 to 180 seconds, unless a vascular closure device is being used.

Patients with a history of PAD require particular attention to history and physical examination. Before the procedure, one should carefully review what types of interventions were performed in the past (e.g.,

balloon angioplasty, patch endarterectomy, arterial conduits, prosthetic grafts). The anatomy should be defined, and additional mapping might become necessary. Suitability at the access point as well as patency to accommodate the equipment proximally is important. Prosthetic peripheral vascular grafts are likely the most problematic, not necessarily because they cannot be penetrated, but rather because of the aftercare to avoid lack of closure as well as thrombotic occlusion. For this reason, these grafts are usually avoided unless no other option is available, in which case the smallest possible access is taken and the procedural extent minimized. Complications arising from femoral access are outlined in the postprocedural care section.

Percutaneous Radial Artery Technique

Radial access has gained popularity in recent years as associated with a lower risk of bleeding and the ease on the patient postprocedurally. Documentation of adequate dual blood supply to the hand by either the Allen or the Barbeau test is recommended. The Allen test entails manual compression of the radial and the ulnar artery during fist clenching until blanching of the hand, at which point the pressure over the ulnar artery is released. Under normal conditions, normal color returns within 10 seconds, and significant reactive hyperemia is absent on release of pressure over the radial artery. The Barbeau test is performed similarly, only with the use of pulse oximetry; it has higher accuracy and reproducibility[28] (**Fig. 19.4**).

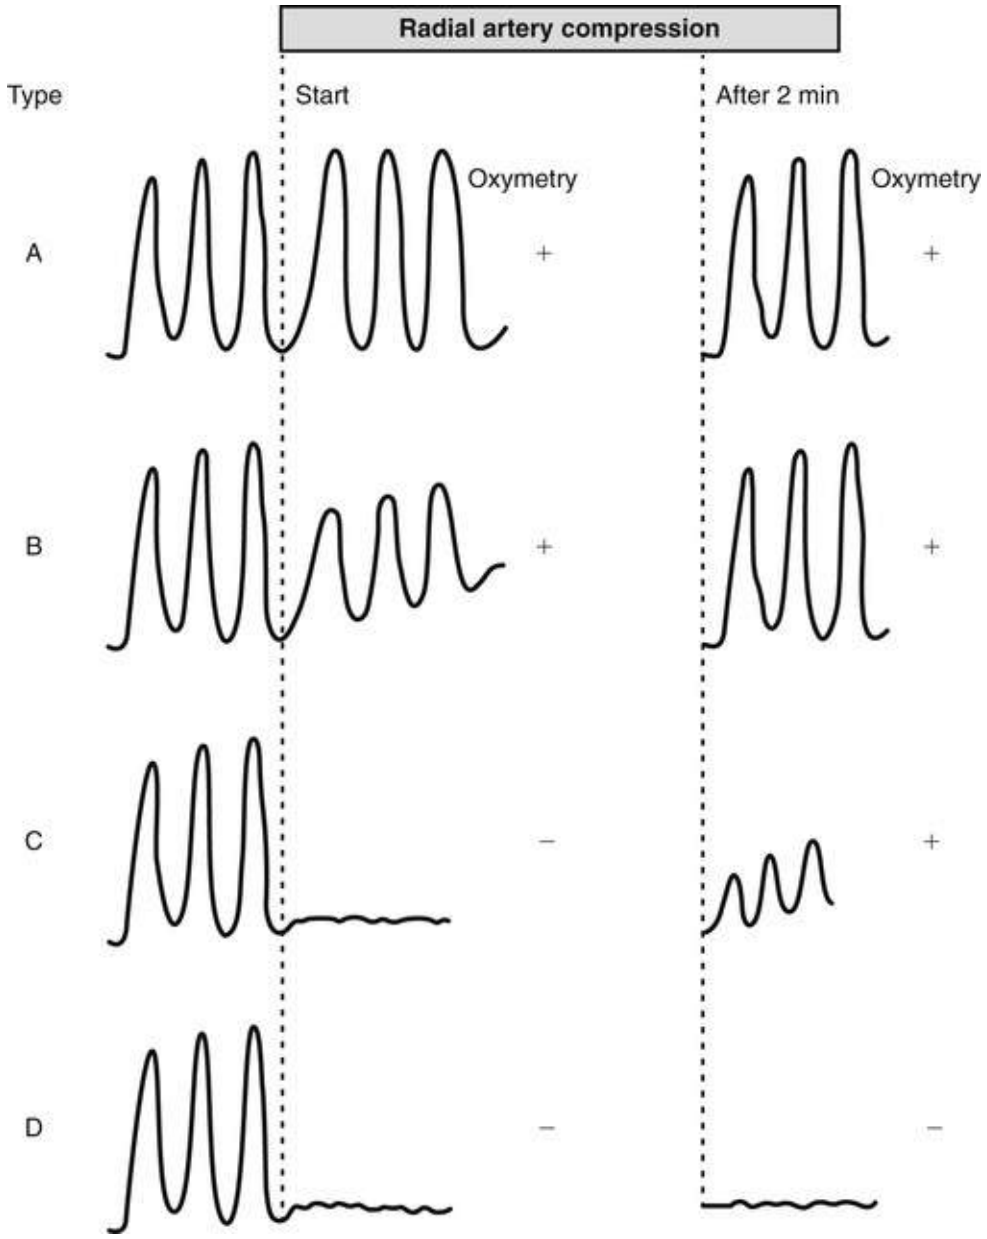

FIGURE 19.4 Four types of ulnopalmar arch patency findings based on plethysmography and oximetry, as recorded with the finger clamp applied on the thumb. Patients with a type **D** response should not undergo transradial catheterization of that wrist. (From Barbeau GR, Arsenault F, Dugas L, et al. Evaluation of the ulnopalmar arterial arches with pulse oximetry and plethysmography: comparison with the Allen's test in 1010 patients. Am Heart J 2004;147:489-93.)

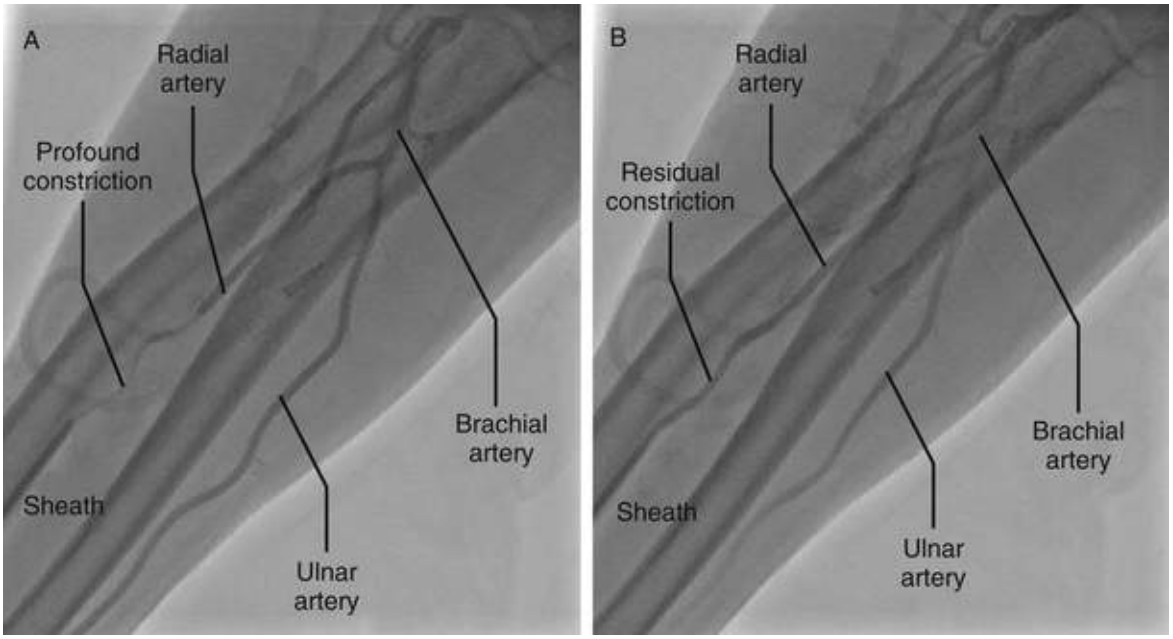
In preparation for radial access, the arm should be placed on an appropriate board and abducted at a 30- to 45-degree angle, and the wrist should be hyperextended over a gauze roll. Unless prompted by anatomy or demand (e.g., left internal mammary artery injection), the right radial artery is used. Its distal course can be mapped by palpation or ultrasound; the latter has been shown to improve first-pass rates here as well.[29] Only up to 1 mL of 1% lidocaine is injected at the skin entry site, which should be approximately 1 to 2 cm (1 inch) proximal to the styloid process of the radius. The radial artery is accessed by either a micropuncture needle (anterior wall technique) or a 20-gauge angiocath needle (posterior wall technique) at a 30- to 45-degree angle. Thereafter, a 0.025-inch wire is introduced very carefully, and one should not proceed if any resistance is felt similar to the femoral access technique. Once a wire is placed safely, a sheath is introduced, again very carefully. Practices differ, but one should consider smaller sizes for women (4F to 5F) but larger sizes (6F; maximum 7F in men) if PCI is likely. Overstretching of the artery is to be avoided because it leads to higher postprocedural occlusion rates. A longer sheath has been considered to protect more against vasospasm at the level of the forearm.[30]

However, other studies suggest that it is the hydrophilic coating rather than the length of the sheath that reduces spasms.[31]

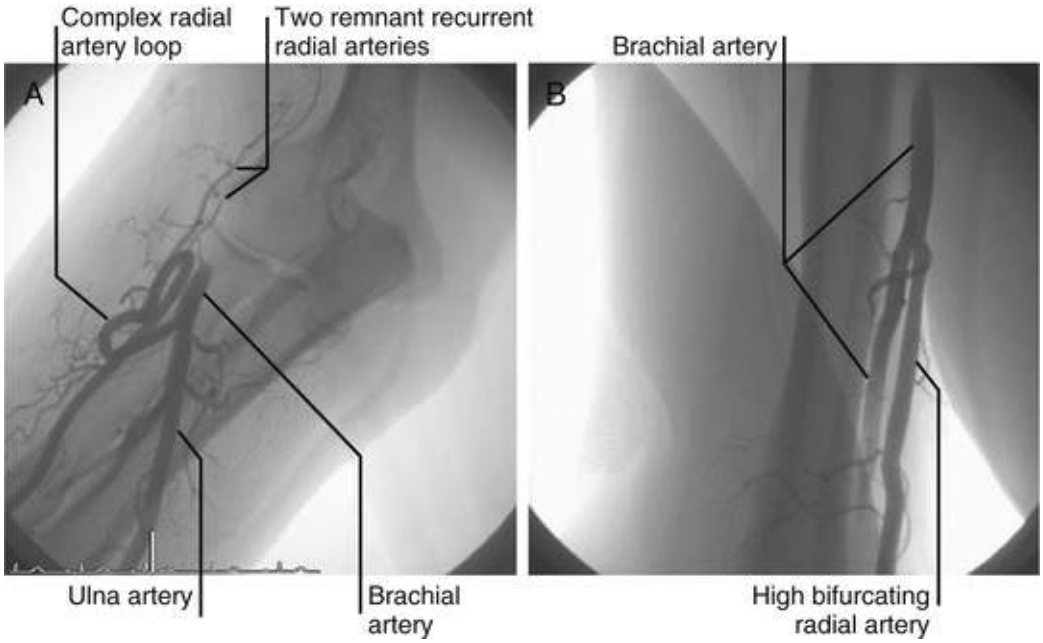
Typical sheath dimensions used for radial access are 4F to 6F in size and 7 to 16 cm in length. Once the sheath is in place, typically 5000 units of unfractionated heparin is given as a bolus, or weight adjusted (50 units/kg), preferably intravenously to prevent postprocedural radial artery occlusion. Arterial vasospasm is a complicating factor and is prevented by adequate sedation, avoidance of limb cooling, and administration of vasodilators (**eFig. 19.5**). Most often, nitroglycerin (100 to 200 µg) and verapamil (2.5 mg) are given. Other approaches are sublingual nitroglycerin and intra-arterial (local) administration of diltiazem or nicardipine. With these preparations, catheters can be advanced over a standard 0.035-inch J-tip wire into the ascending aorta.



EFIGURE 19.5 **A,** Right radial angiogram illustrating profound vasoconstriction directly after the access sheath. **B,** Resolution with administration of 2.5 mg of verapamil and 400 µg of nitroglycerin through the sheath.

Since the anatomic course may not be as straight, the J-tip wire and catheter should only be gently advanced[32] (**eFig. 19.6**). Challenges in advancement can often be overcome by a Glidewire or a Runthrough coronary guidewire (both Terumo Interventional Systems). These wires tend to cannulate not only the main lumen but also side branches more easily and should be exchanged once the catheter is advanced to the brachiocephalic level. In case of radial artery or brachial artery dissection, the procedure can often still be continued because the catheter itself will serve to tamponade. Closure, however, should be documented, as with its initial recognition, with angiography using a 50/50 mix of saline and contrast material. Injection of contrast material is also useful to visualize tortuosity, which can pose major challenges not only distally but also for engagement of the ascending aorta. In these cases the catheter might need to guide the wire around the origin of the brachiocephalic artery rather than vice versa. Deep inspiration can also be helpful under these circumstances. For difficult cases, it is recommended not to lose position and to use an exchange-length 0.035-inch J-tip wire for any additional catheter exchange. The use of diagnostic catheters designed for radial approaches and both coronary ostia (e.g., Tiger catheter) can ease the procedure. Once complete, the equipment is removed, including sheath, and a wristband with an inflatable balloon cuff is used to achieve hemostasis. To avoid thrombotic occlusion,

the site is allowed to bleed back before the cuff is inflated to 2 cc over hemostasis level. Practices should have protocols that guide the deflation process and monitoring of the pulse and perfusion status. “Patent hemostasis” is the key term for care after radial artery access.



EFIGURE 19.6 Anatomic variations of the radial artery. **A,** Large complex radial loop and remnant (recurrent) radial artery. **B,** High bifurcation of radial artery at the level of the midhumerus. (From Rao SV, Stone GW. Arterial access and arteriotomy site closure devices. Nat Rev Cardiol 2016. doi:10.1038/nrcardio.2016.133.)

While the main advantages are reduced risk of bleeding and lack of bed rest requirements, potential disadvantages include, besides propensity for vasospasm and thrombotic radial artery occlusion, dissections and compartment syndrome, limited catheter stability, and poor coronary engagement. Also, the radial artery is not the best approach if larger sheath sizes are required (e.g., for bifurcation interventions). Presentation and management of complications from radial access are summarized in the postprocedural care section (see **eFig. 19.3**).

Randomized controlled trial (RCT) comparisons between the radial versus the femoral approach have been made primarily in cohorts with STEMI. A meta-analysis of 12 studies with 5000 patients showed that a radial approach was associated with a nearly 50% decrease in mortality and major bleeding risk.[33] These primary benefits were confirmed subsequently in 8400 patients with acute coronary syndrome (ACS), with or without STEMI, randomized to a radial or femoral access for coronary angiography and PCI; radial access was associated with a 30% reduction in major bleeding and all-cause mortality.[34]

Percutaneous Brachial Artery Technique

The brachial artery approach is similar to the femoral artery approach but rarely used, as replaced by the radial technique. Using the Seldinger method, a 4F to 6F sheath is placed into the brachial artery and flushed with 3000 to 5000 units of heparin. Subsequent maneuvers are similar to those previously described. Proficient hemostasis after removal of the sheath is critical; the arm should be maintained straight on an arm board for 4 to 6 hours, with close observation of the radial and brachial pulses, access site, and upper arm size.

The main advantage of the brachial artery for percutaneous access is the larger luminal size than the radial artery and accessibility when other access options have failed. This includes access for patients

with severe peripheral arterial disease or such a degree of vascular tortuosity or body size that even with the use of extra-long coronary catheters, the coronary ostia cannot be reached. The percutaneous approach is easier than the cutdown of the brachial artery, which was in fact the first technique introduced for coronary artery catheterization by Sones and colleagues. Given the anatomic location, the access site is very close to the x-ray generator tube or image intensifier, depending on the angle. It may therefore lead to greater x-ray exposure and restriction of angiographic views.

Venous Access

With any concomitant procedure involving the femoral artery, the femoral vein is used most often for venous access. However, when the right-heart catheter is left in place after the procedure, the internal jugular approach is preferable (Videos 19.1 and 19.2). This approach improves patient comfort and allows the patient to sit up in bed. The internal jugular is preferred over the subclavian approach to lessen the risk for pneumothorax. Use of a micropuncture kit with a 21-gauge needle and introducer can minimize potential trauma from inadvertent puncture of the carotid artery or lung. When the jugular vein has been entered, the micropuncture assembly can be exchanged for any larger sheath (e.g., 7F) often used for right-heart catheterization or right ventricular biopsy. In addition, routine adjunctive use of portable vascular ultrasound probes can help to locate and verify the patency of the jugular vein.

For femoral venous access, the femoral artery is the anatomic landmark. The femoral vein is located 1 cm medial to the femoral artery, which is the distance to be taken from the arterial pulse in the horizontal plane, and another 1 cm caudal in the vertical plane. In patients with severe tricuspid regurgitation, venous pulsations should not be mistaken for arterial pulsations. Local anesthesia and the modified Seldinger technique are applied as described earlier. Typically, 7F sheaths are used, which accommodate standard right-heart catheters. Some procedures, however, may require a larger-sized access.

The internal jugular vein is located lateral to the carotid artery access in the anatomic triangle of the two heads of the sternocleidomastoid muscle and the clavicle. For access, the patient is instructed to lie supine with the head turned 30 degrees to the contralateral side. Any pillow should be removed. Patients with low venous pressure may require leg elevation to increase filling. The use of ultrasound is recommended to guide access; it has been shown to reduce the overall risk of complications by 70%, carotid artery puncture in particular.[35] A so-called high anterior approach is taken from the top of the outlined anatomic triangle, and the skin incision should not be lower than two fingerbreadths above the clavicle, to decrease the risk of pneumothorax. In patients with larger-sized necks, the anatomy can be difficult to define. Under these circumstances, it is advisable to palpate the suprasternal notch and then move the finger laterally. The first hump is the medial and the second hump the lateral head of the sternocleidomastoid muscle. The inner edge of the second hump is followed in a superior direction to the top of the triangle.[36] Under local anesthesia and using the modified Seldinger technique, venous access is obtained. “Mini access” or small needle kits have been used to increase procedural safety. These kits consist of a 21-gauge needle, a 0.018-inch floppy-tipped guidewire, and a two-piece dilator. Patients who have undergone multiple procedures (e.g., after heart transplantation) may require the use of multiple dilators sequentially progressive in size. The use of hydrophilic sheaths further helps in these scenarios.

Patent Foramen Ovale Cannulation.

Access to the left atrium can be accomplished via a foramen ovale that is patent to a probe, which is the

case in 20% to 30% of adults. For this approach, a multipurpose catheter is used and advanced to the high right atrium/superior vena cava (SVC) junction. With the tip directed medially and slightly posteriorly, the catheter is then slowly withdrawn until a slight forward and medial motion is observed into the foramen ovale. The catheter should then prolapse further into the left atrium with gentle pressure, and the position can be confirmed by the pressure waveform, blood samples demonstrating arterial saturation, or manual injection of contrast medium. If left atrial access cannot be obtained with this technique, transseptal catheterization should be undertaken.

Transseptal Catheterization.

First described by Brockenbrough, Ross, and Braunwald more than half a century ago (see Classic References), transseptal catheterization more than ever has become an essential element in the current era because of the demands for the evaluation and intervention of structural heart diseases and arrhythmias (**Fig. 19.5**).

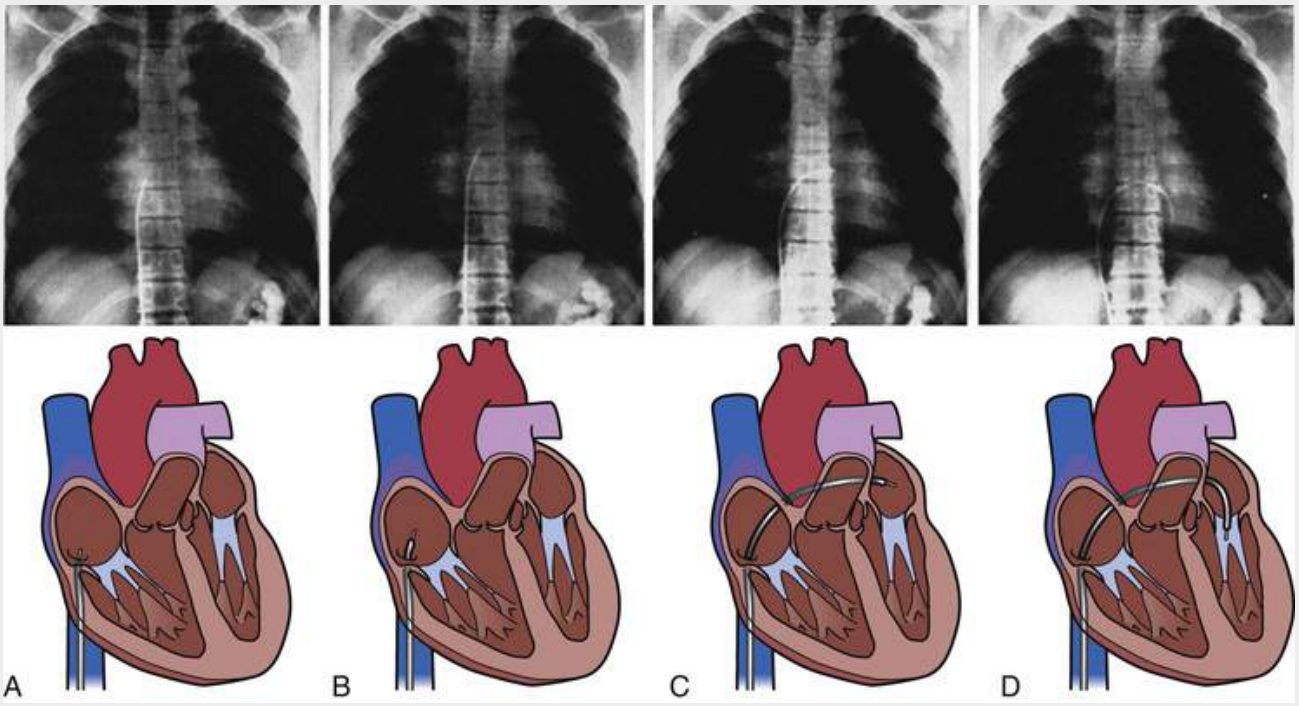


FIGURE 19.5 Steps of transseptal puncture as originally outlined by Brockenbrough and colleagues using a needle that has subsequently become known as the "Brockenbrough needle." **A,** In the first step, a catheter is advanced into the right atrium with the aid of the stylet, which is then withdrawn and replaced by the transseptal needle. **B,** After confirmation of needle tip position in the left atrium, the needle tip is turned from a posteromedial to a medial direction, and the catheter is advanced with the needle until both lie freely within the left atrial cavity. **C,** As the catheter is slipped over the end of the needle, the needle is withdrawn to the point of puncture. **D,** With the needle in place, the tip of the catheter is then advanced into the left ventricle and the needle withdrawn. (From Brockenbrough EC, Braunwald E, Ross J Jr. Transseptal left heart catheterization: a review of 450 studies and description of an improved technic. Circulation 1962;25:15-21.)

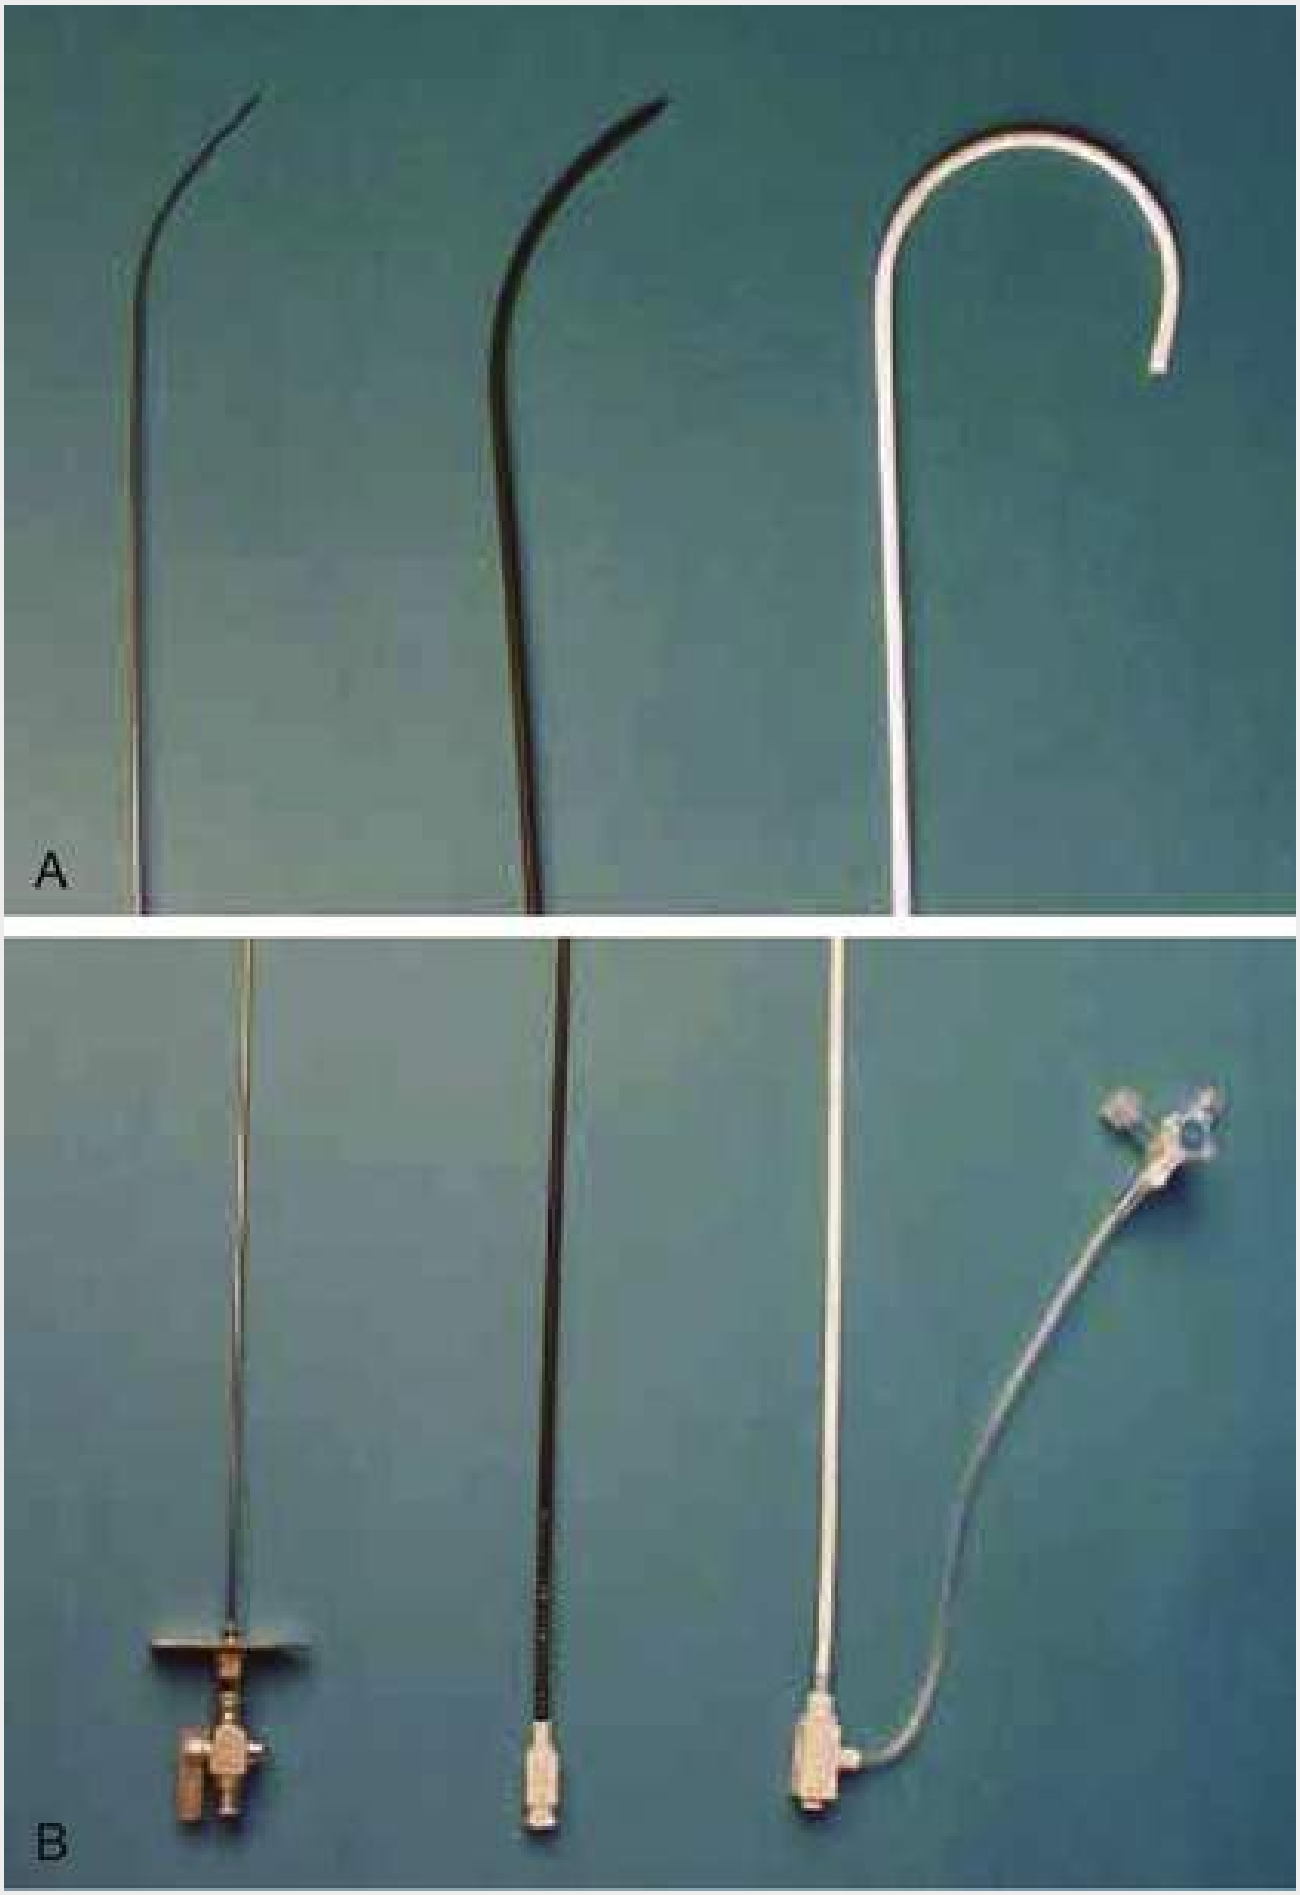
A femoral venous sheath is placed and a 0.032-inch guidewire advanced via the inferior vena cava (IVC) and right atrium into the SVC. Next, an 8F Mullins or transseptal sheath and dilator are advanced into the SVC. The guidewire is then replaced with a Brockenbrough needle, which is an 18-gauge needle that tapers to 21 gauge at the distal tip and whose distal port connects to a pressure manifold (**eFig. 19.7**). The tip of the needle is advanced just proximal to the tip of the Mullins sheath. The entire catheter system is then drawn back into the right atrium and simultaneously rotated from a 12 to a 5 o'clock position. Two abrupt rightward movements should be noted. The first reflects the descent of the catheter

from the SVC into the right atrium, and the second reflects the catheter passing over the limbic edge into the fossa ovalis. Steady gentle pressure may suffice to advance the dilator and needle as a unit through the fossa ovalis into the left atrium. If not, the sheath is held in place toward the fossa ovalis and directs the advancement of the needle across the interatrial septum. Transesophageal or intracardiac echocardiography (**see Chapter 14**) can be helpful, especially in difficult cases (e.g., large right atrium, postsurgical condition, anatomic variant). Once left atrial position in confirmed by the overall increase in pressure, contrast injection, or measurement of oxygen saturation, the unit is rotated toward the 3 o'clock position, and the dilator and sheath are safely advanced 2 to 3 cm into the left atrium. While holding the sheath firmly, the dilator and needle are removed. If pressure measurement or left ventriculography is necessary, the catheter can be advanced into the left ventricle with slight counterclockwise rotation.



EFIGURE 19.7 Transseptal catheters. **A,** Distal catheters. **B,** Proximal catheter. *Right,* Mullins transseptal sheath. *Middle,* Introducer (dilator) placed inside the sheath to add stiffness to the catheter. *Left,* Brockenbrough transseptal needle that is placed inside the sheath and used to penetrate the septum.

The major risk of transseptal catheterization is the puncture of structures within or adjacent to the left

atrium, such as atrial free wall, left atrial appendage, coronary sinus, aortic root, or pulmonary artery. The complication rate in experienced centers is no higher than 1%, with success rates of about 90%.[37] The risk for pericardial tamponade is limited in patients who have previously undergone cardiac surgery because mediastinal fibrosis is present.

Direct Transthoracic Left Ventricular Puncture

This approach is used only if pressure measurement or left ventriculography is necessary and the patient has mechanical prosthetic valves in both the mitral and the aortic position. Mechanical (tilting disc) valves should not be crossed with a catheter because of the risk for catheter entrapment, occlusion of the valve, or possible dislodgment and embolization of the disc[38,39] (**see Chapter 71**).

After localization of the left ventricular (LV) apex by echocardiography and administration of local anesthesia, an 18- or 21-gauge 6-inch Teflon catheter system is inserted at the upper rib margin and directed slightly posteriorly and toward the right second intercostal space until tactile contact with the apical impulse is made. At that point, the needle and sheath are advanced into the left ventricle, the stylet and needle are removed, and the sheath is connected for pressure measurement. For the transapical approach, an intercostal incision is made, and the LV apex is directly exposed for apical puncture using the Seldinger technique. The risks of this procedure include cardiac tamponade, hemothorax, pneumothorax, laceration of the left anterior descending coronary artery, embolism of LV thrombus, vagal reactions, and ventricular arrhythmias.

Left-Heart Catheterization

As in most cases, catheters will not simply advance into the left ventricle; crossing the aortic valve requires careful technique (**Fig. 19.6**). A common approach is the use of a straight pigtail catheter, advanced over a 0.035-inch J-tip guidewire to the level of the aortic valve. The wire is then pulled back into the catheter, allowing its tail to take a “figure 6” configuration in the right anterior oblique (RAO) projection. The catheter is subsequently pushed against the aortic valve to form a U shape. With deep inspiration or under pullback and clockwise rotation, the tip usually falls into the left ventricle. Inside the left ventricle, the catheter resumes again a “6” configuration in the RAO projection with the loop directed toward the apex. The catheter is positioned in front of the mitral valve, but not to interfere with its function or become entangled in the chordae. Repeated repositioning may be required to eliminate ventricular ectopy. The Halo catheters represent an alternative to the pigtail catheters (see Classic References, Caracciolo). They possess a tip with a perpendicular helix, inwardly and upwardly directed, and do not have 6 to 12 side holes along the shaft as do pigtail catheters. These features allow for less ectopy during injections and superior ventricular pressure measurements in hypertrophic cardiomyopathy (HCM).

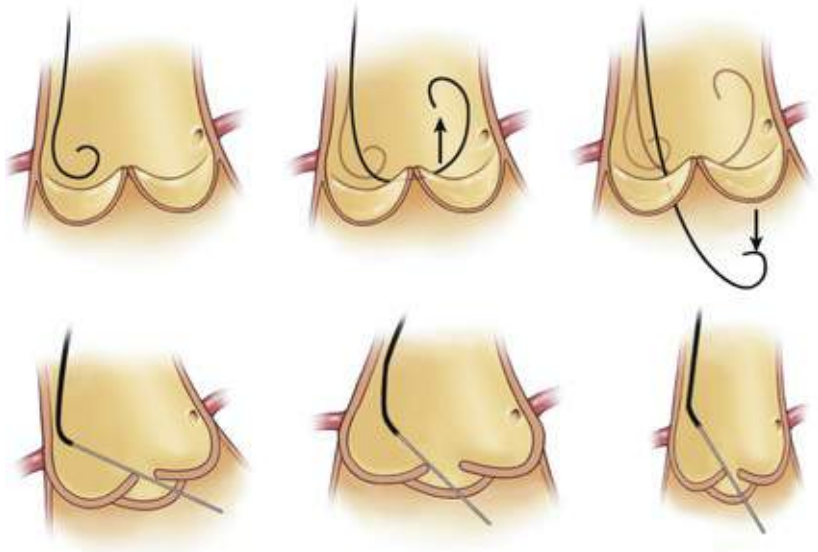


FIGURE 19.6 Technique for retrograde crossing of an aortic valve by a pigtail catheter. **Upper row,** Technique for crossing a normal aortic valve. **Bottom row: Left,** Use of a straight guidewire and pigtail catheter in combination. Increasing the length of the protruding guidewire straightens the curve of the catheter and causes the wire to point more toward the right coronary ostium; reducing the length of the protruding wire restores the pigtail contour and deflects the tip of the guidewire toward the left coronary artery. When the correct length of wire and the correct rotational orientation of the catheter have been determined, repeated advancement and withdrawal of the catheter and guidewire together allow retrograde passage across the valve. **Middle,** In a dilated aortic root an angled pigtail catheter is preferable. **Right,** In a small aortic root a right coronary Judkins catheter may have advantages. In patients with bicuspid valves an Amplatz left catheter is often used because it directs the wire more superiorly.
(From Baim DS, Grossman W. Percutaneous approach including transseptal and apical puncture. In Baim DS, Grossman W, editors. Cardiac Catheterization, Angiography, and Intervention. 6th ed. Philadelphia: Lea & Febiger; 2006, p 93.)

With dilated aortic roots or horizontally oriented hearts, an angled pigtail catheter is preferable, whereas small aortic roots may require a right coronary Judkins for initial wiring and subsequent replacement with a pigtail catheter. In patients with bicuspid valves, a left Amplatz catheter might be useful for placement of a guidewire into the left ventricle, which directs more superiorly. A left Amplatz is also useful in patients with aortic stenosis, or a multipurpose catheter, depending on the angulation of the aortic valve from left ventricle into ascending aorta (more horizontal or more vertical). On occasion, straight rather than J-tipped guidewires have been used, which facilitates probing of the stenotic aortic valve, but also has greater potential for dislodging material from the aortic valve or aorta.

For pressure measurements and contrast injections in the left ventricle, a pigtail catheter should be used because the risk of damaging the wall is reduced and the risk of entrapment of the mitral valve apparatus is low. The gradient across the aortic valve should be measured by simultaneous recording of pressure in the ascending aorta and left ventricle; pullback gradients do not suffice. Pigtail catheters with a dual lumen (distal and proximal) allow for this measurement, but the concordance of pressure should be verified in the aortic root before and after measurement. An alternative is the use of a multipurpose catheter through which a pressure wire is advanced into the left ventricle while the catheter remains in the aorta. A single multipurpose catheter with an end hole is desirable when an intraventricular or LV outflow tract gradient is in question and differentiation of location is needed (intraventricular, subvalvular, and/or transvalvular). For gradients across the mitral valve, LV and wedge or left atrial pressures are recorded simultaneously with two transducers. LV measurements include systolic, diastolic, and end-diastolic pressure; dP/dt can also be calculated.

Left Ventriculography

Once considered an integral part of every cardiac catheterization, a left ventriculogram is infrequently

performed in the current era given the advances in availability and quality of echocardiography (**see Chapter 14**) and concerns for complications. A left ventriculogram is still indicated for the assessment of LV function, ventricular septal defect (VSD), or quantification of mitral regurgitation (MR). It is, however, not encouraged for patients with severe, decompensated heart failure, if the LV end-diastolic pressure (EDP) is greater than 35 mm Hg, or in those at high risk for CIN.

Ideally, left ventriculography should be performed in two planes, and biplane x-ray systems are therefore of great value. The main projection is a 30-degree RAO, which covers the high lateral, anterior, apical, and inferior wall (Video 19.3). Higher views might be required in the setting of MR to separate retrograde contrast ejection from the spine or descending aorta. The axillary projection of 45- to 60-degree left anterior oblique (LAO)/20-degree cranial covers the lateral and septal walls and is of great benefit for assessing the extent of regurgitant contrast volume in the setting of MR (Video 19.4). It is also the best projection to visualize a VSD (Video 19.5), as well as an atrial septal defect (ASD), although the contrast injection then is into the pulmonary artery. The pulmonary artery would also be the site of injection for the evaluation of pulmonic regurgitation. As a general rule, contrast is injected just distal to the valve that is to be evaluated.

After the catheter is appropriately placed, it is connected to the power injector with high-pressure tubing, tight and air free. A test injection 5 to 8 mL is advised to confirm proper, free catheter position. The power injector is then programmed to deliver 20 to 50 mL of contrast at 10 to 15 mL/sec. For smoother delivery and so that maximum pressure (900 to 1200 psi) is not reached instantly but more slowly, a 0.2- to 0.5-second rise can be programmed. To facilitate lower contrast volumes, power injections can also be operator controlled and stopped once the ventricle is satisfactorily opacified. Frame rates of 30/sec suffice for heart rates of less than 95 beats/min. Every effort should be made to avoid ectopy because even one or two premature beats can result in over- or underestimation of the severity of MR and in unreliable measures of cardiac function. The same is true for underfilling, which also leads to underestimation of the degree of MR.

The main complications of left ventriculography are cardiac arrhythmias (both supraventricular and ventricular). Intramyocardial contrast staining during power injection can occur but is not clinically relevant if transient. If it persists, however, perforation needs to be ruled out. This is a concern when end-hole catheters such as the multipurpose catheter are used for power injections into the left ventricle, which should never be done. Embolism and contrast-related complications also may be encountered. Transient hypotension of 15 to 30 seconds was relatively common with the use of ionic high-osmolar contrast media but is not typically seen in the current era.

The wall motion pattern ranges from normokinesis to hypokinesis, akinesis, and dyskinesis. The degree of MR is scored by Sellers class and degree of VSD by calculation of the shunt extent.

Ascending Aortography

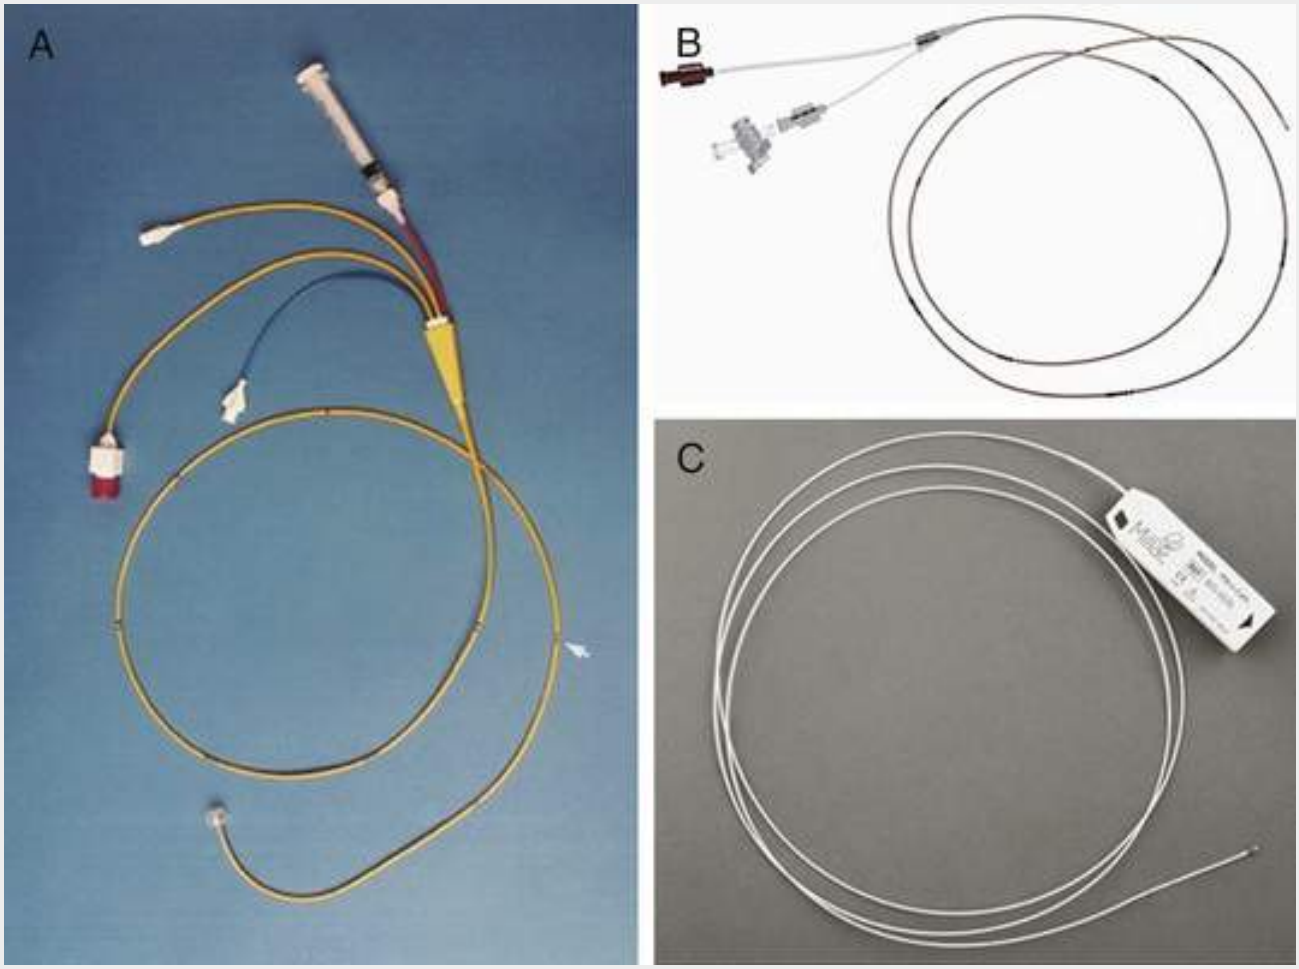
Aortic angiograms are indicated to determine the size of an ascending aortic aneurysm, the presence of aortic dissection, the severity of aortic regurgitation (AR), and the presence of bypass grafts. A side-hole (pigtail) catheter should be used to reduce the risk of aortic injury. In the case of concerns for aortic dissection, one must ascertain that the catheter is not entrapped in the false lumen. The position may be checked with a manual injection of contrast. For dissection, the optimal position is just above the suspected proximal tear, for the aortic valve just above the leaflets. Standard RAO and LAO projections suffice for aortic valve evaluation, and caudal or cranial angulation is of no additional benefit (Video 19.6). The severity of AR is best evaluated in the RAO projection (Video 19.7). The LAO projection is best for the assessment of the ascending aorta, aortic arch, and arch vessels. The typical setup for

power injections is 40 to 60 mL at 15 to 20 mL/sec. Frame rates of 15 frames/sec are adequate.

Right-Heart Catheterization

The right-heart catheterization is one of the central elements in the hemodynamic evaluation in the catheterization laboratory. Percutaneous venous access is accomplished via the internal jugular vein or femoral vein, or less frequently the subclavian or antecubital vein, as previously outlined. The choice of catheter depends on the access approach and clinical scenario.

The Swan-Ganz catheter is the catheter of choice for the internal jugular approach (**eFig. 19.8A**), whereas a so-called pulmonary hypertension Swan is advisable for the femoral approach and for patients with pulmonary hypertension or severe tricuspid valve regurgitation (TR) because it is stiffer and more torquable. End-hole catheters, or "balloon wedge catheters," are equally good for this purpose, with similar rigidity, less catheter whip artifact, and thus higher fidelity (**eFig. 19.8B**), although they lack the capacity to determine cardiac output by thermodilution.



EFIGURE 19.8 **A,** Typical Swan-Ganz catheter. The proximal ports, *left to right,* are the proximal injection hub, thermistor connector, distal lumen hub, and balloon inflation valve with syringe. The distal end of the catheter has a balloon and a distal end hole. The proximal injectate port exits 30 cm from the distal end of the lumen (*arrow*). The thermistor lies just proximal to the balloon. **B,** Example of a balloon wedge catheter (Arrow, Teleflex, Morrisville, NC), which has only one port besides the balloon inflation valve. **C,** Example of a diagnostic pressure catheter (Mikro-Cath, Millar, Houston, Texas). (**A,** From Davidson CJ, Bonow RO. Cardiac catheterization. In Mann DL et al, editors. Braunwald's Heart Disease: A Textbook of Cardiovascular Medicine. 10th ed. Philadelphia: Elsevier; 2012, p 367.)

Using the internal jugular venous approach, the standard Swan-Ganz catheter can be advanced relatively easily into the right atrium and then, with the balloon inflated, into the right ventricle, and on into the pulmonary artery and pulmonary capillary wedge position. Although one can orientate oneself with pressure tracings only, fluoroscopy is advisable, especially if there are any preknown structural and functional difficulties (e.g., severe right atrial enlargement, severe TR, severe right ventricular [RV] dilation). Some maneuvering of the catheter may be required especially in these cases.

The femoral venous approach is technically more demanding because of the acute angle from the IVC into the right ventricle. On occasion, the catheter can be advanced directly through the right atrium and across the tricuspid valve. Once in the right ventricle, the catheter is rotated clockwise so that it points superiorly and directly into the RV outflow tract. Once in the outflow tract, the tip of the balloon usually allows flotation into the pulmonary artery and wedge positions. Deep inspiration or cough can facilitate this maneuver and assist in crossing the pulmonic valve. In patients with high pulmonary artery pressure, a guidewire can be used to stiffen the catheter and allow advancement into the wedge position. However, the operator must use caution to prevent perforation of the pulmonary artery. If the catheter continues to point inferiorly toward the RV apex, another technique should be used because further advancement can risk perforation of the RV apex.

One alternative technique of right-heart catheterization via the femoral approach is to direct the balloon catheter to the lateral right atrial wall and then, by clockwise rotation, posteriorly and up into the SVC (**Fig. 19.7**). The catheter is then pulled back into the right atrium and with another clockwise rotation turned anteromedially, which allows the catheter to face and cross the tricuspid valve. Once the catheter is advanced into the right ventricle with the tip taking a horizontal course, additional clockwise rotation allows the catheter to point up toward the RV outflow tract. The catheter is then advanced into the pulmonary artery and wedge position.

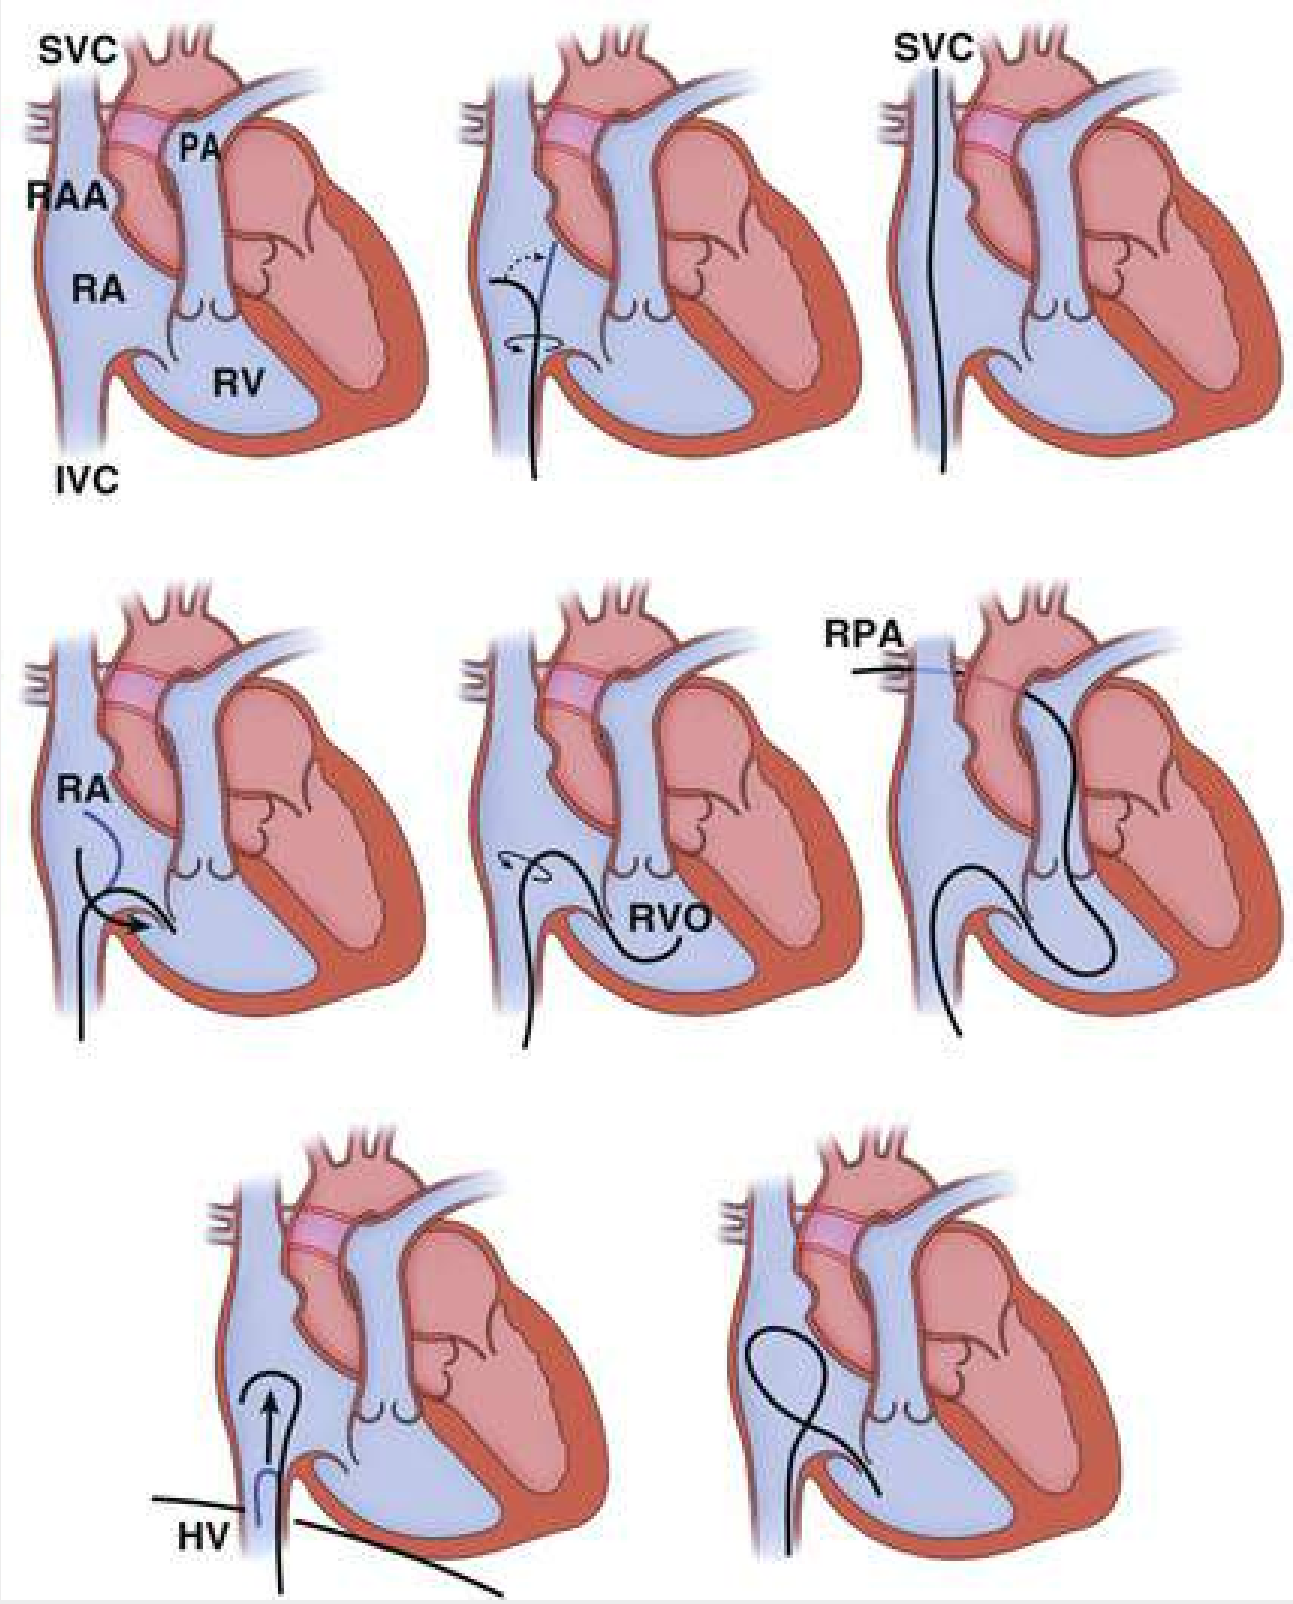


FIGURE 19.7 Right-heart catheterization via the femoral venous approach. **Top row,** The right-heart catheter is initially placed in the right atrium (*RA*) aiming at the lateral atrial wall. Counterclockwise rotation then directs the catheter posteriorly and allows advancement into the superior vena cava (*SVC*). Although it is not evident in the figure, clockwise catheter rotation into an anterior orientation would lead to advancement into the right atrial appendage (*RAA*) and thereby preclude SVC catheterization. *IVC,* Inferior vena cava; *PA,* pulmonary artery; *RA,* right atrium; *RV,* right ventricle. **Center row,** The catheter is withdrawn back into the RA and aimed laterally. Clockwise rotation causes the tip of the catheter to sweep anteromedially and cross the tricuspid valve. With the catheter tip in a horizontal orientation just beyond the spine, it is positioned below the RV outflow (*RVO*) tract. Additional clockwise rotation causes the catheter to point straight up and allows advancement into the main PA and from there into the right PA (*RPA*). **Bottom row,** Two maneuvers useful in catheterization of a dilated right heart. A larger loop with a downward-directed tip may be required to reach the tricuspid valve and can be formed by catching the tip of the catheter in the hepatic vein (*HV*) and advancing the catheter quickly into the RA. The reverse-loop technique **(right)** gives the tip of the catheter an upward direction, aimed toward the outflow tract. (From

Baim DS, Grossman W. Percutaneous approach, including transseptal and apical puncture. In Baim DS, Grossman W, editors. Cardiac Catheterization, Angiography, and Intervention. 7th ed. Philadelphia: Lea & Febiger; 2006, p 86.)

Another technique for the femoral venous approach is to create a loop in the right atrium by hooking the catheter tip on the hepatic vein or by advancing it against the lateral wall of the right atrium. With the loop in place, the catheter is advanced further, and with the tip facing inferiorly and medially, the tricuspid valve is passed and the pulmonary artery and wedge positions are reached. The redundant loop is then removed by slow catheter withdrawal, even into pulmonary artery position, at which point the balloon can be carefully inflated and wedged.

Hemodynamic Data.

The right-heart catheterization allows the measurement of flow (cardiac output), pressures, and vascular resistance. These three central parameters are connected by the Ohm's law: $Q = \Delta P/R$; that is, blood flow is a function of the pressure difference and resistance in the circulatory bed.

Right Ventriculography.

A right ventriculogram is indicated for the assessment of right-to-left ventricular shunts, TR, RV dysplasia, abnormalities of the RV outflow tract (RVOT), and pulmonary stenosis (Video 19.8). A 7F Berman balloon-tipped catheter is used, which has no end hole but eight side holes proximal to the balloon. The anteroposterior (AP) cranial or AP lateral projection is used to visualize the septum and RVOT. Typically, 20 to 30 mL of contrast material is injected at 8 to 10 mL/sec (but if enlarged, could be up to 40 to 50 mL at 12 to 18 mL/sec).

Hemodynamic Measurements

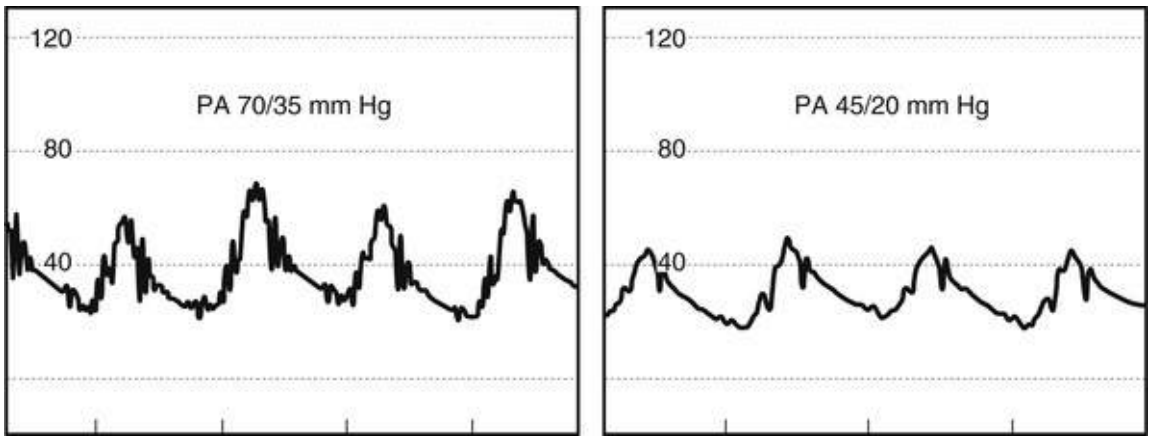
Pressure Measurements

Accurate recording of pressure waveforms and correct interpretation of the physiologic data derived from these waveforms are major goals of the cardiac catheterization. A *pressure wave* is the cyclic force generated by cardiac muscle contraction, and its amplitude and duration are influenced by various mechanical and physiologic parameters. The pressure waveform from a particular cardiac chamber is influenced by the force of the contracting chamber and its surrounding structures, including the contiguous chambers of the heart, pericardium, lungs, and vasculature. Physiologic variables of heart rate and the respiratory cycle also influence the pressure waveform. An understanding of the components of the cardiac cycle is essential for correct interpretation of hemodynamic data obtained in the catheterization laboratory.

Fluid-Filled Systems

Catheter-based pressure recording in the cardiac catheterization laboratory is most frequently accomplished by transducing the force of the pressure wave from the tip of the catheter to the transducer via a fluid-filled system (catheter plus tubing). Within the transducer, the pressure wave leads to the distortion of a diaphragm or wire, and this force is converted to an electrical and then analog signal. Various factors can influence this signal, undermining its accuracy, in which case the output amplitude is not a true representation of the input amplitude. An output-to-input ratio less than 1 represents *damping* (dissipation of energy), as by friction. This cause of error can be reduced by using a short, wide-bore, noncompliant tubing system that is directly connected to the transducer. Air leaks and air bubbles should be removed, and measurement should be taken without the catheter being filled with contrast material.

The higher the density of the liquid within the catheter, the greater is the damping effect. Furthermore, any luminal compromise ("kink") of the catheter-tubing system is a source of damping and needs to be considered with any unexpected and otherwise unexplained pressure drop (e.g., during extensive catheter manipulation or thrombus formation; **eFig. 19.9**). Another explanation of such a scenario is catheter tip obstruction by small vessels or orifices or by engagement against anatomic structures such as walls.



EFIGURE 19.9 Pressure artifacts leading to erroneous pressure measurements. The initial pulmonary artery (*PA*) pressure was 70/35 mm Hg **(left)** but fell to 45/20 mm Hg during the procedure in the absence of any other hemodynamic changes **(right)** because of the formation of a small thrombus in the small distal lumen of a thermodilution catheter. Constant monitoring of the pressure contour and intermittent frequent flushing of the lumen with heparinized saline are recommended to avoid this artifact. Using larger-bore catheters may be necessary to overcome this problem if damping of pressures continues despite the use of these techniques. (From American Heart Association; Nishimura RA, Carabello BA. Hemodynamics in the cardiac catheterization laboratory of the 21st century. Circulation 2012;125:2138.)

Other sources of error are related to motion or impulses on the catheter (*noise*). This includes tapping on any of the connected catheter-tubing system elements and the "whip artifact" (motion of the tip within the chamber). The "impact artifact" can be noted when the catheter is struck by the walls or valves of the cardiac chambers. The operator also needs to be aware of an artificially elevated pressure caused by streaming or high velocity of the pressure wave when using an end-hole catheter, the "end-pressure artifact."

A critical prerequisite for all measurements is the correct calibration of the pressure transducer against a known pressure, or *zeroing*. This is done by placing the transducer at the level of the atria, which is approximately midchest, and if more than one transducer is used, all should be calibrated simultaneously. To address the risk of *drifting*, all transducers should be rebalanced immediately before any simultaneous recordings.

Micromanometer Catheters

Micromanometer catheters allow for superior pressure recording because they have the pressure transducer mounted at the tip (e.g., 3.5F Mikro-Cath, Millar, **eFig. 19.8C**). This eliminates the interposing fluid column and its damping effect as well as the 30- to 40-millisecond delay. The pressure waveform is less distorted and the whip (motion) artifact is greatly reduced. Thus it provides a true pressure reading at any height in fluid. These high-fidelity catheters, although more expansive, have been used to assess the rate of rise in ventricular pressure (dP/dt), wall stress, rate of decay in ventricular pressure (−dP/dt), time constant of relaxation (τ), and ventricular pressure-volume relationships. Catheters with two transducers separated by a short distance allow for accurate determination of gradients within chambers

(e.g., intraventricular gradient in HCM; **see Chapter 78**) and across structures (e.g., stenotic aortic valve). Some of the high-fidelity micromanometer systems allow for over-the-wire insertion and angiography.

Normal Pressure Waveforms.

There are two basic elements in the interpretation of pressure waveforms in a two-dimensional scale: the individual absolute values (*y* dimension) and the contour of the aggregated values over time (*x* dimension). Normal reference values are defined for all hemodynamic parameters (**Table 19.3**).

TABLE 19.3

Normal Pressure and Vascular Resistance Values

PRESSURE	MEAN (mm Hg)	RANGE (mm Hg)
Right Atrium		
a wave	6	2-7
v wave	5	2-7
Mean	3	1-5
Right Ventricle		
Peak systolic	25	15-30
End-diastolic	4	1-7
Pulmonary Artery		
Peak systolic	25	15-30
End-diastolic	9	4-12
Mean	15	9-19
Pulmonary Capillary Wedge		
Mean	9	4-12
Left Atrium		
a wave	10	4-16
v wave	12	6-21
Mean	8	2-12
Left Ventricle		
Peak systolic	130	90-140
End-diastolic	8	5-12
Central Aorta		
Peak systolic	130	90-140
End-diastolic	70	60-90
Mean	85	70-105
VASCULAR RESISTANCE	**MEAN (DYNE-SEC • CM^{-5})**	**RANGE (DYNE-SEC • CM^{-5})**
Systemic vascular resistance	1100	700-1600
Total pulmonary resistance	200	100-300
Pulmonary vascular resistance	70	20-130

The basic principle for the interpretation of pressure waveforms is that the removal of fluid from a compartment leads to a decrease in pressure and the addition of fluid to a compartment leads to an increase in pressure, depending on the confinement and compliance of the system. In the early phase of LV diastolic filling, the normal left ventricle relaxes to such a degree that LV pressure does not rise; in fact, it decreases despite an increase in LV volume after mitral valve opening. Accordingly, the lack of this pattern indicates an abnormal relaxation pattern of the ventricle (also known as diastolic dysfunction). **Fig. 19.8** shows examples of normal pressure waveforms.

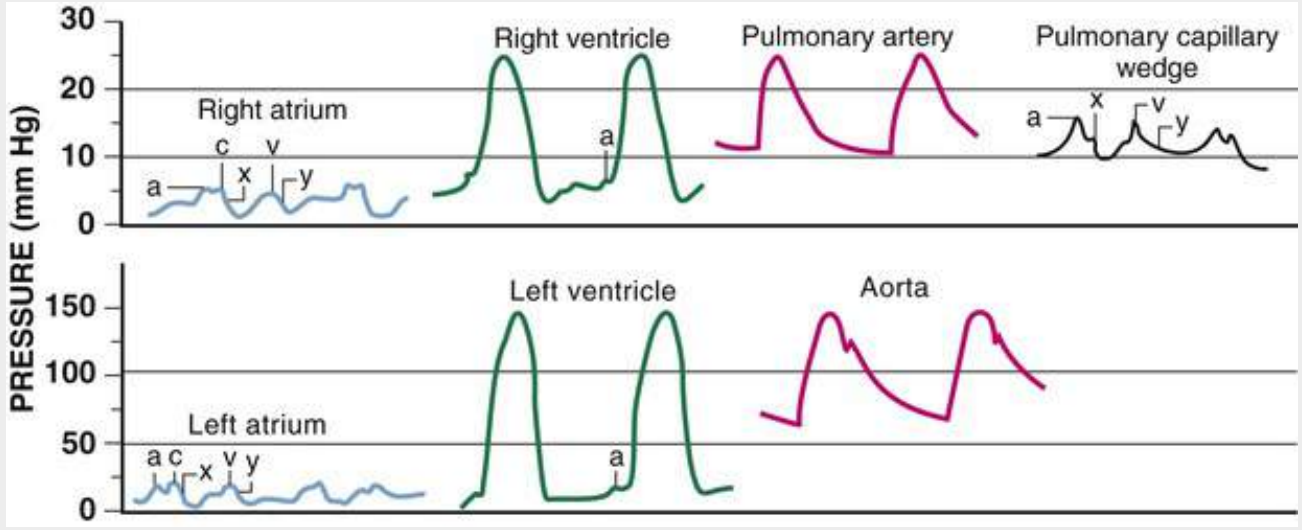


FIGURE 19.8 Normal right- and left-sided heart pressures recorded from fluid-filled catheter systems in a human. (From Pepine C, Hill JA, Lambert CR, editors. Diagnostic and Therapeutic Cardiac Catheterization. 3rd ed. Baltimore: Williams & Wilkins; 1998.)

Atrial Pressure.

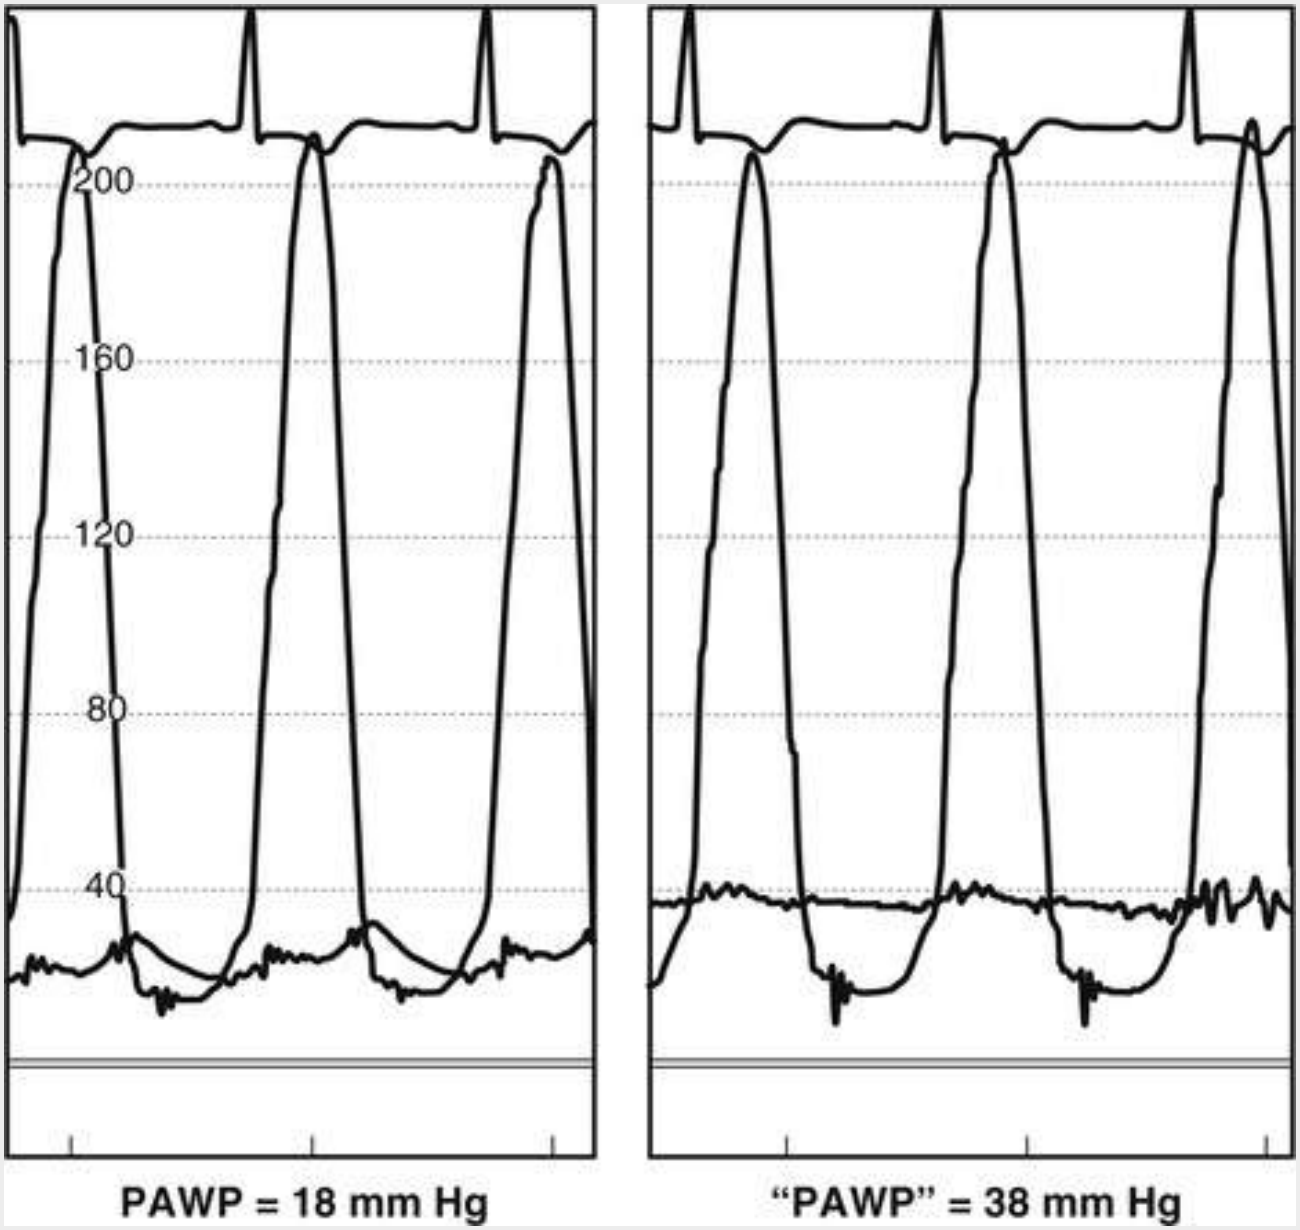
The right atrial pressure waveform has three positive deflections or waves (*a*, *c*, and *v*) and two negative deflections or descents (*x* and *y*). The *a* wave follows the P wave on the ECG and reflects atrial contraction, and atrial contractility and downstream resistance determine its height. It is followed by the *x* descent, which represents atrial relaxation and downward pulling of the tricuspid annulus as the right ventricle contracts. The *x* descent is interrupted as pressure increases again due to protrusion of the closed tricuspid valve into the right atrium with RV contraction: the *c* wave. Passing atrial filling finally terminates the *x* descent, and atrial pressure peaks in (right) ventricular systole: the *v* wave, which follows the R wave on the ECG. Atrial filling and compliance determine the height of the *v* wave, and under normal conditions, the *v* wave is smaller than the *a* wave. With subsequent opening of the tricuspid valve and emptying of the right atrium into the right ventricle, atrial pressure drops again: the *y* descent. Intrathoracic pressure and respiration influence these values. Inhalation leads to a drop in intrathoracic and right atrial pressure, and exhalation has the opposite effect. The reverse is true for patients on mechanical ventilation.

While overall similar, the left atrial pressure is generally higher, with a higher *v* than *a* wave. This occurs because the right atrium can easily decompress through the SVC and IVC, whereas the left atrium is constrained posteriorly by the pulmonary veins.

Pulmonary Capillary Wedge Pressure.

The PCWP waveform represents a slightly damped and delayed reflection of the left atrial pressure waveform, and *c* waves may not be seen. With the normally low resistance of the pulmonary circulation, pulmonary artery diastolic pressure matches mean PCWP. This is not the case under circumstances of elevated pulmonary vascular resistance (hypoxemia, pulmonary embolism, chronic pulmonary hypertension). Also, PCWP may not reflect left atrial pressure as accurately as needed for mitral valve surgery. In general, “overwedging” of the balloon catheter leads to falsely low values, whereas “underwedging” leads to falsely high pressure readings. These two scenarios can be recognized by the pressure waveform lacking its desired atrial waveform configuration: noticeably flat with overwedging and appearing as a dampened pulmonary artery pressure tracing with underwedging (**eFig. 19.10**). True wedge position of the catheter should always be confirmed by a blood sample documenting systemic oxygen saturation (normally near 100%). To avoid collapse of the vasculature distal to the inflated balloon, the blood should be aspirated slowly and gently, or if a larger-bore (balloon wedge) catheter is

used, simply by letting the blood bleed back into an ABG tube.



EFIGURE 19.10 For pulmonary artery wedge pressure (*PAWP*) readings, a large-bore end-hole catheter is recommended as well as confirmation of correct position by proper contour and respiratory variations of the pressure waveform and a >95% oxygen saturation. **Left,** PAWP was taken with a large-bore 7F balloon wedge catheter with appropriate respiratory variation and a proper contour as well as 98% saturation confirmation. **Right,** PAWP determination with a small-lumen thermodilution catheter, most likely representing a damped pulmonary artery pressure, no confirmation by saturation. (From Nishimura RA, Carabello BA. Hemodynamics in the cardiac catheterization laboratory of the 21st century. Circulation 2012;125:2138.)

Ventricular Pressure.

Although similar in morphology, the magnitude of the LV waveform is higher than that of the RV waveform. Duration of systole, isovolumic contraction, and relaxation are longer, and the ejection period is shorter in the left than in the right ventricle. In the early, rapid filling phase of diastole, ventricular pressure initially drops quickly and then increases again, reaching a plateau. This plateau is extended over the slow filling phase but ended by a slow rise due to atrial contraction. The EDP is taken at the *C point*, that is, at the onset of isovolumic contraction and thus just before the notable sudden rise in ventricular pressure. If it cannot be well visualized, the C point can be estimated by drawing a line from the R wave on the simultaneous ECG to the ventricular pressure waveform.

Aortic and Pulmonary Artery Pressure.

The three key elements of the pressure waveform in the great vessels are the *systolic wave* (the ejection of the stroke volume through the open semilunar valves), the *incisura* (the closure of the semilunar valves), and the *diastolic phase* of gradual decline in pressure. The difference between the systolic and diastolic pressure, also known as pulse pressure, is a reflection of the stroke volume and the compliance of the arterial system. Mean pressure more accurately reflects peripheral resistance. As the pressure wave travels distally, an increase in systolic amplitude can be noted, whereas the diastolic amplitude decreases initially up to midthoracic level, then increases again.

The greater the peripheral vascular compliance (e.g., younger patients), the higher the peripheral (femoral, brachial, or radial artery) systolic pressure and the greater the difference in relation to the central aorta. These differences can impact important measurements such as those of aortic gradients. Accordingly, in general, it is advisable to measure the central aortic pressure at the level of the coronary arteries. This also avoids interference with the effect of pressure recovery, which can become relevant in patients with mild to moderate aortic stenosis, particularly when the aorta is small.

Abnormal Pressure Characteristics.

Abnormal pressure waveforms may be diagnostic of specific pathologic conditions. **eTable 19.2** summarizes the more commonly encountered waveforms.

ETABLE 19.2

Pathologic Waveforms

I. Right atrial pressure waveforms
A. Low mean atrial pressure
Hypovolemia
Improper zeroing of the transducer
B. Elevated mean atrial pressure
Intravascular volume overload states
RV failure caused by valvular disease (tricuspid or pulmonic stenosis or regurgitation)
RV failure caused by myocardial disease (RV ischemia, cardiomyopathy)
RV failure caused by left-sided heart failure (mitral stenosis or regurgitation, aortic stenosis or regurgitation, cardiomyopathy, ischemia)
RV failure caused by increased PVR (pulmonary embolism, chronic obstructive pulmonary disease, primary pulmonary hypertension)
Pericardial effusion with tamponade physiology
Obstructive atrial myxoma
C. Elevated *a* wave (any increase in ventricular filling)
Tricuspid stenosis
Decreased ventricular compliance as a result of ventricular failure, pulmonic valve stenosis, or pulmonary hypertension
D. Cannon *a* wave
Atrial-ventricular asynchrony (atria contract against a closed tricuspid valve, as during complete heart block, following premature ventricular contraction, during ventricular tachycardia, with a ventricular pacemaker)
E. Absent *a* wave
Atrial fibrillation, flutter, or atrial standstill
F. Elevated *v* wave
Tricuspid regurgitation
RV heart failure
Reduced atrial compliance (restrictive myopathy)
G. *a* wave equal to *v* wave
Tamponade
Constrictive pericardial disease
Hypervolemia
H. Prominent *x* descent
Tamponade
Subacute constriction and possibly chronic constriction
RV ischemia with preservation of atrial contractility
I. Prominent *y* descent
Constrictive pericarditis
Restrictive myopathies
Tricuspid regurgitation
J. Blunted *x* descent
Atrial fibrillation
Right atrial ischemia
K. Blunted *y* descent
Tamponade
RV ischemia
Tricuspid stenosis

L. Miscellaneous abnormalities
Kussmaul sign (inspiratory rise or lack of decline in right atrial pressure): constrictive pericarditis, right ventricular ischemia
Equalization (≤5 mm Hg) of mean right atrial ventricular diastolic, pulmonary artery diastolic, pulmonary capillary wedge, and pericardial pressures in tamponade
M or W patterns: RV ischemia, pericardial constriction, congestive heart failure
Ventricularization of right atrial pressure: severe tricuspid regurgitation
Sawtooth pattern: atrial flutter
Dissociation between pressure recording and intracardiac ECG: Ebstein anomaly

II. Left atrial pressure–pulmonary capillary wedge pressure waveforms
A. Low mean pressure
Hypovolemia
Improper zeroing of the transducer
B. Elevated mean pressure
Intravascular volume overload states
LV failure caused by valvular disease (mitral or aortic stenosis or regurgitation)
LV failure caused by myocardial disease (ischemia or cardiomyopathy)
LV failure caused by systemic hypertension
Pericardial effusion with tamponade physiology
Obstructive atrial myxoma
C. Elevated *a* wave (any increased resistance to ventricular filling)
Mitral stenosis
Decreased ventricular compliance because of LV failure, aortic valve stenosis, or systemic hypertension
D. Cannon *a* wave
Atrial-ventricular asynchrony (atria contract against a closed mitral valve, as during complete heart block, following premature ventricular contraction, during ventricular tachycardia, or with a ventricular pacemaker)
E. Absent *a* wave
Atrial fibrillation, flutter, or atrial standstill
F. Elevated *v* wave
Mitral regurgitation
Ventricular septal defect
LV heart failure
Reduced atrial compliance (restrictive myopathy)
G. *a* wave equal to *v* wave
Tamponade
Constrictive pericardial disease
Hypervolemia
H. Prominent *x* descent
Tamponade
Subacute constriction and possibly chronic constriction
Right ventricular ischemia with preservation of atrial contractility
I. Prominent *y* descent
Constrictive pericarditis
Restrictive myopathies
Mitral regurgitation
J. Blunted *x* descent
Atrial fibrillation
Atrial ischemia
K. Blunted *y* descent
Tamponade
LV ischemia
Mitral stenosis
L. Pulmonary capillary wedge pressure not equal to LV end-diastolic pressure
Mitral stenosis
Left atrial myxoma
Cor triatriatum
Pulmonary venous obstruction
Decreased ventricular compliance
Increased pleural pressure

III. Pulmonary artery pressure waveforms
A. Elevated systolic pressure
Primary pulmonary hypertension
Mitral stenosis or regurgitation
Congestive heart failure
Restrictive myopathies
Significant left-to-right shunt
Pulmonary disease (pulmonary embolism, hypoxemia, chronic obstructive pulmonary disease)
B. Reduced systolic pressure
Hypovolemia
Pulmonary artery stenosis
Subvalvular or supravalvular stenosis
Ebstein anomaly
Tricuspid stenosis
C. Reduced pulse pressure
Right heart ischemia
RV infarction
Pulmonary embolism
Tamponade
D. Bifid pulmonary artery waveform
Large left atrial *v* wave transmitted backward (i.e., mitral regurgitation)
E. Pulmonary artery diastolic pressure higher than pulmonary capillary wedge pressure
Pulmonary disease
Pulmonary embolus
Tachycardia

IV. Ventricular pressure waveforms

A. Systolic pressure elevated
Pulmonary or systemic hypertension
Pulmonary valve or aortic stenosis
Ventricular outflow tract obstruction
Supravalvular obstruction
RV pressure elevation with significant atrial or ventricular septal defect
RV pressure elevation because of factors that increase PVR (see factors that increase right atrial pressure)
B. Systolic pressure reduced
Hypovolemia
Cardiogenic shock
Tamponade
C. End-diastolic pressure elevated
Hypervolemia
Congestive heart failure
Diminished compliance
Hypertrophy
Tamponade
Regurgitant valvular disease
Pericardial constriction
D. End-diastolic pressure reduced
Hypovolemia
Tricuspid or mitral stenosis
E. Diminished or absent a wave
Atrial fibrillation or flutter
Tricuspid or mitral stenosis
Tricuspid or mitral regurgitation when ventricular compliance is increased
F. Dip and plateau in diastolic pressure wave
Constrictive pericarditis
Restrictive myopathies
Right ventricular ischemia
Acute dilation associated with tricuspid or mitral regurgitation
G. LV end-diastolic pressure higher than RV end-diastolic pressure
Restrictive myopathies

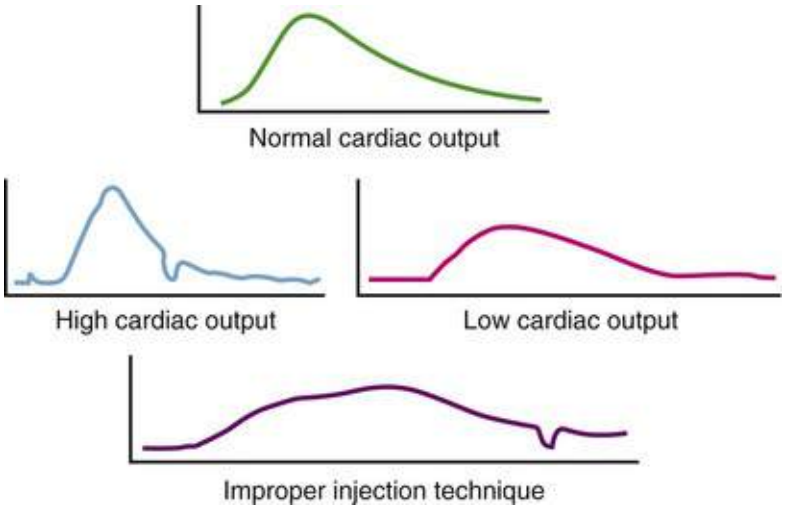
V. Aortic pressure waveform
A. Systolic pressure elevated
Systemic hypertension
Arteriosclerosis
Aortic insufficiency
B. Systolic pressure reduced
Aortic stenosis
Heart failure
Hypovolemia
C. Widened pulse pressure
Systemic hypertension
Aortic insufficiency
Significant patent ductus arteriosus
Significant rupture of sinus of Valsalva aneurysm
D. Reduced pulse pressure
Tamponade
Congestive heart failure
Cardiogenic shock
Aortic stenosis
E. Pulsus bisferiens
Aortic insufficiency
Obstructive hypertrophic cardiomyopathy
F. Pulsus paradoxus
Constrictive pericarditis
Tamponade
Obstructive airway disease
Pulmonary embolism
G. Pulsus alternans
Congestive heart failure
Cardiomyopathy
H. Pulsus parvus et tardus
Aortic stenosis
I. Spike-and-dome configuration
Obstructive hypertrophic cardiomyopathy

Cardiac Output Measurements

Although extremely important, often requested and tested, cardiac output measurements represent only estimates of the true cardiac output on the basis of several assumptions. Three methods are used in the catheterization laboratory: thermodilution, Fick, and ventriculography.

Thermodilution Method

Thermodilution is based on the principle of washout of a temperature change induced by injection of a defined fluid volume cooler than the body temperature. The faster the circulation or flow (i.e., cardiac output), the quicker the neutralization of the temperature change. In practice a bolus of liquid (usually 10 mL of normal saline kept at room temperature) is injected into the proximal port of the catheter, and the change in temperature from baseline is measured by a thermistor at the distal end of the catheter and displayed as a function over time. Cardiac output correlates inversely with the area under the curve and can be calculated when the temperature and specific gravity of the injectate and the blood as well as the volume of the injectate are known (**eFig. 19.11**).



EFIGURE 19.11 Display of a normal cardiac output reading by the thermodilution method **(top),** which plots temperature change over time; the area under the curve is converted into flow L/min by the Stewart-Hamilton formula. Configurations of thermodilution curves in high and low cardiac output states **(middle)** and with improper injection technique **(bottom).** (Modified from Davidson CJ and Bonow RO: Cardiac Catheterization. In Mann DL, et al. [eds]: Braunwald's Heart Disease: A Textbook of Cardiovascular Medicine. 10th ed. Philadelphia, Elsevier, 2012: p 364.)

The advantage of this method is the relative ease of use and results. However, thermodilution is less accurate in patients with significant tricuspid or pulmonic regurgitation, intracardiac shunts, low cardiac output, or irregular rhythms.

Fick Method

The Fick method relies on the principle that blood flow is proportional to the difference in the concentration of oxygen between arterial and venous blood and the rate of oxygen uptake in the lungs (**Fig. 19.9**) and the assumption that pulmonary blood flow (PBF) is equal to systemic blood flow (SBF) in the absence of an intracardiac shunt. In other words, the same number of red blood cells (RBCs) that enter the lung must leave the lung in the absence of an intracardiac shunt. Therefore, if the number of oxygen molecules attached to RBCs entering the lung, the number of oxygen molecules attached to RBCs leaving the lung, and the number of oxygen molecules consumed during travel through the lung are known, the rate of RBC flow through the lung can be determined. This can be expressed in the following terms:

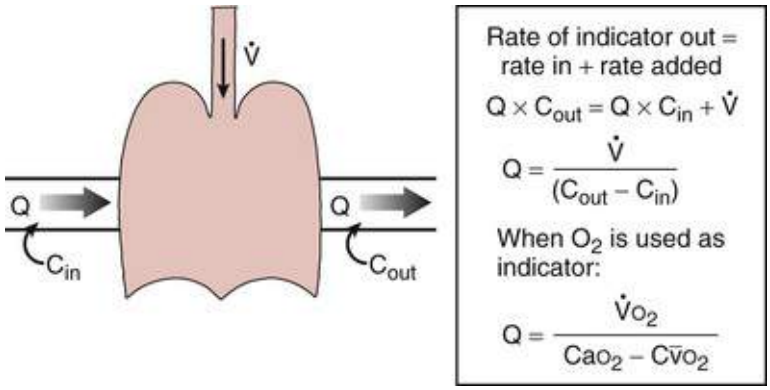


FIGURE 19.9 Schematic illustration of flow measurement by the Fick principle. Fluid containing a known concentration of an indicator (C_{in}) enters a system at a given flow rate, adding to the concentration of the indicator already present and thereby raising the concentration of the indicator in the outflow (C_{out}). In a steady state, the rate of indicator leaving the system must equal the rate at which it enters plus the rate at which it is added. When oxygen is used as the indicator, cardiac output can be determined by measuring oxygen consumption (V), arterial oxygen content (CaO_2), and mixed venous oxygen content ($C\bar{v}O_2$). (From Winniford MD, Kern MJ, Lambert CR. Blood flow measurement. In Pepine CJ, Hill JA, Lambert CR, editors. Diagnostic and Therapeutic Cardiac Catheterization. 3rd ed. Baltimore: Williams & Wilkins; 1998, p 400.)

$$\text{Fick cardiac output (L/min)} = \frac{\text{Oxygen consumption (mL/min)}}{\text{A-V}O_2 \times 1.36 \times \text{Hb} \times 10}$$

where A-VO_2 is the arterial-venous oxygen saturation difference, Hb is the hemoglobin concentration, and 1.36 the constant to adjust for the oxygen carrying capacity of hemoglobin.

Although the oxygen content in blood samples can be reliably measured, measurement of oxygen consumption may represent a source of variability, especially if steady-state conditions are difficult to establish. It is determined by a polarogram, which is connected to the patient by a plastic hood or mouthpiece and tubing and relates the difference between the oxygen concentration in the expired air and the known concentration of oxygen in room air.

The Fick method retains accuracy in patients with low cardiac output and TR. However, the Fick method should not be used in patients with significant MR or AR and is not suitable under conditions of rapid changes in flow. Also, patients should not be on supplemental oxygen.

An “assumed Fick” is often calculated; the oxygen consumption index is assumed based on the patient's age, sex, and body surface area or is estimated (125 mL/m^2) based on the body surface area. This can lead to large errors, however, as much as 40% in cardiac output estimates, compared with the measured oxygen consumption.[40]

Ventriculographic Method

As a third method, the cardiac output can be calculated based on determination of the stroke volume multiplied by the heart rate. The stroke volume equals the difference between end-diastolic and end-systolic volumes. The borders of the contrast-filled left ventricle are traced in end diastole and end systole, and these two-dimensional (2D) values are converted into three-dimensional (3D) volumes based on calibration algorithms with grids and phantoms.

Inaccuracies can easily be introduced in the calibration and tracing steps as well as heartbeat irregularities (e.g., atrial fibrillation, ventricular ectopy). The ventriculographic method, however, is

preferred in patients with significant aortic or mitral regurgitation.

Determination of Vascular Resistance

The analogy with Ohm's law defines *vascular resistance* as the ratio of the decrease in pressure over flow in a vascular segment. Even though it represents an oversimplification of the complex cardiovascular hemodynamics, it has proved very useful in clinical practice. Accordingly, the pressures at the proximal and the distal ends of a vascular bed are measured, and the difference is divided by the cardiac output: mean pressure gradient (mm Hg)/mean flow (L/min). For the systemic vascular resistance (SVR), this is mean aortic minus mean right atrial pressure divided by systemic blood flow (cardiac output), and for the pulmonary vascular resistance (PVR), mean pulmonary arterial pressure minus mean left atrial (mean pulmonary capillary wedge, although not always the same) pressure divided by pulmonary blood flow (in the absence of an intracardiac shunt equal to cardiac output). The corresponding values are in Woods units, which multiplied by 80 yield vascular resistance in the SI units dyne-sec • cm^{-5}.

Omitting the left atrial or PCWP yields the total pulmonary resistance. However, it is a less accurate means to assess the severity of pulmonary vascular disease. PVR, as described, reflects the pressure across the entire pulmonary circulation (main arteries, precapillary arterioles, and pulmonary capillaries).

An additional assessment often performed in the catheterization laboratory is whether any resistance elevation can be induced, as by exercise, or reduced, as by sodium nitroprusside systemically or inhalation of nitric oxide in the pulmonary circulation. Whether any resistance elevation is fixed or reversible, however, is an important question in various clinical scenarios (e.g., heart transplantation).

A more accurate measure to describe the dynamic relationship between pressure and flow is *vascular impedance*, which accounts for blood viscosity, pulsatile flow, reflected waves, and arterial compliance. However, it requires simultaneous measurement of pressure and flow data and is not easy to obtain. Thus, vascular impedance has not gained widespread acceptance as a routinely reported variable.

Clinical Aspects and Integration Into Patient Care

Evaluation of Valvular Stenosis

The cardiac catheterization takes an important part in the evaluation of patients with valvular stenoses, especially if there is discordance in the degree of severity by physical examination and noninvasive tests such as echocardiography. For a number of cases, determination of the pressure gradient will suffice, but the valve should be calculated as well.

Determination of Pressure Gradients

Aortic Valve Stenosis (see Chapter 68)

Although easily accessible, the femoral artery pressure, recorded through the access sheath, should not be used for the calculation of the gradient across the aortic valve because it is unreliable, for various reasons (**Fig. 19.10A**). The best location to measure the poststenotic valve pressure is on the level of the coronary arteries, and the LV pressure can be simultaneously recorded using a double-lumen pigtail catheter with

proximal lumen on the aortic side and distal lumen on the ventricular side of the aortic valve. Another option is to use a multipurpose catheter, which is kept in ideal aortic position, and a pressure wire that is advanced through the catheter just across the aortic valve. With either catheter type, it is important to validate that the side holes (pigtail catheter) or end holes (coronary catheter) are in proper position to avoid erroneous readings (**Fig. 19.10B**). The smaller aortic lumen of the dual lumen pigtail catheter should be continually flushed to avoid damping, and before and after the measurement of the gradient it should be verified that the pressure is identical in both lumina. Pullback recordings from the left ventricle into the aorta with one single catheter should be taken only as a screening technique. Importantly in patients with aortic valve area less than 0.7 cm^2, pullback of a 7F or 8F catheter can lead to an increase in peak arterial pressure of 5 mm Hg or more that has been related to partial obstruction of an already narrowed aortic valve by the retrograde catheter and relief of this obstruction with catheter withdrawal, the “Carabello sign.”[46]

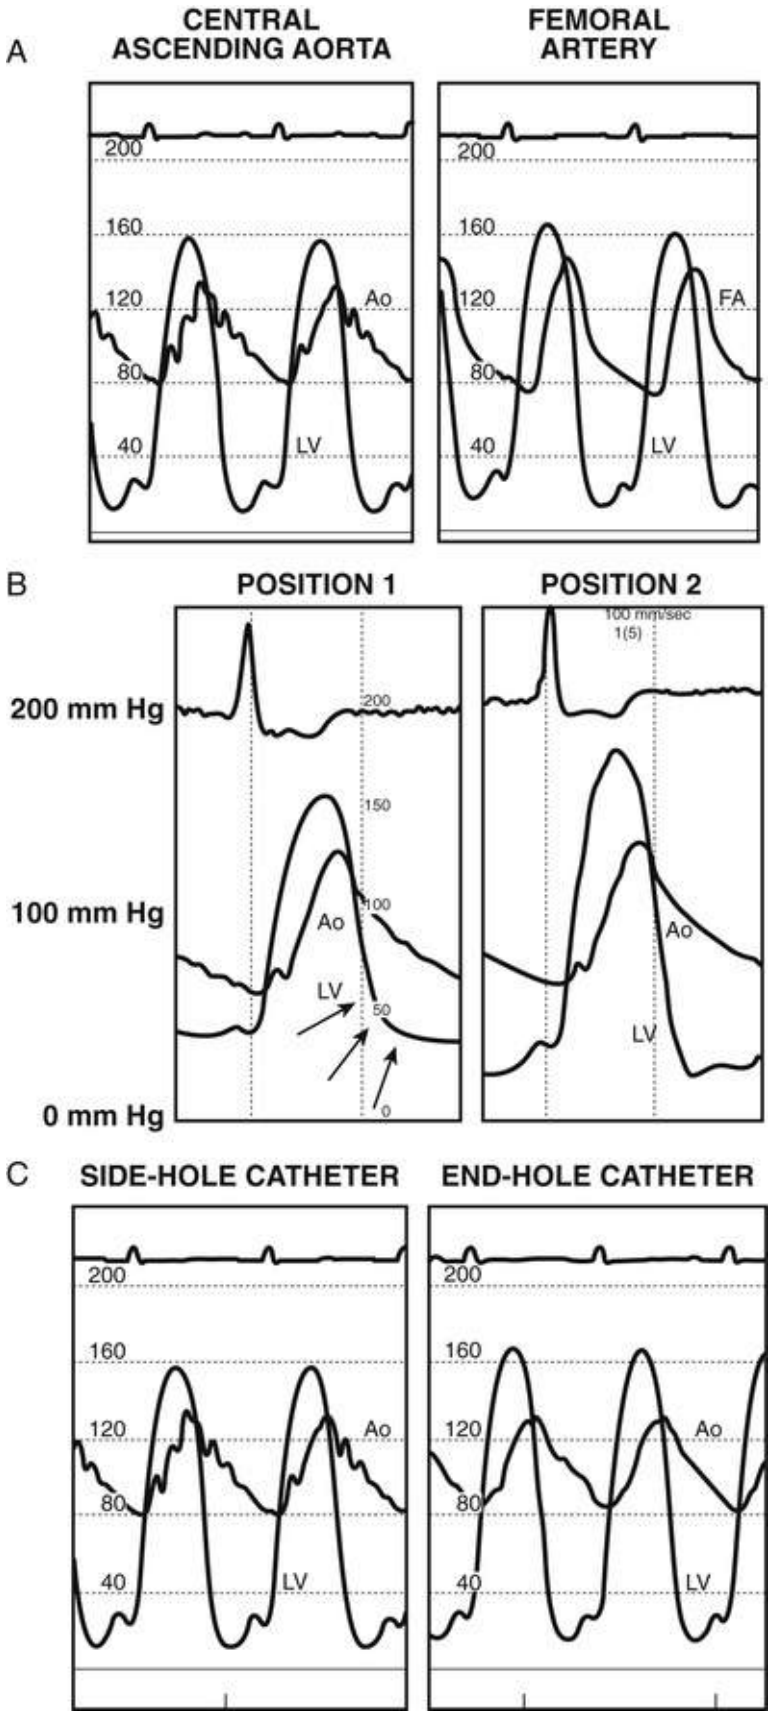

FIGURE 19.10 Examples of erroneous measurements of the transaortic gradient. **A,** The simultaneous left ventricular (*LV*) and femoral artery (*FA*) pressures may yield a falsely low gradient due to peripheral amplification and a falsely high gradient due to peripheral artery stenosis, in addition to the temporal delay that will affect the calculation of the mean gradient. **B,** Incomplete advancement of a pigtail catheter into the LV cavity leads to a marked delay in the fall of pressure during early diastole on the LV waveform due to straddling of some of the multiple side holes in the pigtail catheter at the level of the aortic valve, resulting in a fusion of LV and aortic pressure (*Ao*) (position 1), which is subsequently corrected (position 2). **C,** Typical damping of the aortic pressure (*Ao*) when an end-hole catheter is used instead of a sidehole catheter. (From American Heart Association; Nishimura RA, Carabello BA. Hemodynamics in the cardiac catheterization laboratory of the 21st century. Circulation. 125:2138, 2012.)

The mean pressure gradient is the best parameter for the determination of the severity of aortic stenosis, which is the integrated gradient between the left ventricle and aortic pressure curve throughout the entire systolic ejection period (**Fig. 19.11**). The peak-to-peak gradient should not be used because it does not represent a physiologic measure of the difference at the same point in time. This is different from the peak instantaneous gradient on echocardiography (**see Chapter 14**), which represents a true measure of the maximum difference in pressure between the left ventricle and aorta when both are measured simultaneously.

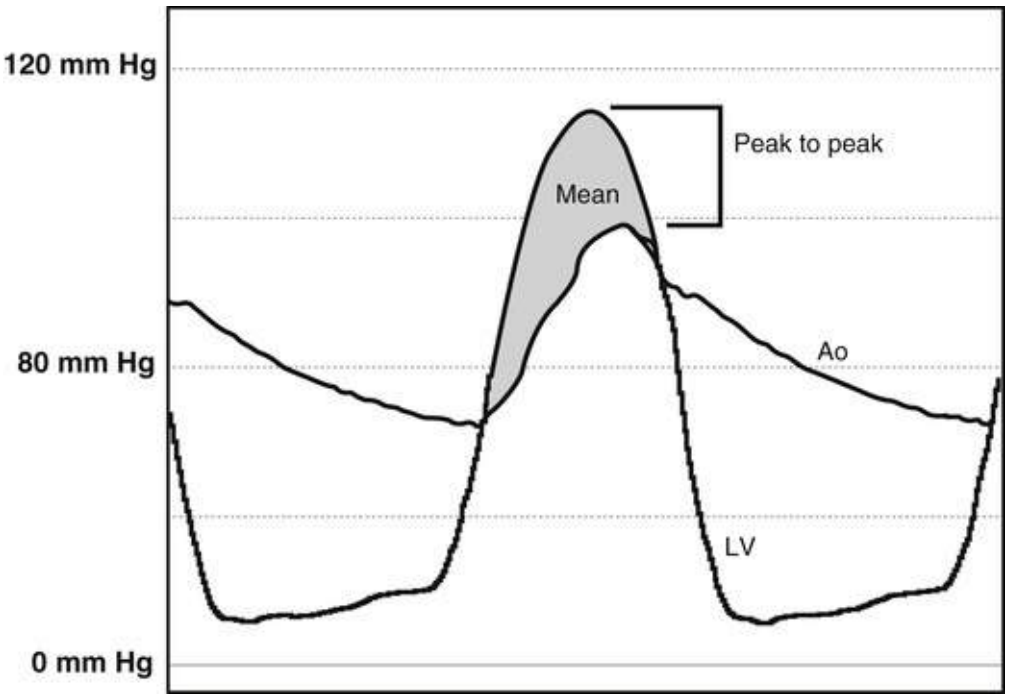

FIGURE 19.11 The optimal way to measure the gradient in a patient with aortic stenosis is to use simultaneous left ventricular (*LV*) and central aortic (*Ao*) pressure and to calculate the mean pressure gradient (the integrated gradient between LV and Ao pressure throughout the entire systolic ejection period). The peak-to-peak gradient, which is the difference between the peak LV and peak Ao pressures, should not be used because it represents a nonphysiologic measurement because of the temporal difference in peak pressures. (From Nishimura RA, Carabello BA. Hemodynamics in the cardiac catheterization laboratory of the 21st century. Circulation 2012;125:2138.)

In patients with low-gradient severe aortic stenosis (i.e., valve area <1 cm^2 but mean gradient <40 mm Hg), pharmacologic maneuvers can be helpful (**see Chapter 68**). This includes dobutamine in patients with a reduced ejection fraction (**Fig. 19.12A, B**) and nitroprusside in those with a preserved ejection fraction (**Fig. 19.12C**) (see later, Physiologic and Pharmacologic Maneuvers). In patients with nonsevere aortic stenosis, the valve area should increase by more than 0.2 cm^2 with minimal or no change in the transvalvular gradient in response to low-dose dobutamine and an increase in contractility. Patients who lack an adequate contractile reserve (stroke volume increase <20%) do poorly with or without surgery. In patients with low-gradient severe aortic stenosis, preserved ejection fraction, relaxation abnormalities, and impaired ventriculovascular coupling, lowering of the peripheral resistance with nitroprusside should lead to an increase in aortic valve gradient without a change in valve area.

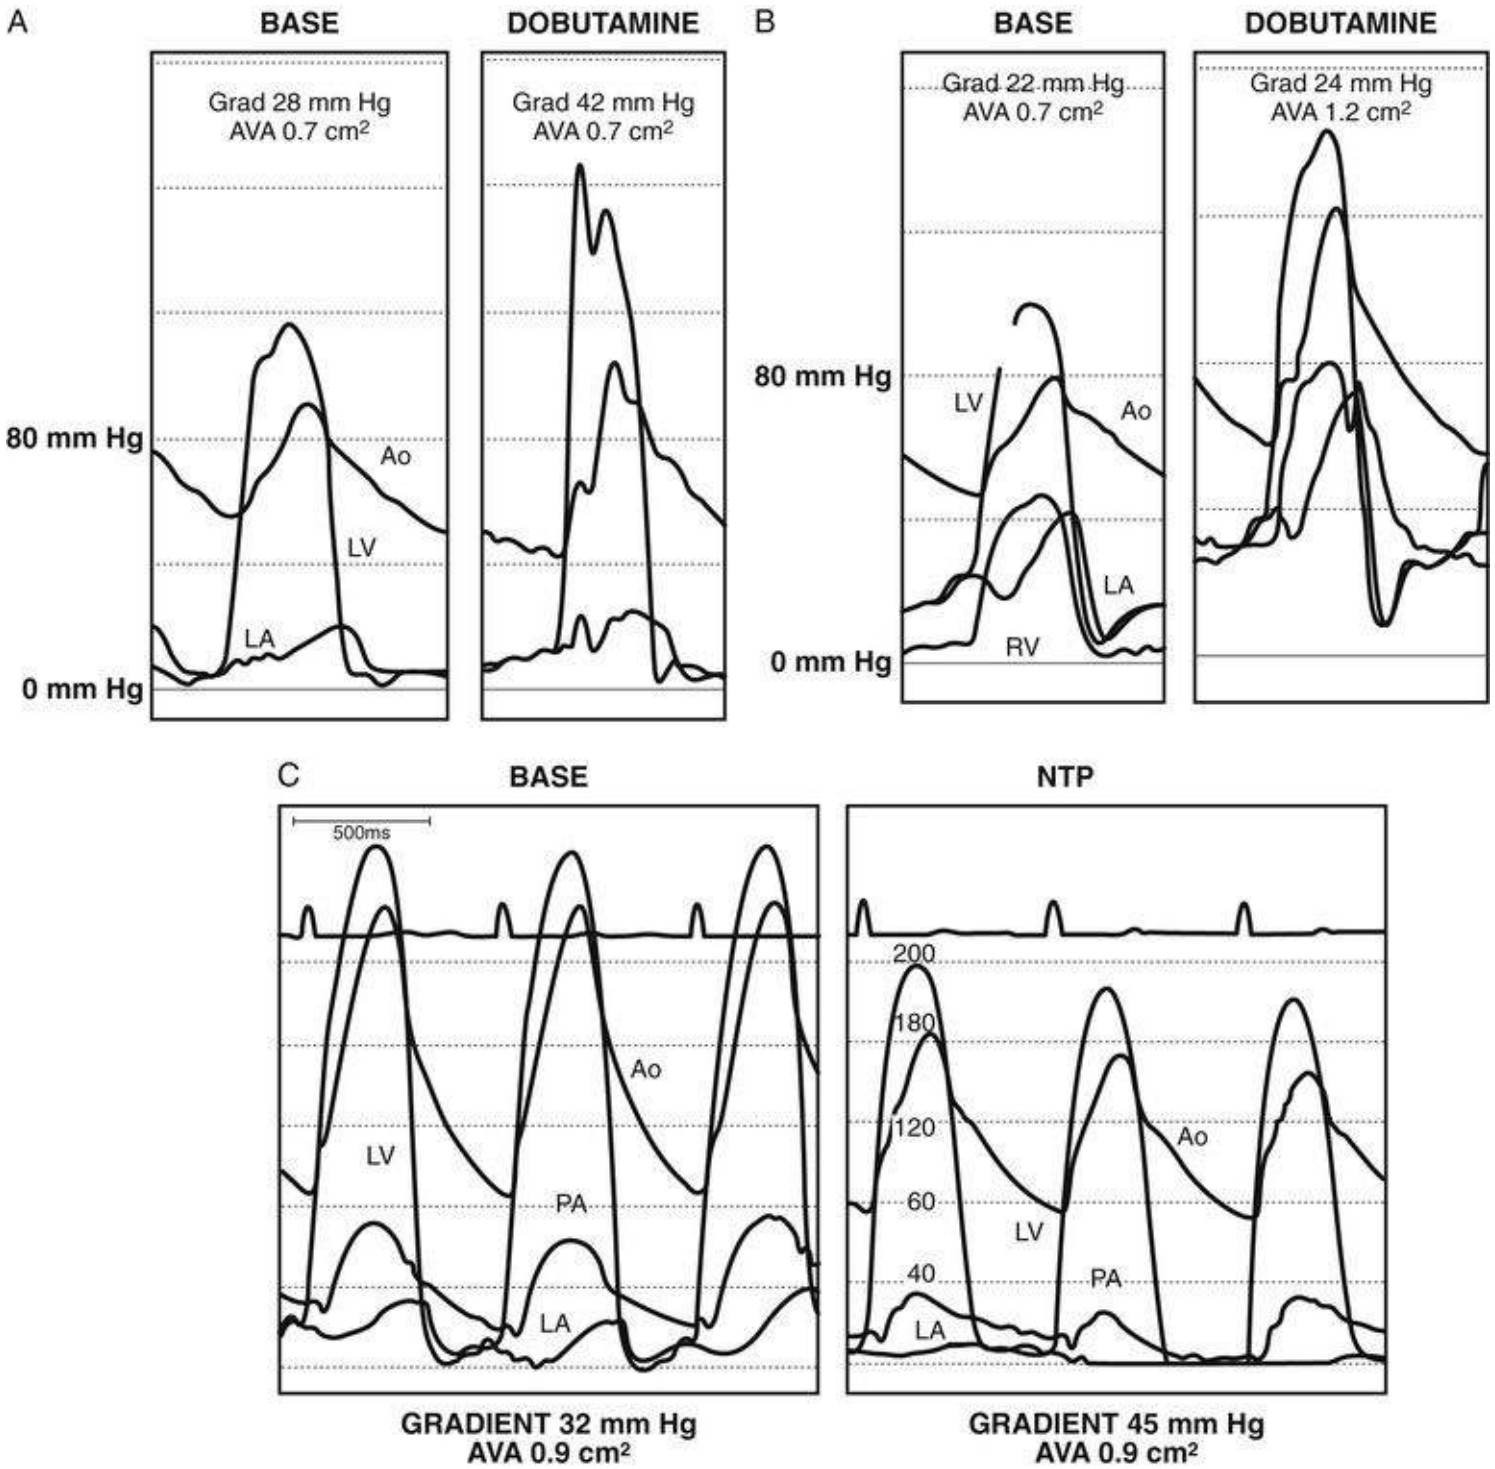

FIGURE 19.12 Pharmacologic testing in low-output, low-gradient (*Grad*) states for differentiation between true aortic stenosis (AS) and pseudo-AS. **A,** In a patient with reduced ejection fraction (EF), increase in contractility with dobutamine stimulation leads to an increase in the gradient from 28 to 42 mm Hg while the valve area remains small at 0.7 cm^2, indicating severe fixed valvular stenosis. **B,** While resting hemodynamics are similar, no increase in the gradient with dobutamine infusion can be noted in this patient, whereas the valve area increases to 1.2 cm^2; this exemplifies pseudo-AS, in which the valve area is small at baseline because of the lack of force generated by the ventricle to fully open a mildly stenotic aortic valve. **C,** Example of a patient with low-gradient AS in the presence of a preserved EF due to a high additional afterload from a noncompliant aortic system. In this case, lowering of the peripheral resistance with sodium nitroprusside (*NTP*) unmasks true AS by demonstrating an increase in aortic valve gradient and a fixed valve area. *Ao,* Central aortic pressure; *AVA,* aortic valve area; *LA,* left atrial; *LV,* left ventricular pressure; *PA,* pulmonary artery pressure. (From Nishimura RA, Carabello BA. Hemodynamics in the cardiac catheterization laboratory of the 21st century. Circulation 2012;125:2138.)

Mitral Valve Stenosis (see Chapter 69)

Similar to the aortic valve, the mitral valve gradient is best measured by direct and simultaneous measurement of left atrial and LV pressure over several cardiac cycles and integral quantification of the pressure difference in diastole (**Fig. 19.13**). To avoid the transseptal puncture and its inherent risks, PCWP rather than left atrial pressure is typically used, carefully realigned with the LV tracing for accurate determination of the mean gradient. Although a satisfactory estimate, PCWP may overestimate left atrial pressure by 2 to 3 mm Hg and thus the mitral valve gradient. This applies even more to the case when the balloon catheter is overwedged, resulting in more profound damping and lower pressure recordings. Attention to technique and detail is especially important if the goal of the evaluation is to define how much mitral valve stenosis is contributing to a patient's clinical presentation. In some patients, it might become necessary to perform provocation maneuvers such as exercise to unmask the abnormality (**eFig. 19.12**). Occasionally, a transseptal approach might be required to measure the left atrial pressure directly and to define the transvalvular gradient more definitively. A simplified formula for the estimation of the mean mitral valve gradient (MVG) has become known as the Cui formula: MVG = Mean left atrial pressure – LVEDP/2.[41]

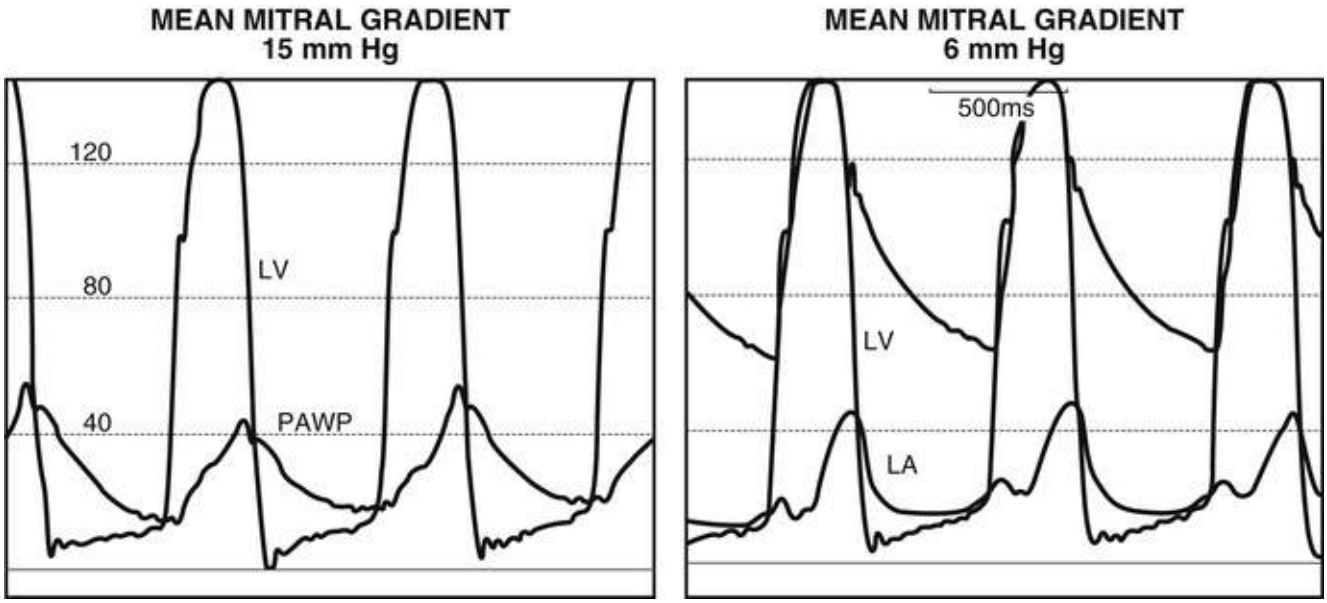

FIGURE 19.13 Overestimation of the transmitral gradient using pulmonary artery wedge pressure (*PAWP*) readings. **Left,** Simultaneous left ventricular pressure (*LV*) and PAWP in a patient with mitral stenosis. The measured mean gradient is 15 mm Hg. **Right,** In the same patient, the transmitral gradient is measured with a left ventricular and direct left atrial pressure (*LA*). The true mean transmitral gradient is only 6 mm Hg. (From Nishimura RA, Carabello BA. Hemodynamics in the cardiac catheterization laboratory of the 21st century. Circulation 2012;125:2138.)

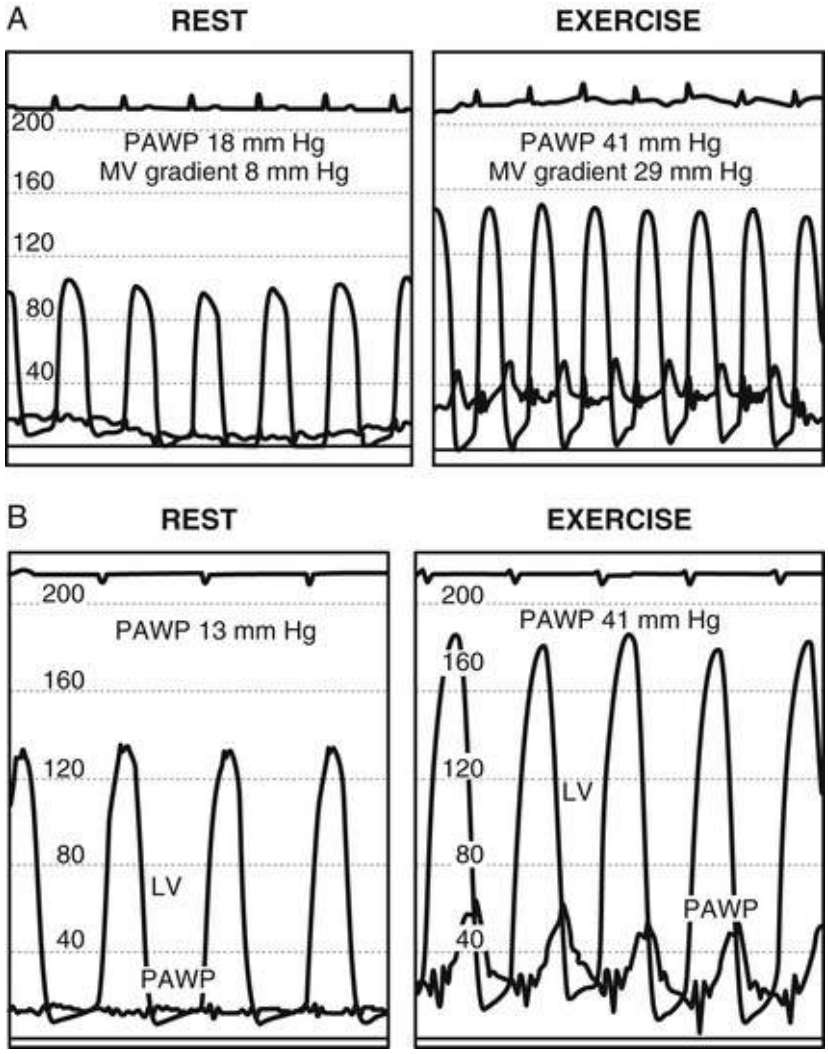

EFIGURE 19.12 Effects of exercise to unmask abnormalities not present in the resting state. **A,** Patient with mitral stenosis and significant symptoms out of proportion to the resting hemodynamics, which showed a mean resting mitral valve (*MV*) gradient of only 8 mm Hg and pulmonary artery wedge pressure (*PAWP*) of only 18 mm Hg. With supine bicycle exercise, the mean gradient rose to 29 mm Hg and PAWP to 41 mm Hg, indicating that the mitral stenosis was hemodynamically significant and clinically relevant. **B,** Patient with significant dyspnea on exertion but no significant valve disease and normal left ventricular (*LV*) systolic function. In the resting state, PAWP was only 13 mm Hg but increased to 41 mm Hg, with a large V wave at low levels of supine bicycle exercise. Mitral regurgitation was not present on simultaneous echocardiography, indicating that these symptoms were caused by noncompliance of the left atrium and left ventricle. (From Nishimura RA, Carabello BA. Hemodynamics in the cardiac catheterization laboratory of the 21st century. Circulation 2012;125:2138.)

Pulmonary and Tricuspid Valve Stenosis (see Chapter 70)

The same principles and techniques apply for right-sided valves, using simultaneous pressure recordings. This can be done using multilumen catheters or two separate catheters. For the pulmonic valve, the gradient may be obtained on catheter pullback from the pulmonary artery to the right ventricle, although ideally it should be measured simultaneously.

Calculation of Stenotic Valve Orifice Areas.

The orifice area of a valve can be calculated based on hydraulic principles. The volume of flow (F) across an orifice equals the area of the orifice (A) times the velocity of flow (V): $F = A \times V$, and accordingly, the orifice area can be calculated as $A = F/V$. F equals the cardiac output, and V can be calculated from the transvalvular gradient based on Toricelli's law: $V = \sqrt{2gh}$, whereby g is the gravity-

related acceleration of velocity and h the pressure gradient.[40]

Gorlin and Gorlin refined this equation in 1951, which has become known as the "Gorlin formula" for the calculation of valve areas: $A = F/(C_c \times C_v \times \sqrt{2gh})$ (see Classic References). C_c is the coefficient of orifice contraction, which accounts for the fact that fluids tend to move through the center of an orifice, generating a physiologic orifice that is smaller than the anatomic orifice. C_v is the velocity coefficient, which allows for the pressure gradient not being fully converted to flow because some of the velocity is lost to friction. Neither of these two coefficients has ever been determined. Instead, an empiric value has been used to align the calculated area with the actual area on autopsy or surgery in 11 patients with mitral valve disease. The maximal discrepancy between the actual mitral valve area and calculated values was just 0.2 cm^2 for a constant C of 0.85. Importantly, such direct comparison data were never obtained for any of the other three valves, and not even empiric constants were developed for these. Rather, a constant of 1.0 has been assumed for any valve other than the mitral valve, which points out that the areas derived are best estimates only.

To derive a more accurate aortic valve area, because flow across the aortic valve occurs only during systole, the cardiac output often is divided by the actual systolic ejection period (SEP: the period from opening to closure of the aortic valve) times the heart rate (HR). In agreement with the Gorlin formula and factoring in a combined constant of 44.3 for C_c and C_v, the aortic valve area (AVA) can be calculated as follows:

$$\text{AVA } (cm^2) = [\text{Cardiac output } (mL/min) \div (\text{SEP} \times \text{HR})] \div [44.3 \times \sqrt{\text{Mean gradient}}]$$

The normal aortic valve area is 2.6 to 3.5 cm^2 in adults. Valve areas less than 1.0 cm^2 represent severe aortic stenosis (**see Chapter 68**).

The calculation is similar for the mitral valve area (MVA). Because mitral flow occurs only during diastole, cardiac output is corrected for the diastolic filling period (DFP; the period of opening to closure of the mitral valve), yielding the following formula:

$$\text{MVA } (cm^2) = [\text{Cardiac output } (mL/min) \div (\text{DFP} \times \text{HR})] \div [37.7 \sqrt{\text{Mean gradient}}]$$

The normal mitral valve area is 4 to 6 cm^2, and severe mitral stenosis is present with valve areas smaller than 1.0 cm^2 (**see Chapter 69**).

A simplified formula has been proposed by Hakki and colleagues (see Classic References). The effects of SEP and DFP are relatively constant at normal heart rates, which leads to the following equation:

$$\text{AVA } (cm^2) = \text{Cardiac output } (L/min) \div \sqrt{\text{Peak-to-peak or Mean gradient}}$$

Of note, mean aortic transvalvular gradient and peak-to-peak gradient yield similar correlation with the Gorlin formula and thus can be used in this formula. For the MVA, only the mean gradient was validated:

$$\text{MVA (cm}^2\text{)} = \text{Cardiac output (L/min)} \div \sqrt{\text{Mean gradient}}$$

The valve area using the Hakki formula can differ by almost 20% from the valve area using the Gorlin formula in patients with bradycardia or tachycardia.

Accurate measurements of pressure gradient and cardiac output are crucial because major management decisions rely on these. This is even more relevant in patients with borderline or low-pressure gradients. For this reason, it is essential to know the potential sources of error.

Because the square root of the mean gradient is used, miscalculation of the cardiac output leads to more erroneous valve areas than miscalculation of the gradient. Ironically, the imprecision in calculating the cardiac output is greatest in patients with a low cardiac output, in whom the pressure gradient is often inappropriately low and the severity of stenosis relies even more on accurate valve area determinations. In these patients, as well as in those with TR, the Fick method should be used. Neither thermodilution nor the Fick method should be used in patients with mixed valvular disease (stenosis and regurgitation) of the same valve because it overestimates stenosis severity in this setting. In patients with AR or MR, cardiac output is best measured by left ventriculography. If both AR and MR are present, accurate assessment of either the aortic or the mitral valve area is not possible.

Inherent to the Gorlin formula is the dependence of the calculated valve area on transvalvular flow. Although greater flow could lead to greater opening pressure and thus greater valve area, correlation studies with planimetry by transesophageal echocardiography (TEE) argue against it. Accordingly, even under increasing flow conditions, the aortic valve area by planimetry remains unchanged, whereas it increases with use of the Gorlin formula.

Intraventricular Pressure Gradients.

An outflow gradient can be present not only at the valvular level of the aortic valve but also at the subvalvular level of the ventricle. Whereas the aortic type is structural in nature, the LV type is caused by dynamic functional obstruction by hypertrophic myocardium (**see Chapter 78**). The aortic and LV waveforms display characteristics that are uniquely different (**Fig. 19.14A**). An easy assessment for any intracavitary gradient is by pullback of a multipurpose end-hole catheter from the LV apex to a posterior position just beneath the aortic valve. Even though a straightforward assessment, entrapment of the catheter by hypertrophic myocardium should be avoided because it leads to erroneous values. The level of loss of the aortic-LV gradient defines the gradient level, which is just slightly below. Accordingly, for any intracavitary gradient, the pressure difference between aorta and left ventricle is lost when the catheter is pulled back just below the aortic valve, and a LV waveform should still be present.

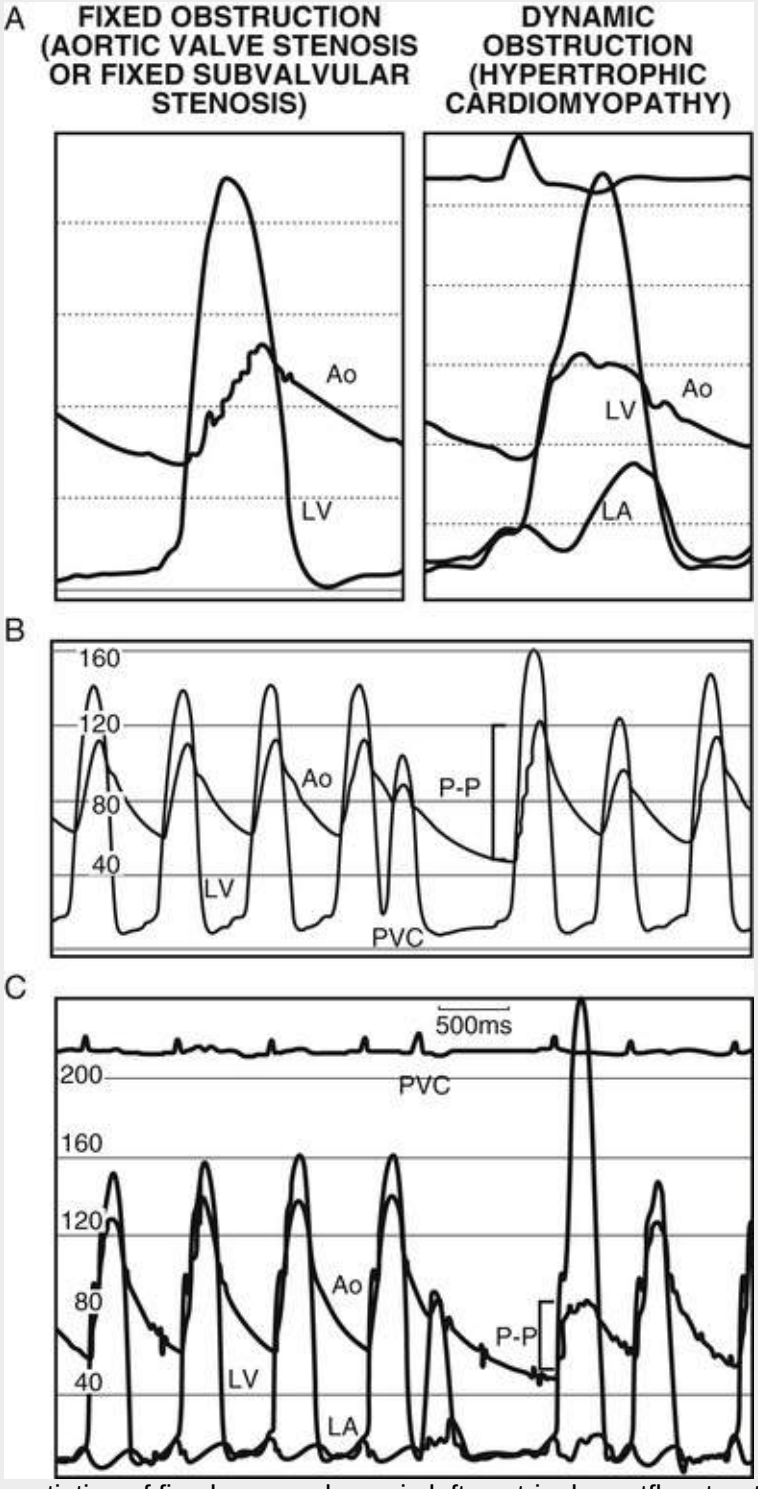

FIGURE 19.14 Differentiation of fixed versus dynamic left ventricular outflow tract obstruction. **A,** Fixed obstruction (either valvular stenosis or fixed subvalvular stenosis) typically leads to a parvus and tardus upstroke of the aortic pressure. Dynamic obstruction, however, such as related to hypertrophic cardiomyopathy (HCM), leads to a rapid rise of the aortic pressure (*Ao*) at the onset of aortic valve opening, which is subsequently blunted into a spike-and-dome contour as obstruction evolves in late systole. The left ventricular pressure (*LV*) also has a late peak because of the mechanism of this dynamic obstruction. **B,** In valvular aortic stenosis, pulse pressure (*P-P*) is increased on the first beat after the premature ventricular complex (*PVC*). **C,** In HCM, the opposite is observed. *LA,* Left atrial pressure. (From Nishimura RA, Carabello BA. Hemodynamics in the cardiac catheterization laboratory of the 21st century. Circulation 2012;125:2138.)

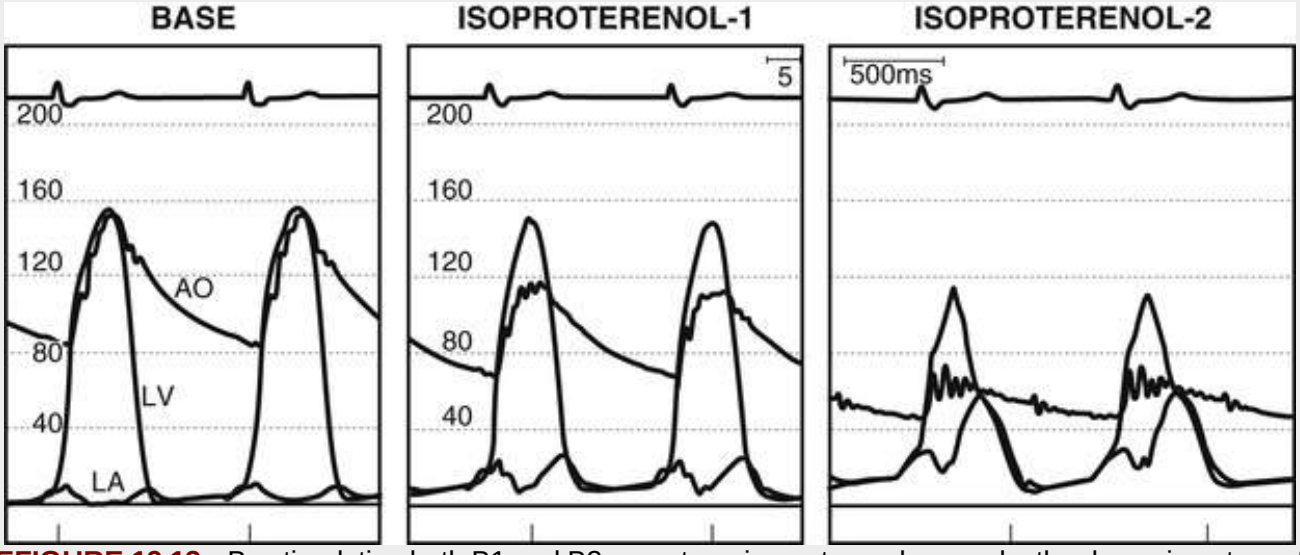
Alternative methods for the assessment of intracavitary gradients are based on simultaneous pressure recordings in two different locations by use of a dual-lumen catheter, a double-sensor micromanometer catheter, or an end-hole catheter in the LV outflow tract and a second catheter in the left ventricle, placed by transseptal puncture. Provocation maneuvers to aid in the diagnostic evaluation of intracavitary

gradients include the introduction of a premature ventricular beat (subsequent drop in aortic pulse pressure is indicative of HCM, “Braunwald-Brockenborough-Morrow sign”; **Fig. 19.14B, C**), Valsalva maneuver, inhalation of amyl nitrate, or infusion of dobutamine or isoproterenol (**eFig. 19.13**).



EFIGURE 19.13 By stimulating both B1 and B2 receptors, isoproterenol unmasks the dynamic nature of the left ventricular (*LV*) outflow tract gradient in hypertrophic cardiomyopathy. **Left,** Absent LV outflow gradient at rest. *Middle,* Development of a 40 mm Hg gradient across the LV outflow tract with initial infusion of isoproterenol. *Right,* Progression to a 65 mm Hg LV outflow gradient with greater infusion of isoproterenol,. *AO,* Central aortic; *LA,* left atrial pressure. (From Nishimura RA, Carabello BA. Hemodynamics in the cardiac catheterization laboratory of the 21st century. Circulation 2012;125:2138.)

Valvular Regurgitation.

The determination of the severity of valvular regurgitation in the cardiac catheterization laboratory is usually done by visual assessment and occasionally by calculation of the regurgitant fraction. Moreover, a complete hemodynamic evaluation by right-heart catheterization might provide very valuable information. In particular, pulmonary artery and PCWP at rest and with exercise are important parameters. With severe MR, a prominent *v* wave is characteristic, and the hemodynamic consequence is postcapillary pulmonary hypertension, especially under conditions of increased workload (**see Chapter 69**). It is a class I ACC/AHA guideline recommendation to perform a hemodynamic evaluation of either AR or MR when pulmonary artery pressures are disproportionate to regurgitation severities on noninvasive testing or when clinical and noninvasive findings are inconsistent.

Visual Assessment of Regurgitation.

The visual assessment relies on the injection of radiographic contrast material distal to the valve in question and the subsequent grading of opacification intensity and washout rapidity in the chamber proximal to it. It is important to be cognizant that the results are influenced by catheter position, volume of contrast, and chamber size and contractility, not regurgitant volume alone. Nevertheless, the semiquantitative classification scheme by Sellers and colleagues remains the reporting standard:

+	Minimal regurgitant jet seen. Clears rapidly from the proximal chamber with each beat.
++	Moderate opacification of the proximal chamber and clearing with subsequent beats.
+++	Intense opacification of the proximal chamber that becomes equal to that of the distal chamber.
++++	Intense opacification of the proximal chamber that becomes more dense than that of the distal chamber. Opacification often persists over the entire series of images obtained.

Regurgitant Fraction.

As a more quantitative measure, the regurgitant volume can be calculated, which is the fraction of the stroke volume that does not contribute to net cardiac output:

$$\text{Regurgitant stroke volume} = \text{Angiographic stroke volume} - \text{Forward stroke volume}$$

The angiographic stroke volume is calculated by the cardiac output measurement on the left ventriculogram, and the forward stroke volume by Fick or thermodilution cardiac output measurements; either value is then divided by the heart rate. Prerequisites to relate these output measurements to each other are similar heart rates, stable hemodynamic states between measurements, and the presence of only a single regurgitant valve.

The regurgitant stroke volume can also be determined in relation to the overall stroke volume, which is the regurgitant fraction:

$$\text{Regurgitant fraction (RF)} = \text{Regurgitant stroke volume} \div \text{Angiographic stroke volume}$$

The approximate correlation between RF and the visual grade of regurgitation severity is as follows: 1+ regurgitation is approximately equivalent to an RF of 20% or less, 2+ to an RF of 21% to 40%, 3+ to an RF of 41% to 60%, and 4+ to an RF of greater than 60%.

Shunt Determinations

The systemic and pulmonary circulations operate in series, and thus normally their output is the same. Any abnormal communication between them then generates a circuit shortcut or shunt. This can be from the systemic circulation to the pulmonary circulation (left-to-right shunt), from the pulmonary circulation to the systemic circulation (right-to-left shunt), or in both directions (bidirectional shunt). Given its ease, most shunt assessments in the cardiac catheterization laboratory are made by determination of the oxygen content in the blood at different levels of the circuit, given the normally very well-defined and distinct oxygenation values in the systemic and pulmonary circulations.

Even when using thermodilation, it is advisable to always obtain a pulmonary artery oxygen saturation. Values exceeding 80% should raise the suspicion for a left-to-right shunt. On the other hand, systemic arterial oxygen saturation less than 93% that persists after several deep breaths to counteract alveolar hypoventilation (as seen with oversedation or pulmonary venous congestion) should raise suspicion for a right-to-left shunt.

Oximetric Method

In addition to pulmonary artery sampling, a screening oxygen saturation should also be obtained from the SVC routinely with right-heart catheterization, possibly to detect even small left-to-right shunts. If the difference in oxygen saturation between these two samples is 8% or greater, a left-to-right shunt may be

present, and the oximetry run should be extended to include samples from the IVC, right atrium, and right ventricle. In fact, if an interatrial shunt is suspected, samples should be obtained at the level of the low, middle, and high right atrium, and for an interventricular shunt from the RV inflow tract, apex, and outflow tract. An absolute increase in oxygen saturation by 5% or more defined a significant step-up and the location of the shunt.

A small left-to-right shunt might be missed if the right atrium is used for screening purposes because of incomplete mixing of blood in the right atrium from the SVC, IVC, and coronary sinus. The coronary sinus blood has one of the lowest oxygen saturations, and the catheter should always be directed away from the coronary sinus when taking right atrial samples. However, oxygen saturation in the IVC is higher than in the SVC because oxygen extraction of the internal organs and lower extremity muscles is lower in a fasting and resting state than that of the brain. The best method for determination of the mixed venous saturation is by the Flamm formula, which is based on IVC and SVC samples (see below).

A full saturation run entails samples from the high and low IVC; high and low SVC; high, middle, and low right atrium; RV inflow, midcavity, and outflow tract; main pulmonary artery; left or right pulmonary artery; pulmonary vein and left atrium, if possible; left ventricle; and distal aorta. Right-to-left shunt assessments require samples from the pulmonary veins, left atrium, left ventricle, and aorta. A decrease (step-down) in oxygen saturation is expected in these cases.

Sampling error is reduced by obtaining multiple samples at each location, but this is rarely done in clinical practice because of cost and time restraints. Even with single samples and not being a very sensitive method in general, clinically significant shunts are still usually detected with oximetry runs. Balloon-tipped fiberoptic catheters have been developed that allow continuous registration of oxygen saturation during right-heart catheterization but are rarely used.

Shunt Quantification

To quantify the extent of a shunt, PBF and SBF need to be calculated, which is simply oxygen consumption divided by the difference in oxygen content across the pulmonary or systemic bed. The effective blood flow (EBF) is the fraction of mixed venous return received by the lungs without contamination by shunt flow. Under normal conditions, PBF, SBF, and EBF are equal.

The equations are as follows:

$$PBF = Vo_2 \div [(Pvo_2 - Pao_2) \times Hb \times 1.36 \times 10]$$

$$SBF = Vo_2 \div [(Sao_2 - Mvo_2) \times Hb \times 1.36 \times 10]$$

$$EBF = Vo_2 \div [(Pvo_2 - Mvo_2) \times Hb \times 1.36 \times 10]$$

Vo_2 (oxygen content) is determined as outlined previously. Pvo_2, Pao_2, Sao_2, and Mvo_2 are oxygen saturation of pulmonary venous, pulmonary arterial, systemic arterial, and mixed venous blood,

respectively.

MvO_2 is calculated by the Flamm formula:

$$MvO_2 = [3 \times (SVC\ O_2 \times Hb \times 1.36 \times 10) + 1 \times (IVC\ O_2 \times Hb \times 1.36 \times 10)] \div 4$$

Systemic arterial oxygen saturation may be substituted for pulmonary venous sampling, if at least 95%. Otherwise, in the absence of a right-to-left shunt, systemic arterial oxygen content is used. If a right-to-left shunt is present, pulmonary venous oxygen content is calculated as 98% of the oxygen capacity.

The size of an isolated left-to-right shunt is:

$$L \rightarrow R\ shunt = PBF - SBF$$

If an additional right-to-left shunt is present (bidirectional shunt), the approximate size of the left-to-right shunt is:

$$L \rightarrow R\ shunt = PBF - EBF$$

The approximate size of the right-to-left shunt is:

$$R \rightarrow L\ shunt = SBF - EBF$$

Clinically, the ratio of PBF to SBF (or Qp/Qs) is often used to express shunt significance. A ratio less than 1.5 indicates a small left-to-right shunt, a ratio of 1.5 to 2.0 a moderate-sized shunt, and a ratio greater than 2.0 a large left-to-right shunt. A flow ratio less than 1.0 indicates a net right-to-left shunt.

If oxygen consumption is not measured, the PBF/SBF ratio may be calculated as follows:

$$PBF/SBF\ ratio = (SaO_2 - MvO_2) \div (PvO_2 - PaO_2)$$

where SaO_2, MvO_2, PvO_2, and PaO_2 are systemic arterial, mixed venous, pulmonary venous, and pulmonary arterial blood oxygen saturation, respectively.

Physiologic and Pharmacologic Maneuvers

Not infrequently, potentially significant cardiac abnormalities are absent under resting conditions and require unmasking by physiologic and/or pharmacologic provocation maneuvers.

Dynamic Exercise.

Dynamic exercise is still the most physiologic way of testing. In the catheterization laboratory, this is

performed with a supine bicycle ergometry. Once a balloon flotation catheter is inserted in a sterile manner via an antecubital or internal jugular vein, even an upright bicycle and treadmill exercise can be performed under hemodynamic monitoring outside the catheterization laboratory.

Under normal conditions, the increased oxygen demand induced by exercise is met by an increase in cardiac output and peripheral oxygen extraction. Cardiac dysfunction impairs the increase in cardiac output, and the demands of exercise can only be met by increased peripheral oxygen extraction, leading to often profound drops in mixed venous oxygen saturation and thus profound increases in arteriovenous oxygen difference. The fact that cardiac output and oxygen consumption are in linear correlation allows for a prediction of the cardiac index at a given level of oxygen consumption. The exercise index represents the ratio of the actually observed to the predicted cardiac index. A value of 0.8 or greater reflects a normal cardiac output response to exercise. Another way of expressing the same relationship is the *exercise factor*, defined as the increase in cardiac output divided by the increase in oxygen consumption. An exercise factor of 6 or higher is normal; that is, for every 100-mL/min increase in oxygen consumption, cardiac output should increase by at least 600 mL/min with exercise.

Although the most suitable approach for the catheterization laboratory, there are important nuances to supine exercise. In the early phase, there is increased venous return, augmenting LV end-diastolic volume and stroke volume. However, at progressively higher levels of exercise, LV end-systolic volume and LV end-diastolic volume decrease, minimizing stroke volume increase. The augmentation in cardiac output with this form of stress testing is therefore accomplished primarily by an increase in heart rate. It can therefore remain low, for instance, because of chronotropic incompetence alone.

However, this type of invasive hemodynamic exercise testing still is very useful for the diagnostic workup of patients with presumed heart failure with preserved ejection fraction (HFpEF) and valvular heart disease of no or borderline significance in the resting state[42] (**see Chapter 26**). Exercise increases LVEDP, PCWP, and pulmonary artery pressure in patients with HFpEF. It increases transvalvular mitral gradient and pulmonary artery pressure in mitral stenosis. In patients with clinically relevant valvular regurgitation, exercise increases LVEDP, PCWP, and SVR in conjunction with a reduced exercise index (<0.8) and abnormal exercise factor (<6). Simultaneous echocardiographic evaluation of valvular regurgitation and invasive hemodynamic assessment is also useful in equivocal cases (**see Chapter 14**).

Pacing Tachycardia.

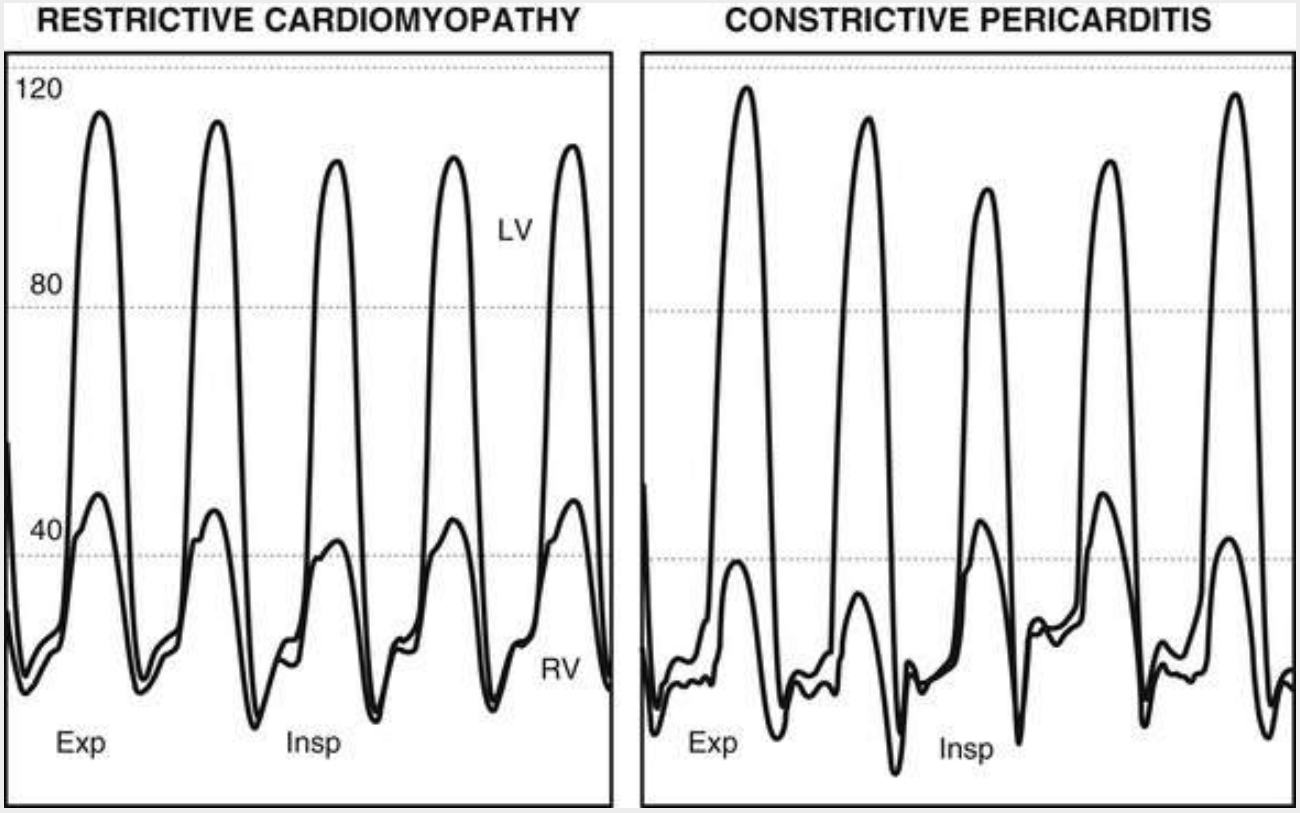
Rapid atrial or RV pacing increases myocardial oxygen consumption and myocardial blood flow, LV end-diastolic volume decreases, and there is little change in cardiac output. It can be a useful method to define the severity of mitral valve stenosis. The immediate on-and-off effect is of benefit.

Physiologic Stress.

Various forms of physiologic stresses can be used, all of which alter the filling conditions of the heart. For example, the Valsalva maneuver in the strain phase decreases venous return and thus LV preload, which increases the systolic LV outflow tract pressure gradient in patients with HCM. In these patients, induction of a premature ventricular beat (Brockenbrough maneuver) paradoxically decreases the pulse pressure and accentuates the spike-and-dome configuration on the aortic pressure waveform of the subsequent ventricular beat as the outflow gradient increases.

Another very useful physiologic challenge is rapid volume loading, which may unmask and/or distinguish pericardial constriction from myocardial restriction (**see Chapter 83**). Both conditions share early rapid filling dynamics and equalization of LV and RV pressure at end-expiration. One of the distinguishing features of constriction, however, is that the pericardial restraint does not allow any overall volume expansion of the cardiac chambers. Accordingly, any volume expansion of the right

ventricle will be at the cost of volume contraction of the left ventricle, and vice versa, so-called exaggerated ventricular interdependence. On inspiration, therefore, because of increased venous return, there is an increase in RV filling, volume, and pressure, reflected in an increase in the systolic pressure-time area on the RV pressure tracing. Concomitantly, LV volume and pressure decrease, reflected in a decrease in the LV systolic pressure-time area on the simultaneous LV pressure tracing (**eFig. 19.14**). The ratio of the RV to the LV systolic pressure–time area in inspiration versus expiration, the *systolic area index*, is positive in constriction but not in restriction (1.4 ±0.2 versus 0.92 ±0.019; $P < 0.0001$).[51] A systolic area index greater than 1.1 has a sensitivity of 97% and predicted accuracy of 100% for identifying constriction.[43] In real time, ventricular interdependence is often assessed in the catheterization laboratory by visual assessment of the LV and RV waveform dynamics relative to each other over the course of multiple respiratory cycles. It shows dyssynchrony in constriction and synchrony in restriction (**eFig. 19.14**).



EFIGURE 19.14 **Left,** In restrictive cardiomyopathy, there is a drop in left ventricular (*LV*) pressure and a drop in right ventricular (*RV*) pressure during inspiration (*Insp*). This indicates that the elevation of ventricular filling pressures is caused by a myocardial restrictive disease. *Right,* In constrictive pericarditis, there is ventricular discordance, with an increase in RV pressure and a decrease in LV pressure during inspiration. This is caused by the enhancement of ventricular interaction and dissociation of intrathoracic and intracardiac pressures. *Exp,* Expiration. (From Nishimura RA, Carabello BA. Hemodynamics in the cardiac catheterization laboratory of the 21st century. Circulation 2012;125:2138.)

A rapid *y* descent is indicative of rapid early diastolic filling and corresponds to the dip of the square root sign on the diastolic ventricular pressure tracing. It is present in both restriction and constriction, but a rapid *y* descent is absent in patients with tamponade. The patients usually have a marked pulsus paradoxus, which is a greater than 10 mm Hg drop in systemic systolic blood pressure during inspiration. It can also be present in constrictive pericarditis and is an expression of the ventricular interdependence. The lack of decline or more obvious increase in atrial (venous) pressure during inspiration (Kussmaul sign) reflects impaired compliance of either the pericardium or myocardium and thus is not a

distinguishing feature between constriction and restriction.

Pharmacologic Maneuvers

A number of drugs are used in the cardiac catheterization laboratory. One of the most common indications is the determination of reversibility of pulmonary hypertension either by nitric oxide or sodium nitroprusside (**see Chapter 85**).

Nitric oxide is an endothelium-derived vasodilator, and if administered by inhalation, it is rapidly inactivated. Thus it can be used safely without causing systemic hypotension and effectively to assess a pulmonary vasodilator response, which is a fairly accurate predictor of the response to medical therapy. The dose can be doubled in 5- to 10-minute intervals from 10 to 80 ppm, but a single uniform dose of 80 ppm is equally feasible. Cardiac output, pulmonary artery pressure, and PCWP are the key study parameters, allowing calculation of PVR. A positive vasodilator response (reversibility) is defined as a decrease in mean pulmonary artery pressure of at least 10 mm Hg to an absolute mean pulmonary artery pressure of less than 40 mm Hg without a decrease in cardiac output.

If PCWP is elevated at baseline, inhaled nitric oxide is not to be used as a reduction in PVR would lead to increased forward flow through the pulmonary vasculature and thus increased filling of left-sided heart chambers that have already reached their maximum compliance, precipitating further increase in PCWP with the risk of pulmonary edema.

With elevated PCWP, sodium nitroprusside is to be used to document if reduction in afterload and LV filling pressure lowers pulmonary artery pressure and possibly improves cardiac output. This holds true in cases of MR, dilated cardiomyopathy, and HFpEF. A typical protocol is to commence the infusion at 0.25 to 0.5 µg/kg/min following acquisition of baseline hemodynamic data and to uptitrate at the same dose range in 3- to 5-minute intervals until PCWP is less than 18 mm Hg, systemic blood pressure less than 90 mm Hg, or development of symptoms (e.g., lightheadedness).[44,45] Hemodynamic measurements are then repeated, and a positive response is usually defined as a drop in PVR of at least 20%. This intervention can also be useful to define the degree of aortic stenosis in those with a severely narrowed valve area but low gradient and systemic hypertension[46] (**see Chapter 68**).

Up to one third of patients with low-flow, low-gradient aortic stenosis—a mean aortic gradient below 30 mm Hg and low cardiac output/low ejection fraction (<40%)—may be incorrectly defined as having severe aortic stenosis by the Gorlin formula. In order to differentiate true from pseudo–severe aortic stenosis, dobutamine can be infused at 5 µg/kg/min and increased by 3 to 10 µg/kg/min every 5 minutes. The test is ended once a maximum dose of 40 µg/kg/min is reached, the heart rate is greater than 140 beats/min, and/or cardiac output is increased by 50%, or the mean gradient increased to more than 40 mm Hg. Patients with a final aortic valve area smaller than 1.2 cm^2 and mean gradient greater than 30 mm Hg are considered to have severe aortic stenosis. A coronary angiogram is advised before dobutamine infusion in those at high risk for severe coronary artery disease as an explanation for the reduced cardiac function.

In patients with HCM, various manipulations can be performed to confirm the dynamic nature of the outflow tract gradient (**see Chapter 78**). The gradient is increased by isoproterenol due to increased inotropy and chronotropy, and by nitroglycerin or amyl nitrate due to decreased preload and afterload. Phenylephrine, by increasing afterload (SVR), is used to reduce the dynamic outflow tract gradient in obstructive HCM.

Endomyocardial Biopsy

The technique of percutaneous endocardial and myocardial biopsy is more than 50 years old with only slight refinements over time (**Fig. 19.15**). Currently it is mainly used to monitor for rejection after cardiac transplantation (**see Chapter 28** and Classic References, Konno). For native hearts, there are two class I indications, both directed toward giant cell myocarditis (**see Chapter 79**), amenable to immunosuppressive therapy and heart transplantation (**Table 19.4**). The first class I indication is new-onset heart failure of less than 2 weeks' duration associated with either normal or enlarged LV size and hemodynamic compromise, in essence fulminant myocarditis. The second class I indication is new-onset heart failure of up to 3 months' duration complicated by LV dilation, new ventricular arrhythmias, advanced heart block, or failure to respond to treatment within 2 weeks. The use of biopsy for suspected anthracycline toxicity (**see Chapter 81**) or restrictive disease is considered a class IIa indication.[47]

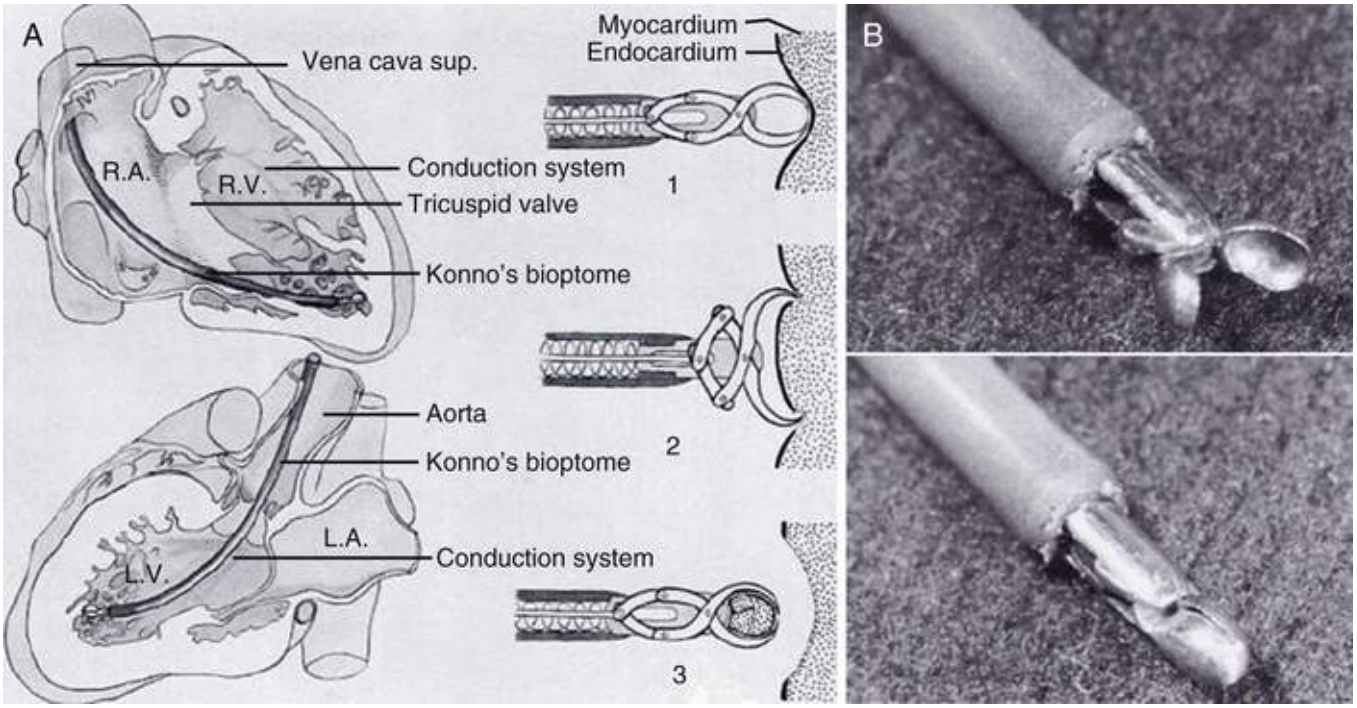


FIGURE 19.15 **A,** Original illustration by Konno and Sakakibara of the percutaneous technique of endocardial and myocardial specimen collection by use of a bioptome. **B,** Biopsies are taken by opening and closing the cutting claw at the tip of the catheter. TABLE 19.4

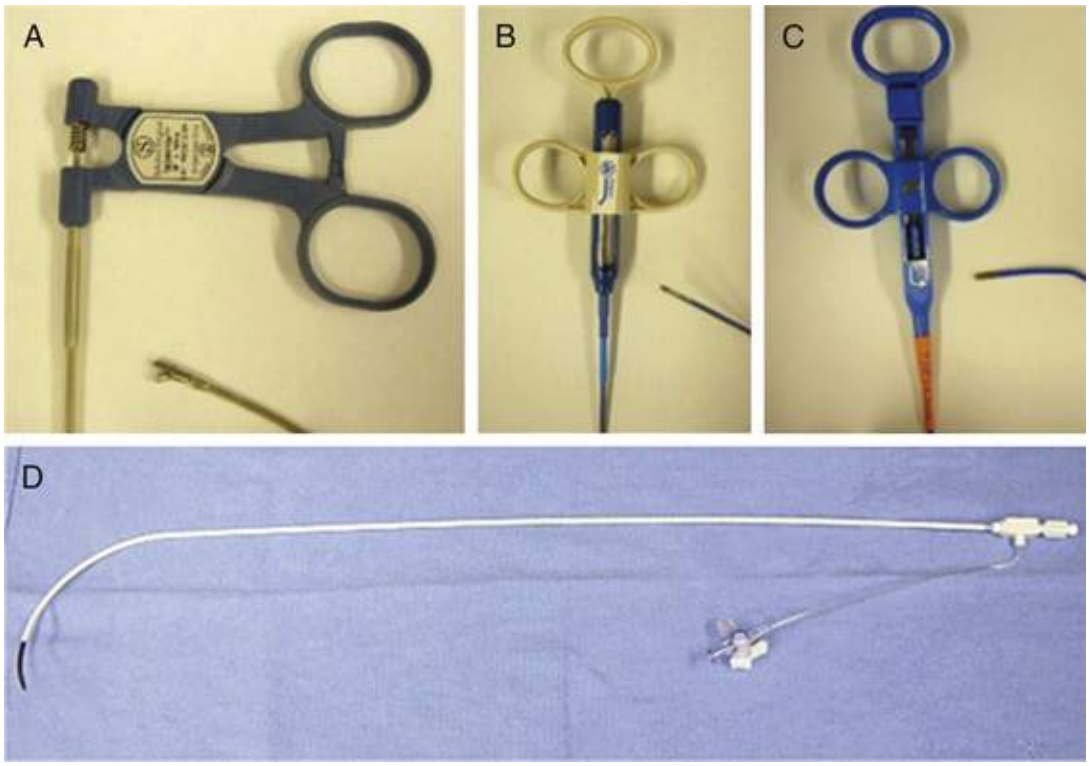
Endomyocardial Biopsy Recommendations

CLINICAL SCENARIO	CLASS OF RECOMMENDATION	LEVEL OF EVIDENCE
New-onset heart failure of <2 weeks' duration associated with a normal-sized or dilated left ventricle and hemodynamic compromise	I	B
New-onset heart failure of 2 weeks' to 3 months' duration associated with a dilated left ventricle and new ventricular arrhythmias, second- or third-degree heart block, or failure to respond to usual care within 2 weeks	I	B
Heart failure >3 months' duration associated with a dilated left ventricle and new ventricular arrhythmias, second- or third-degree heart block, or failure to respond to usual care within 2 weeks	IIa	C
Heart failure associated with dilated cardiomyopathy of any duration and suspected allergic reaction and/or eosinophilia	IIa	C
Heart failure associated with suspected anthracycline-induced cardiomyopathy	IIa	C
Heart failure associated with unexplained restrictive cardiomyopathy	IIa	C
Suspected cardiac tumors	IIa	C
Unexplained cardiomyopathy in children	IIa	C
New-onset heart failure of 2 weeks' to 3 months' duration associated with a dilated left ventricle, without new ventricular arrhythmias or second- or third-degree heart block, that responds to usual care within 2 weeks	IIb	B
Heart failure >3 months' duration associated with a dilated left ventricle, without new ventricular arrhythmias or second- or third-degree heart block, that responds to usual care within 2 weeks	IIb	C
Heart failure associated with unexplained hypertrophic cardiomyopathy	IIb	C
Suspected arrhythmogenic RV dysplasia	IIb	C
Unexplained ventricular arrhythmias	IIb	C
Unexplained atrial fibrillation	III	C

From Cooper LT et al. The role of endomyocardial biopsy in the management of cardiovascular disease. J Am Coll Cardiol 2007;50:1914.

Endomyocardial biopsy is performed mainly with disposable bioptomes, most often preshaped 50-cm bioptomes, delivered through the right internal jugular vein[48] (**eFig. 19.15**). To overcome potential sources of complications, as in the case of chronic, adherent thrombus or difficult atrial suture lines, it is advisable to use a long sheath. With a right internal jugular vein occlusion, one may consider a left internal jugular vein approach with a long catheter sheath to overcome the resistance of the two acute angles along this approach (1) into the left innominate/brachiocephalic vein and (2) into the SVC. Another alternative is the right subclavian vein approach, but it still needs to be addressed beforehand if the occlusion extends into the SVC. Often, a femoral venous approach is thus taken. LV biopsies are performed on rare occasions by the femoral arterial approach.[49,50]



EFIGURE 19.15 Commonly used bioptomes. **A,** Single-use 50-cm Novatome (Sholten Surgical Instruments, Lodi, Calif) with a 2.3-mm tip that requires a 9F sheath. **B,** Argon endomyocardial biopsy forceps (Argon Medical Devices, Athens, Texas) with a 1.8-mm tip that requires a 6F sheath or a 2.3-mm tip that requires a 7F sheath. **C,** Bipal 7 bioptome, 50 cm and 104 cm (Cordis, Miami Lakes, Fla) with a 2.3-mm tip that requires a 7F sheath. **D,** 8F Transseptal Mullens (Medtronic, Minneapolis, Minn) sheath when using the longer Bipal 7 bioptome through right femoral vein access to improve tip control and placement. (From AM, Maleszewski JJ, Rihal CS. Current status of endomyocardial biopsy. Mayo Clin Proc 2011;86:1095.)

For the right internal jugular venous approach, a 7F short straight sheath or long curved sheath (e.g., FastCath 45-cm introducer sheath with 30-degree curve type; St. Jude Medical, St. Paul, Minnesota) is introduced in Seldinger technique, ideally under ultrasound guidance and using a micropuncture kit for initial access. If a short sheath is used, the atrial suture line may be felt as a ridge that is passed as a 7F bioptome is advanced under fluoroscopic guidance. Any resistance or unusual deviation of the bioptome to the side should prompt reorientation to avoid perforation. Within the right atrium, a slight counterclockwise rotation usually allows the device to advance across the tricuspid valve, maintaining the torque unto the interventricular septum. Again, the lateral wall of the right atrium should be avoided, and force should never be used since perforations can occur. A too-medial orientation and associated risk of probing into the coronary sinus should also be avoided. The same general maneuvers apply to the placement of long preshaped sheaths, which are advanced through a 0.035-inch J-tip wire into the right ventricle and are positioned against the RV septum. The sheath should be aspirated and flushed to avoid thrombus formation, and RV pressure monitoring should exclude damping from engagement against the wall. The bioptome is then passed through the sheath directly onto the septum. However, this needs to be confirmed visually. For all these aspects of the procedure, 2D echocardiography can be of superior guidance than fluoroscopy. For the latter, both the 30-degree RAO and the 40-degree LAO view are advisable. The RAO view is to confirm that the device is in the midventricle away from the apex, the LAO view that the tip is oriented toward the interventricular septum. If long sheaths are used, infusion of contrast material through the side port can help confirm position.

For the femoral venous approach, a long 7F sheath (e.g., Mullins-style introducer sheath) is introduced and under fluoroscopy directed toward the septum. The conventional sheath has a 45-degree angle on its distal end; however, specifically designed sheaths have dual curves: the usual 180-degree curve and an

additional distal perpendicular septal plane curve of 90 degrees. This allows for improved manipulation and positioning toward the interventricular septum. With long sheaths, and especially if the Mullins sheath is used, continuous slow flush is recommended given the predisposition of this sheath to thrombus formation.

Regardless of access, contact of the bioptome with the myocardium is confirmed by induction of premature ventricular complexes (PVCs), resistance to further advancement, and device transmission of the RV impulse. The bioptome is then, under imaging, drawn back slightly from the septum, the jaws are opened, and the bioptome is readvanced to make contact with the myocardium; thereafter the jaws are closed. In good position, a slight tug is usually felt on removal of the device. Four to five biopsy samples, each at least 1 mm in size, often suffice for pathologic analysis. Preprocedural consultation with a pathologist or transplant cardiologist may be required to ensure appropriate biopsy sampling and processing. This includes addressing whether a global or a focal process is being addressed. For example, in patients with suspected sarcoidosis (**see Chapter 77**), the biopsy should be directed to areas that were identified as active on noninvasive imaging. Special cases may even require electromechanical mapping to orient the bioptome to the right location.

If an LV biopsy is to be performed, a long sheath is advanced from the common femoral artery into the left ventricle just below the mitral apparatus and away from the posterobasal wall over a wire and supported by an interior multipurpose or pigtail catheter, which forms the tip. Once in position, the sheath is advanced, and the catheter is exchanged for a long LV bioptome. Directing the LV bioptome by appropriate imaging is key again. As previously outlined, a constant slow infusion through the sheath minimizes the chances of thrombus formation and air embolism, which is even of greater risk with LV biopsies.

Potential complications of endomyocardial biopsy include cardiac perforation with tamponade (usually free wall sampling); emboli of air, tissue, or thrombus; arrhythmias; electrical conduction disturbances; injury to the tricuspid valve; vasovagal reactions; and pneumothorax (upper chest access complication). Another complication is the generation of coronary to LV or RV (coronary-cameral) fistula.[51] Overall, the cited complication rate may be as high as 6%, but the risk for cardiac perforation with tamponade is less than 0.1%. Importantly, endomyocardial biopsy is the most common cause of severe TR after heart transplantation.[48] This risk can be reduced with the use of longer sheaths and/or echocardiographic assistance at the time of biopsy to direct away from the tricuspid valve apparatus. Echocardiography is also useful to direct away from the moderator band, the disruption of which can cause a right bundle branch block (BBB); this is of greater significance in those with left BBB. In general, echocardiography, and more recently 3D echocardiography, has been found to improve positioning of the sheath and bioptome tip in one half and one third of the patients, respectively[52] (**see Chapter 14**).

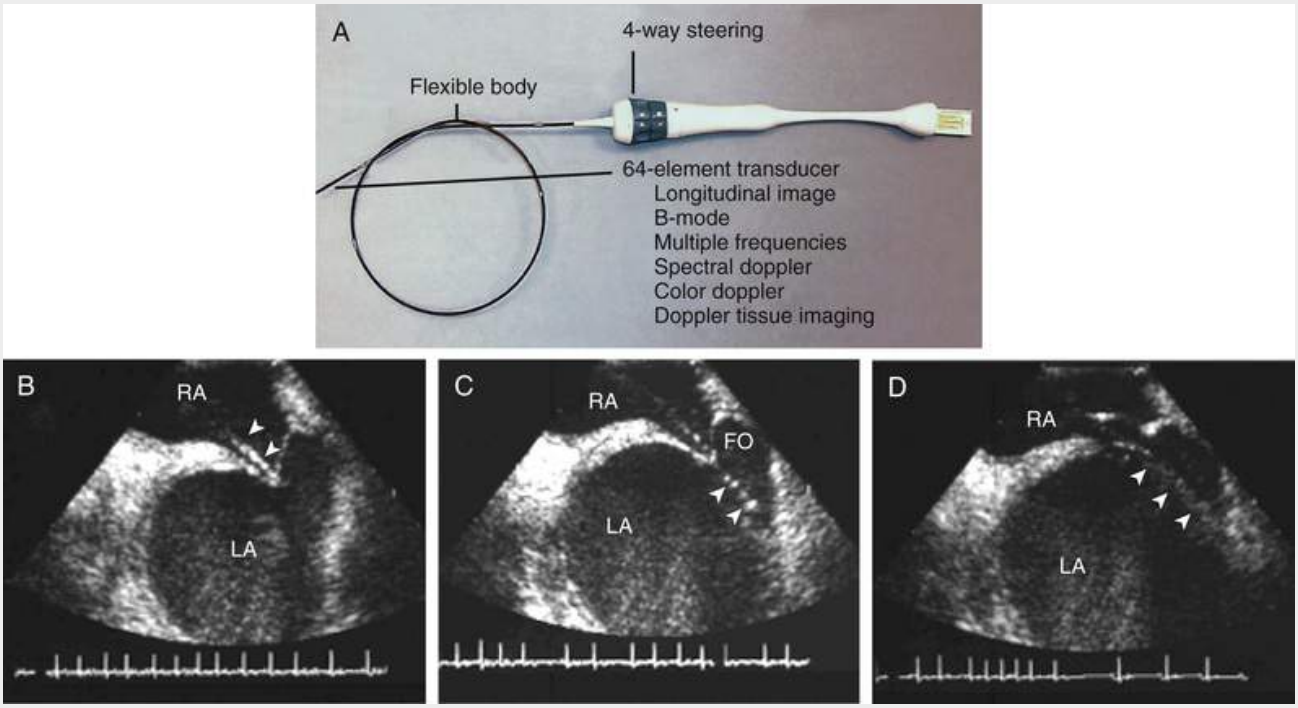
Systemic embolization and ventricular arrhythmias are more common with LV biopsy. LV biopsy should generally be avoided in patients with right bundle branch block because of potential for the development of complete atrioventricular block, as well as in patients with known LV thrombus.

Adjunctive Diagnostic and Therapeutic Techniques

Intracardiac Echocardiography

Intracardiac echocardiography (ICE) provides excellent imaging of the interatrial or interventricular

septum and left-sided heart structures from either the right atrium or ventricle. It is thus used to guide procedures, which are performed mainly at the atrial level, including transseptal puncture or percutaneous closure of atrial septal defects (ASDs) and patent foramen ovale. ICE has also been used in electrophysiologic procedures to identify structures difficult to view with fluoroscopy, such as pulmonary veins. A great advantage is the mitigation of the need for TEE and anesthesia (**eFig. 19.16**).



EFIGURE 19.16 **A,** ICE disposable transducer (Acuson) with a steering apparatus on proximal end and a flexible body with a transducer on distal tip of the catheter. **B,** Tenting of membranous fossa by dilator-needle assembly. Transseptal needle assembly (*arrowheads*) is advanced to indent fossa membrane. **C,** Advancement of transseptal needle across membranous fossa. Here the needle (*arrowheads*) is seen near posterosuperior left atrial wall. The membrane remains tented because the dilator has not yet crossed the septum. **D,** Passage of dilator and sheath across interatrial septum. The dilator and sheath assembly has now advanced into the left atrium, thereby releasing the tenting of the membranous fossa. *FO,* Fossa ovalis; *LA,* left atrium; *RA,* right atrium. (From Johnson SB, Seward JB, Packer DL. Phased-array intracardiac echocardiography for guiding transseptal catheter placement: utility and learning curve. Pacing Clin Electrophysiol 2002;25:402.)

The ICE imaging probe's catheter is available in 8F or 10F size and in 90- or 110-cm length and has two steering planes: anterior-posterior and left-right. The transducer operates at frequencies of 5 to 10 MHz and allows for 2D, color, and spectral Doppler echocardiographic imaging. The penetration length is up to 15 cm. The ICE probe is introduced by femoral venous access in the usual way, using an adequately sized sheath. The catheter has a stiffness that matches standard right-heart catheters and thus operates as such (short access sheath and careful advancement under fluoroscopy).

Percutaneous Hemodynamic Support

For patients with significant hemodynamic compromise, four main modalities of support are available in the catheterization laboratory: intra-aortic balloon pump (IABP), Impella, TandemHeart, and extracorporeal membrane oxygenation (ECMO)[53] (**Fig. 19.16** and **Table 19.5**).

Intra-Aortic Balloon Pump

The IABP operates by inflation of a balloon (30 to 50 mL in volume) with a helium gas in diastole and deflation in systole gated by the surface ECG or the pressure tracing.[53] This action of "counterpulsation" augments diastolic perfusion pressure in the coronary arteries and reduces LV afterload stress for the myocardium. There is also a reduction in LV preload, LVEDP, and PCWP. The volume shift by the balloon pump increases LV stroke volume by 15% to 30% and cardiac output by 1 L/min. The greatest benefit is seen in patients with severely reduced cardiac output. However, these patients may need greater augmentation in cardiac output than provided under most optimal conditions with an IABP. Furthermore, such patients may have poor RV function and possibly even poor oxygenation and may require more extensive biventricular and cardiopulmonary support.

IABPs have been traditionally used for patients with refractory angina, severe left main disease, cardiogenic shock, or mechanical complications of myocardial infarction (including severe MR and VSD) (**see Chapter 58**). An IABP may also be valuable at the time of MI and even after primary PCI, depending on the hemodynamics. It has been used as a support tool for patients undergoing high-risk PCI.

Randomized controlled trials (RCTs) and meta-analyses, however, argue against a general benefit in terms of morbidity and mortality. Despite an increase in coronary perfusion pressure, coronary blood flow may not be augmented significantly once severe coronary artery stenosis or acute coronary syndrome is present. The ACC/AHA STEMI guidelines give a class IIa indication for the use of IABP for patients with acute MI with cardiogenic shock, whereas the European Society of Cardiology (ESC) gives a class IIb indication. Contraindications include moderate or severe AR, aortic dissection, aortic aneurysm, patent ductus arteriosus, severe PAD, bleeding disorders, and sepsis.

The IABP is placed through the femoral artery in the standard Seldinger technique using 7F or 8F sheaths and a 0.025-inch wire. The size of the balloon is based on the patient's height. Under fluoroscopy, the tip is placed 2 to 3 cm below the level of the left subclavian artery. Chest radiographs should be obtained daily thereafter, and the optimal position is 2 cm above the carina.[54] Timing of the balloon inflation is adjusted in the 1 : 2 mode (every other beat inflation) using the ECG or pressure tracing. The optimal timing of inflation coincides with the dicrotic notch on the aortic pressure waveform and of deflation immediately before systole, which ensures maximal diastolic flow augmentation and maximal systolic unloading (**Fig. 19.17**). All patients should undergo anticoagulation, even though heparin-free use of IABP has been reported.

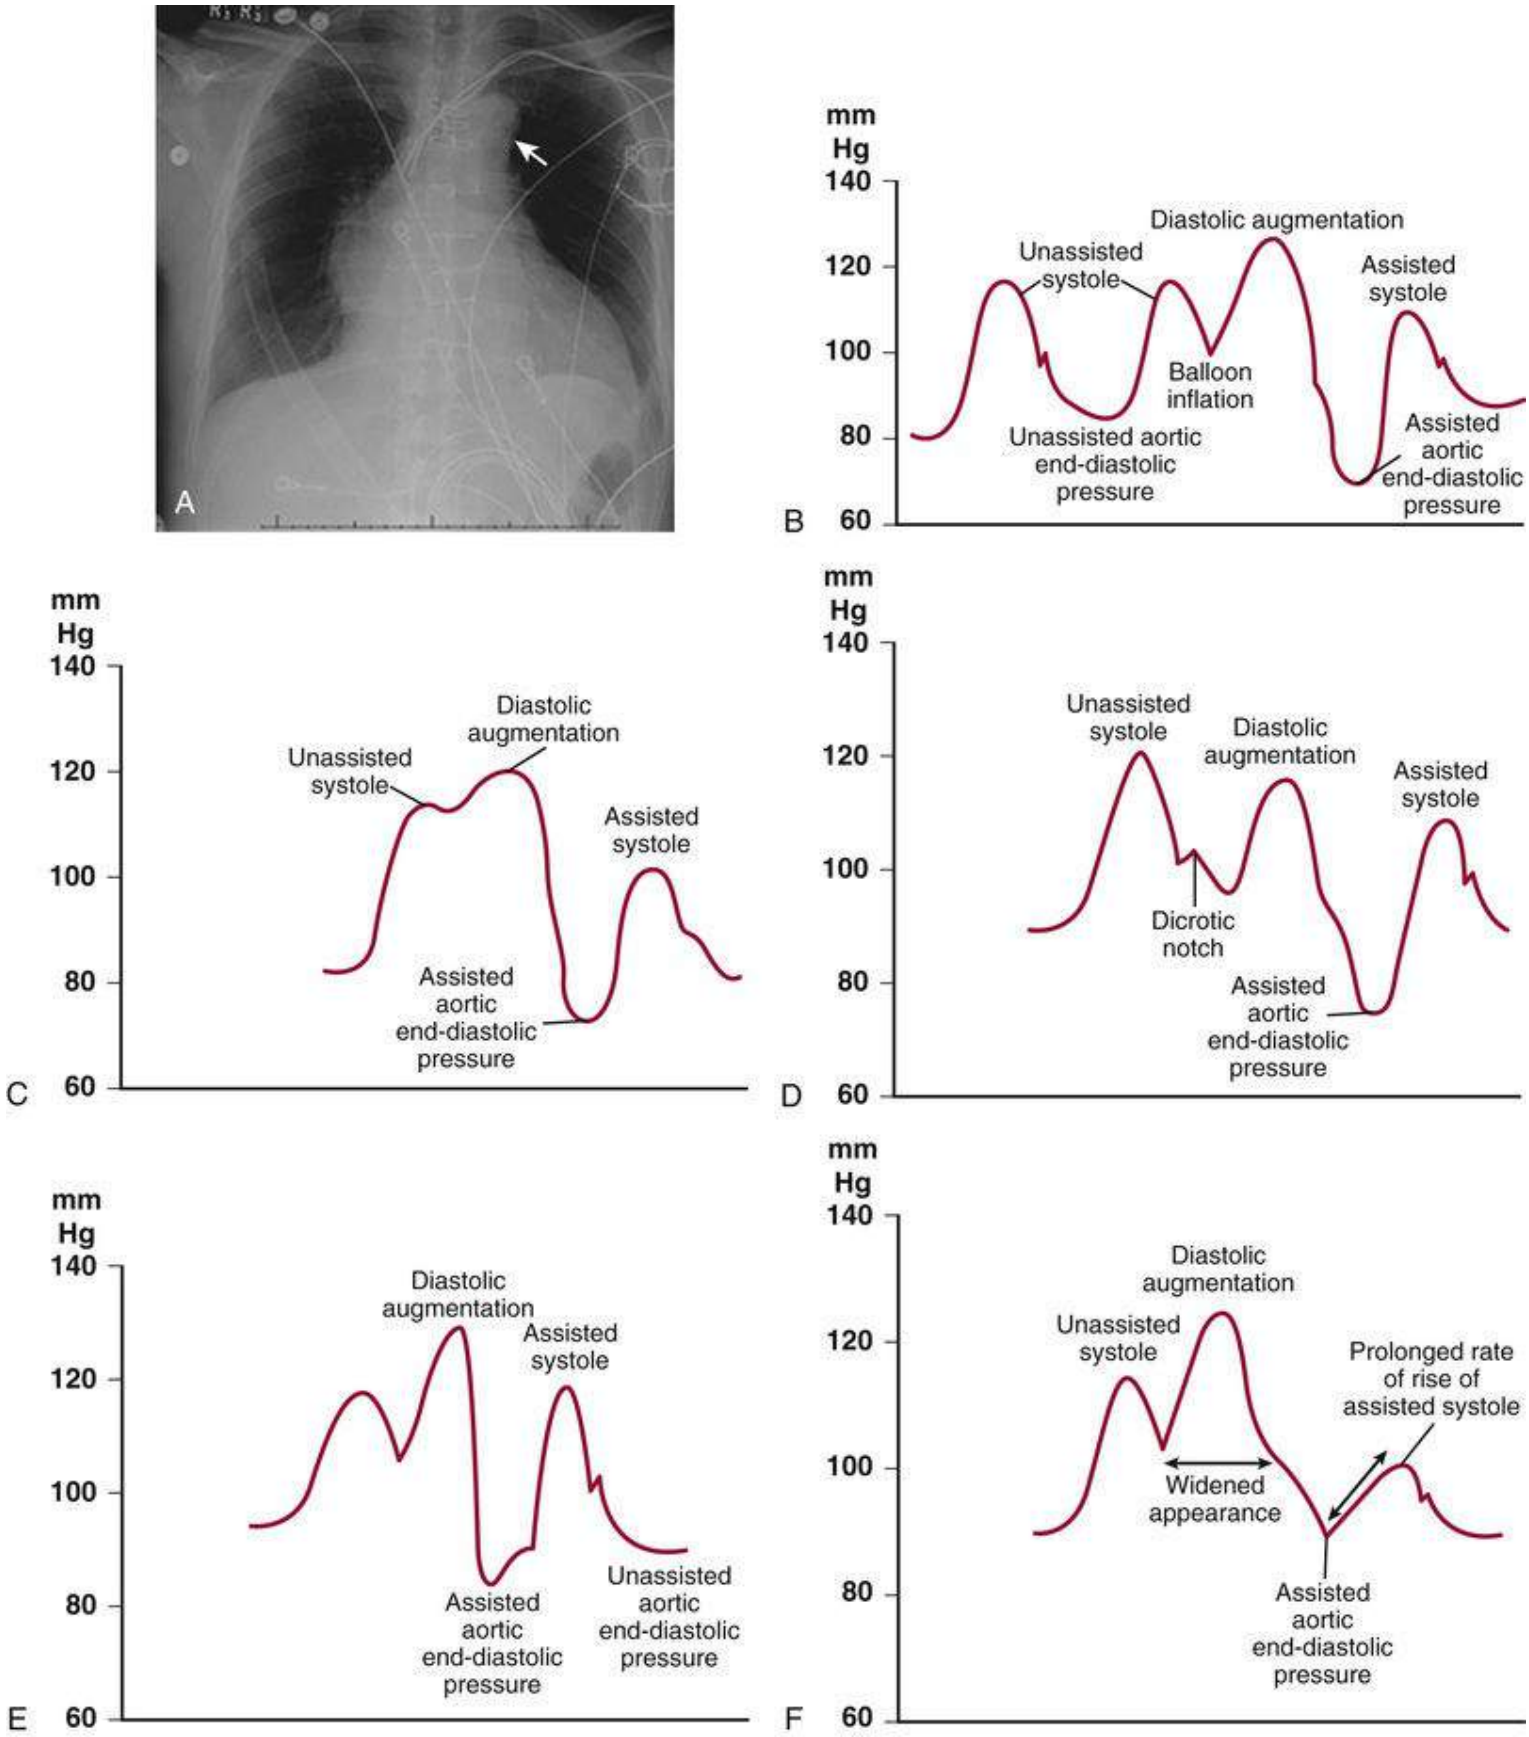

FIGURE 19.17 Intra-aortic balloon pump (IABP) position and arterial waveforms. **A,** Anteroposterior chest radiograph showing the proximal IABP marker (*arrow*) in proper position 2 cm above the carina. **B,** Normal systemic arterial pressure waveform with the IABP device programmed in 1 : 2 mode (i.e., to inflate during every other cardiac cycle). With the first beat, aortic systolic and end-diastolic pressures are shown without IABP support and are therefore unassisted. With the second beat, the balloon inflates with the appearance of the dicrotic notch, and peak-augmented diastolic pressure is inscribed. With balloon deflation, assisted end-diastolic pressure and assisted systolic pressure are observed. To confirm that the IABP is producing maximal hemodynamic benefit, the peak diastolic augmentation should be greater than the unassisted systolic pressure, and the two assisted pressures should be less than the unassisted values. **C,** Systemic arterial pressure waveform from a patient in whom balloon inflation occurs too early,

before aortic valve closure. Consequently, the left ventricle is forced to empty against an inflated balloon; the corresponding increase in afterload may increase myocardial oxygen demand and worsen systolic function. **D,** Systemic arterial pressure waveform from a patient in whom balloon inflation occurs too late, well after the beginning of diastole, thereby minimizing diastolic pressure augmentation. **E,** Systemic arterial pressure waveform from a patient in whom balloon deflation occurs too early, before the end of diastole. This may shorten the period of diastolic pressure augmentation. A corresponding transient decrease in aortic pressure may promote retrograde arterial flow from the carotid or coronary arteries and possibly induce cerebral or myocardial ischemia. **F,** Systemic arterial pressure waveform from a patient in whom balloon deflation occurs too late, after the end of diastole, thereby producing the same deleterious consequences as early balloon inflation (increased LV afterload with a resultant increase in myocardial oxygen demand and worsening of systolic function). (**A,** From American Heart Association; Tabit CE et al. Positional obstruction of the superior mesenteric artery by an intra-aortic balloon pump through subclavian artery approach. Circ Heart Fail 2014;7:864-7; **B-F,** From Trost JC, Hillis LD. Intra-aortic balloon counterpulsation. Am J Cardiol 2006;97:1391.)

Complications such as balloon rupture or entrapment are rare. The risk of infection increases with the acuity and the trauma of the placement, the initial and daily site care, as well as the duration of placement. Bleeding complications at the site are uncommon as long as no multiple access attempts have been made. The greater concern relates to limb ischemia, which may occur in 10% to 40% of patients. Patients with PAD (postinsertion ankle-brachial index <0.8), diabetes, and smaller-caliber vessels (women) are at higher risk. In at-risk populations, smaller catheters (7F) should be used. In case ischemia develops, the key is prompt recognition and prompt removal of the IABP, which usually suffices to resolve ischemia. Surgical intervention (thrombectomy, vascular repair, fasciotomy, or amputation) is rarely required.

Impella.

The Impella device is an axial flow pump in form of a pigtail catheter placed across the aortic or pulmonic valve, so that the inlets/outlets are positioned in the left ventricle/ascending aorta and right ventricle/pulmonary artery. Four versions are currently available: Impella 2.5, Impella CP, Impella 5.0, and Impella RP, providing up to 2.5, 4, 5, and 4 L/min in output, respectively. Because of the larger size, placement of the Impella 5.0 device requires surgical cutdown of the femoral or axillary artery, whereas the other types can be placed percutaneously through 13F, 14F, and 23F sheaths. The direct assist and mechanical unloading of the left ventricle with the Impella reduces end-diastolic wall stress and PCWP; myocardial oxygen consumption is reduced as well. The increased output improves coronary perfusion pressure and coronary blood flow. The right-sided Impella improves pulmonary perfusion and LV filling.

In patients with cardiogenic shock enrolled in the ISAR-SHOCK trial, the Impella 2.5 device led to greater increase in cardiac index and mean arterial pressure and lower lactate levels at no higher risk of complications than with the IABP.[55] Mortality outcomes were nevertheless similar. A lower mortality rate than with IABP, however, has been reported for the Impella 5.0 device in patients with postcardiotomy low-output syndrome. It has therefore been argued that greater levels of support may be required in patients in cardiogenic shock. Even so, as outlined next, even with greater levels of hemodynamic support, survival may not be improved. While the Impella device is safe, hemolysis caused by the high rotational speed of the axial flow pump, access bleeding, and limb ischemia are known complications.

The AHA/ACC and ESC guidelines for the management of STEMI give a class IIb recommendation for the use of left ventricular assist devices in refractory cardiogenic shock (especially those deteriorating on IABP). This includes Impella, TandemHeart, and ECMO.[53]

TandemHeart.

The TandemHeart involves the continuous centrifugal pump circulation of oxygenated blood from the left

atrium (via transseptal cannula placement) into the lower abdominal aorta or iliac arteries (via cannula placement through common femoral artery).[56] In comparison with IABP, it provides greater increase in cardiac output (up to 4 L/min) and mean arterial pressure and greater decrease in PCWP, central venous pressure, and pulmonary artery pressure. LV and RV filling pressures are reduced as is cardiac workload and oxygen demand.

Complications remain a concern and argue for suitable device experience. Indeed, performing a fluoroscopy-guided transseptal puncture and to advance a 21F inflow cannula into the left atrium in a patient in cardiogenic shock requires courage and skill. Registry data indicate that approximately 0.8% of patients may sustain a wire-related perforation of the left atrium after transseptal puncture, and a similar number with common femoral artery dissection. More common complications are groin hematomas (5.1%), bleeding around cannula site (29.1%), device-related limb ischemia (3.4%), sepsis/SIRS (29.9%), gastrointestinal bleeding (19.7%), coagulopathy (11%), and stroke (6.8%), as well as blood transfusions in 71%. Taken together, while conceptually intriguing, the challenges of the insertion of the TandemHeart may limit its use.

Extracorporeal Membrane Oxygenation.

The ECMO system consists of a centrifugal pump, a heat exchanger, and a membrane oxygenator. Deoxygenated blood is aspirated from the right atrium into the centrifugal pump by a cannula placed through a common femoral venous approach. The oxygenated blood is then returned into the descending aorta by an outflow cannula placed through a common femoral artery. ECMO generates full circulatory support with up to 4.0 L/min and reduces LV preload. However, it does not reduce, and in fact may increase, LV afterload and thus oxygen demand. Complications include systemic inflammatory response syndrome (SIRS), renal failure, limb ischemia, and bleeding. Despite these adverse effects, ECMO has been successfully used in cardiogenic shock patients with STEMI, myocarditis, and postcardiotomy syndrome. It has also been used in the cardiac catheterization laboratory for patients who developed cardiorespiratory arrest during interventional procedures.

In single-center retrospective comparisons with historic controls, 30-day survival was almost twofold higher in the ECMO group. It is particularly useful for patients with pulmonary oxygenation impairment. Disadvantages are potential bleeding complications, limb ischemia, and the need for specialized care, including the availability of perfusionists.

Coronary Angiography and Intravascular Imaging

Roxana Mehran, George D. Dangas

Coronary angiography consists of the visualization of the coronary anatomy under fluoroscopy, facilitated by direct injection of contrast media into the epicardial coronary arteries through a catheter advanced from a peripheral artery to the aortic root and into the coronary ostia.

The history of coronary angiography starts in the 19th century with the discovery of x-rays by Roentgen in 1895. One month later, Haschek and Lindenthal injected a mixture of calcium carbonate in the blood vessels of an amputated hand and were able to visualize the vascular bed using a roentgenogram. Meanwhile, Frédérick Cournand and Dickinson Richards at Columbia University performed the first experiments on cardiac catheterization in animals, which led to the description of heart hemodynamics and the development of crucial techniques and principles, such as the Fick method to measure cardiac output and pressure manometry (**see Chapter 19**). Forssmann performed the first human cardiac catheterization on himself in 1928, advancing a catheter through an antecubital vein into his right atrium, and acquired roentgenograms to document it.

Selective coronary angiography was first attempted in 1958 by Mason Sones, who cannulated a right coronary artery with a catheter inserted through a brachial artery.[1] In the 1960s, angiographic studies for the determination of coronary artery disease (CAD) were performed in extremely ill patients in the few tertiary care centers in the United States with the necessary resources. Coronary angiography remained a purely diagnostic technique until 1977, when Gruentzig performed the first percutaneous transcatheter coronary angioplasty (see Classic References, Ryan). In the early 1990s the field of coronary angiography entered a period of explosive growth, such that by 2010, an estimated 1,029,000 inpatient diagnostic cardiac catheterizations procedures and 954,000 inpatient percutaneous coronary intervention (PCI) procedures (**see Chapter 62**) were performed per year in the United States alone.[2] Recent years have seen rapid development and maturation of the field, with continuous introduction of new materials, techniques, and innovations for coronary angiography and intracoronary interventions.

Despite the availability of noninvasive imaging techniques such as computed tomographic coronary angiography (CTCA) and magnetic resonance coronary angiography (MRCA) that allow visualization of

the coronary anatomy without the risks related to an invasive percutaneous procedure (**see Chapters 17 and 18**), selective coronary angiography remains the “gold standard” to determine the extent of CAD because it is the only technique that can simultaneously provide both functional and anatomic information for the estimation of ischemic burden of CAD. Although coronary angiography technique is well established, it is important to keep in mind that it is an invasive procedure with potential complications. Therefore, indications for coronary angiography are clearly defined in the current American Heart Association and American College of Cardiology (AHA/ACC) clinical practice guidelines.[3,4] In this chapter, we review the indications for coronary angiography, the basic technique, and interpretation of angiographic images, with an overview of the available intravascular imaging techniques.

Indications for Coronary Angiography

Selection of candidates for invasive coronary angiography is based on the pretest probability of CAD, which is estimated on the basis of the clinical evaluation of the patient, the patient's clinical presentation, and the results of noninvasive diagnostic testing such as electrocardiography, echocardiography, blood tests, stress test, and CTCA or MRCA if performed[5,6] (**see Chapters 13, 14, and 16 to 18**). Current guidelines and indications for coronary angiography by clinical presentation are summarized in **Chapters 59, 60, and 61** (**see also eTable 20.1**).[3,7]

ETABLE 20.1

Current Clinical Practice Guidelines on the Indications for Coronary Angiography in Stable CAD, UA/NSTEMI, and STEMI

CLASS I	CLASS IIA	CLASS IIB	CLASS III
Stable CAD			
1. Patients with SIHD who have survived sudden cardiac death or potentially life-threatening ventricular arrhythmia. (*LOE: B*) 2. Patients with SIHD who develop symptoms and signs of HF should be evaluated to determine whether coronary angiography should be performed for risk assessment. (*LOE: B*) 3. Patients whose clinical characteristics and results of noninvasive testing indicate a high likelihood of severe IHD and in whom the benefits are deemed to exceed risk. (*LOE: C*) 4. Patients with presumed SIHD who have unacceptable ischemic symptoms despite optimal medical therapy and who are amenable to, and candidates for, coronary revascularization. *(LOE: C)*	1. Patients with suspected SIHD whose clinical characteristics and results of noninvasive testing (exclusive of stress testing) indicate a high likelihood of severe IHD and who are amenable to, and candidates for, coronary revascularization. *(LOE: C)* 2. Patients with suspected symptomatic SIHD who cannot undergo diagnostic stress testing, or have indeterminate or nondiagnostic stress tests, when there is a high likelihood that the findings will result in important changes to therapy. *(LOE: C)* 3. Patients with SIHD who have depressed LV function (EF <50%) and moderate-risk criteria on noninvasive testing with demonstrable ischemia. (*LOE: C*) 4. Patients with SIHD and inconclusive prognostic information after noninvasive testing or patients for whom noninvasive testing is contraindicated or inadequate. (*LOE: C*) 5. Patients with SIHD who have unsatisfactory quality of life due to angina, have preserved LV function (EF >50%), and have intermediate-risk criteria on noninvasive testing. (*LOE: C*)	1. Patients with stress test results of acceptable quality that do not suggest the presence of CAD when clinical suspicion of CAD remains high and there is a high likelihood that the findings will result in important changes to therapy. *(LOE: C)*	1. Patients with SIHD who elect not to undergo revascularization or who are not candidates for revascularization because of comorbidities or individual preferences. (*LOE: B*) 2. Patients with SIHD who have preserved LV function (EF >50%) and low-risk criteria on noninvasive testing. (*LOE: B*) 3. Patients who are at low risk according to clinical criteria and who have not undergone noninvasive risk testing. (*LOE: C*) 4. Coronary angiography is not recommended to assess risk in asymptomatic patients with no evidence of ischemia on noninvasive testing. (*LOE: C*)
ACS—UA and NSTEMI			
1. An urgent/immediate invasive strategy (diagnostic angiography with revascularization if appropriate) is indicated in patients with NSTE-ACS who have refractory angina or hemodynamic or electrical instability (without serious comorbidities or contraindications to such procedures). *(LOE: A)* 2. An early invasive strategy (diagnostic angiography with revascularization if appropriate) is indicated in initially stabilized patients with NSTE-ACS (without serious comorbidities or contraindications to such procedures) who have an elevated risk for clinical events. *(LOE: B)*	1. It is reasonable to choose an early invasive strategy (within 24 hours of admission) over a delayed invasive strategy (within 25 to 72 hours) for initially stabilized high-risk patients with NSTE-ACS. For those not at high/intermediate risk, a delayed invasive approach is reasonable. *(LOE: B)*	1. An ischemia-guided strategy may be considered for initially stabilized patients with NSTE-ACS (without serious comorbidities or contraindications to this approach) who have an elevated risk for clinical events. *(LOE: B)* 2. An ischemia-guided strategy in initially stabilized patients (without serious comorbidities or contraindications to this approach) may be reasonable after considering clinician and patient preference. *(LOE: C)*	1. An early invasive strategy (i.e., diagnostic angiography with intent to perform revascularization) is not recommended in patients with: a. Extensive comorbidities (e.g., hepatic, renal, or pulmonary failure; cancer), in whom the risks of revascularization and comorbid conditions are likely to outweigh the benefits of revascularization. *(LOE: C)* b. Acute chest pain and a low likelihood of ACS who are troponin negative *(LOE: C)*, especially women *(LOE: B)*.
ACS—STEMI			
1. Immediate angiography and PCI when indicated should be performed in resuscitated out-of-hospital cardiac arrest patients whose initial ECG shows STEMI. (*LOE: B*) 2. Primary PCI should be performed in patients with STEMI and ischemic symptoms of less than 12 hours' duration. (*LOE: A*) 3. Primary PCI should be performed in patients with STEMI and ischemic symptoms of less than 12 hours' duration who have contraindications to fibrinolytic therapy, irrespective of the time delay from first medical contact. (*LOE: B*) 4. Primary PCI should be performed in patients with STEMI and cardiogenic shock or acute severe HF, irrespective of time delay from MI onset. (*LOE: B*)	1. Primary PCI is reasonable in patients with STEMI if there is clinical and/or ECG evidence of ongoing ischemia between 12 and 24 hours after symptom onset. (*LOE: B*)		1. PCI should not be performed in a noninfarct artery at the time of primary PCI in patients with STEMI who are hemodynamically stable. (*LOE: B*)

ACS, Acute coronary syndrome; *CAD,* coronary artery disease; *ECG,* electrocardiogram; *EF,* ejection fraction; *HF,* heart failure; *IHD,* ischemic heart disease; *LOE,* level of evidence; *LV,* left ventricular; *MI,* myocardial infarction; *NSTE-ACS,* non–ST-segment elevation acute coronary syndrome; *NSTEMI,* non–ST-segment elevation myocardial infarction; *PCI,* percutaneous coronary intervention; *SIHD,* stable ischemic heart disease; *STEMI,* ST-segment elevation myocardial infarction; *UA,* unstable angina.

In patients with low pretest probability of CAD, first-line noninvasive assessment of cardiovascular

risk is necessary to decide whether to proceed to coronary angiography. Traditionally, stress test findings can be defined as low, intermediate, or high risk, which are associated with a cardiac mortality of less than 1%, 1% to 3%, and greater than 3% per year, respectively. For patients with intermediate-risk pretest probability, coronary angiography may be considered, whereas for patients with high-risk pretest probability, angiography should be performed without delay and with no need for further testing. Patients presenting with acute coronary syndrome (ACS), unstable angina (UA), or non–ST-segment elevation myocardial infarction (NSTEMI) with hemodynamic instability, or who are at high clinical risk (as determined by the presence of any of the risk factors listed in **eTable 20.2**) should undergo early invasive evaluation. For hemodynamically stable UA/NSTEMI patients without high clinical risk, a delayed invasive strategy may be justified, although an initially noninvasive risk stratification may be practiced outside the United States. Patients presenting with ST-segment elevation myocardial infarction (STEMI) should generally undergo urgent invasive intervention as soon as possible after symptom onset.[7] Patients with delayed cases may be treated conservatively, as described in other chapters.

ETable 20.2

Risk Factors That Support Early Invasive Evaluation of Patients Presenting with ACS

Significant troponin increase
Diagnostic ST or T wave changes
GRACE score >140
Diabetes mellitus
Reduced LV function (ejection fraction <40%)
Early postinfarction angina
Recent PCI
Prior CABG
Intermediate to high GRACE risk score

ACS, Acute coronary syndrome; *CABG,* coronary artery bypass graft surgery; *GRACE,* Global Registry of Acute Coronary Events; *LV,* left ventricular; *PCI,* percutaneous coronary intervention.

Appropriate Use Criteria

In 2012 the appropriate use criteria (AUC) for diagnostic coronary angiography were released.[4] This and a more recent focused update document provide a classification schema for procedures into *appropriate*, *may be appropriate*, and *rarely appropriate care* based on specific criteria. The proportion of "inappropriate" nonacute PCI has been reduced overall.[8] Clinical indications for PCI are beyond the scope of this chapter, but the AUC for diagnostic catheterization are mentioned here to highlight the appropriate selection of patients referred for coronary angiography for diagnostic purposes, since coronary angiography itself may be an unnecessary invasive procedure that could trigger an inappropriate coronary intervention in some cases.[9] The rate of angiographically normal or minimally diseased coronary arteries in patients undergoing elective procedures is approximately 39%.[10] In particular, the use of coronary angiography and PCI in asymptomatic patients is uncertain. A recent study showed that among a sample of 300,000 patients receiving coronary angiography in the United States, 25% were asymptomatic at the time of the elective coronary angiography. Furthermore, the rate of angiographic procedures in asymptomatic patients directly correlated with the number of inappropriate PCI procedures performed.[9] Therefore, strategies to verify the correct referral of patients for diagnostic coronary angiography are required to avoid unnecessary procedures, reduce health care costs, and prevent the therapeutic cascade that may lead from diagnostic angiography to inappropriate PCI.

Contraindications to Coronary Angiography

There are no absolute contraindications to coronary angiography listed in the clinical practice guidelines. However, specific conditions should be taken into account when weighing risks and benefits of the procedure. Based on the patient's cardiovascular risk and the clinical presentation, a decision should be made whether to avoid or postpone the procedure or proceed with coronary angiography using prophylactic measures to reduce the probability of periprocedural complications. Relative contraindications that should be taken into account are known anaphylactoid reaction to contrast media, moderate to severe kidney impairment, decompensated heart failure and pulmonary edema that prevent the patient from lying down during the procedure, uncontrolled hypertension, active infection, coagulopathy, and gastrointestinal bleeding.[12] In addition, coronary angiography requires the use of radiation to visualize the wires and catheters advanced through the blood vessels and to obtain images of the coronary arteries. Therefore, pregnant women should not undergo angiography unless strictly necessary and on exhaustive explanation of the risks related to radiation exposure, medications, and contrast media for both the mother and the fetus.[13] The presence of comorbidities that can increase the risk of complications should be critically considered before referring patients for coronary angiography.[14]

Complications of Coronary Angiography

Complications during coronary angiography are rare, occurring in approximately 2% of patients, with serious complications such as cerebrovascular accident (CVA, stroke) or myocardial infarction (MI) accounting for less than 1% of all patients. Mortality rate is lower than 0.1%.[14] Complications during PCI are more common (**see Chapter 62**). **Table 20.1** lists complications that may be encountered during coronary angiography.

TABLE 20.1

Risks Associated with Coronary Angiography

COMPLICATION	RISK (%)
Mortality	0.11
Myocardial infarction	0.05
Cerebrovascular accident	0.07
Arrhythmias	0.38
Vascular complications	0.43
Contrast agent reaction	0.37
Hemodynamic complications	0.26
Perforation of heart chamber	0.03
Other complications	0.28
Total of major complications	1.70

Modified from Scanlon P, Faxon D, Audet A, et al. ACC/AHA guidelines for coronary angiography. J Am Coll Cardiol 1999;33:1756.

Although rare, the most common complications are allergic reactions to contrast, vascular complications, and worsening of kidney function (see next section). Vascular complications at the access site include hematoma, pseudoaneurysm, aneurysm, and dissection. The risk of a vascular complication increases with the diameter of the sheath used, age of the patient, and degree of local calcifications. Iatrogenic coronary dissection or perforation occurs infrequently but is potentially life threatening and could require urgent coronary stenting[15] (**Fig. 20.1**). Ventricular and atrial arrhythmias are relatively common. Intracoronary injection of contrast media itself can induce arrhythmias. In particular, during injection of contrast media into the right coronary artery (RCA), one should take care to avoid deep

cannulation of the RCA and injection of contrast media directly into the conus branch, because this can result in ventricular fibrillation (VF).[16] In addition, when performing ventriculography, the mechanical stress of the catheter on the ventricular walls can trigger ventricular arrhythmias ranging from isolated premature ventricular complexes (PVCs) to runs of ventricular tachycardia (VT). Usually, these arrhythmias are self-resolving with catheter relocation and do not require medical intervention. Embolic events are rare but can occur and may involve the coronary arteries, central nervous system, or peripheral arteries.[17] Highly calcific axillary or subclavian arteries can increase the likelihood of embolization.

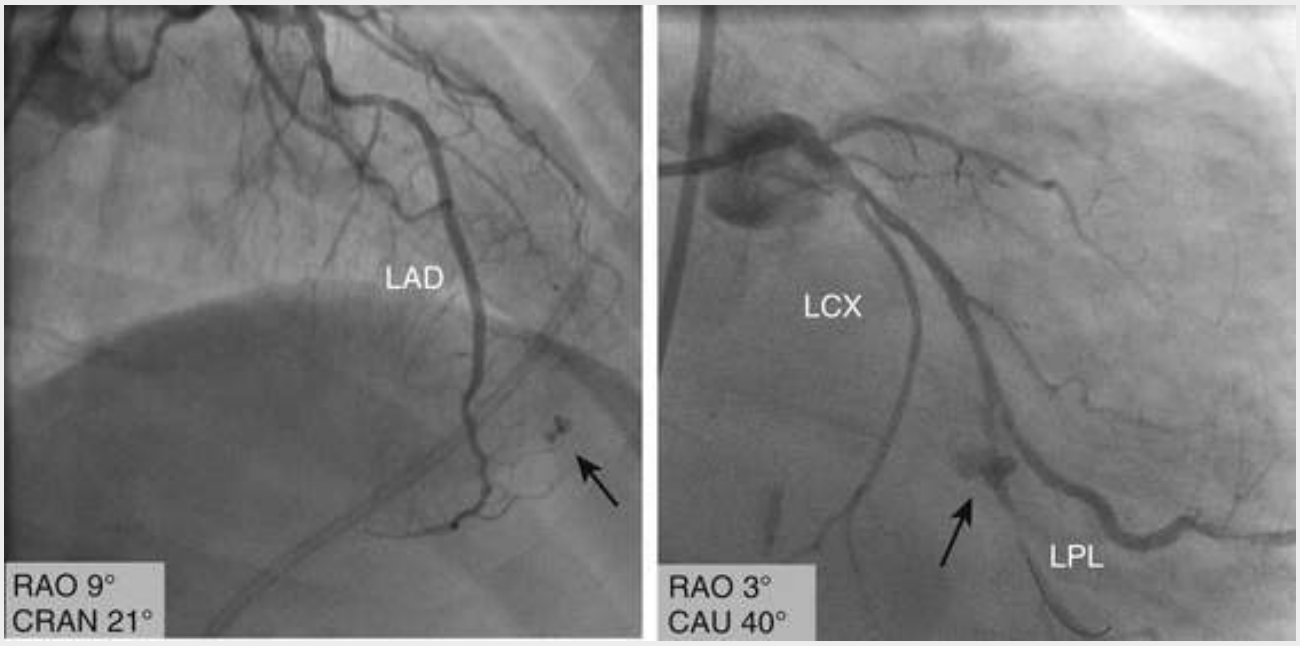

FIGURE 20.1 Iatrogenic coronary perforations. **Left,** Wire perforation of distal left anterior descending artery (*LAD*). **Right,** Perforation of a left posterolateral branch (*LPL*) after rotational atherectomy. *Black arrows* indicate contrast media extravasation. *LCX,* Left circumflex artery. RAO, Right anterior oblique; CRAN, cranial; CAU, caudal. (Angiographic images courtesy Dr. Annapoorna Kini, Icahn School of Medicine at Mount Sinai, New York City, NY.)

In addition, advanced age, diabetes mellitus, emergency coronary angiography, prior stroke, renal failure, and congestive heart failure (CHF) have been reported as risk factors for periprocedural stroke.[17] Infections are exceptionally rare in immunocompetent patients, and prophylactic antibiotic therapy is not usually required. Bleeding is usually minor, except when precipitated by vascular complications. In general, the use of anticoagulation during diagnostic angiography should be dosed based on the length of the procedure, weight of the patient, and presence of comorbidities such as kidney impairment, to avoid the risk of bleeding when the sheath is removed from the access site. Use of radial access rather than femoral access has significantly reduced the rate of vascular and bleeding complications[18] (**see Chapter 19**).

Contrast-Induced Acute Kidney Injury

Contrast-induced acute kidney injury (CI-AKI) is defined as an acute deterioration of renal function, defined as an increase in creatinine of 0.5 mg/dL or more, or 25% or greater compared to baseline. It generally develops 24 to 72 hours after administration of an intravascular contrast agent in the absence of other identifiable causes (see Classic References, Goldenberg). This complication significantly impacts the duration of hospital stay and related health care costs. CI-AKI also has marked repercussions on

short- and long-term morbidity and mortality.[19] In particular, studies in patients with moderate to severe renal dysfunction (estimated glomerular filtration rate [eGFR] <60 mL/min/1.73 m^2) undergoing coronary angiography or angioplasty show that the development of CI-AKI in such patients is a negative prognostic factor of clinical outcome both short and long term.[20] The incidence of CI-AKI ranges from 2% in low-risk patients to 12% to 50% in patients with diabetes and known chronic kidney disease (CKD) (**see Chapters 51 and 98**). The mechanisms of CI-AKI are only partially understood. Certainly, toxic damage caused by the passage of iodine molecules in the interstitial kidney is one of the causes. Another mechanism is related to the redistribution of flow in the kidney tissue secondary to contrast administration. In particular, after injection of contrast media, blood flow increases in the cortex and decreases in the medulla. Unfortunately, the medulla is particularly vulnerable to ischemic injury for the basal hypoxic condition (P_{O_2} = 20 mm Hg) because of high metabolic activity (e.g., sodium transporter channels). Therefore, blood flow reduction in the medulla after contrast injection further decreases oxygen tension, leading to endothelial dysfunction. Other important elements affecting kidney function are the physical and chemical characteristics of the contrast agents, in particular osmolality and viscosity. Contrast agents with a high osmolality and viscosity significantly increase hypoxemia and tubular stress. The downstream effect consists of an increase of free radicals, a reduction of nitric oxide (NO) bioavailability, and an increase in cellular death.[19,20]

The risk of CI-AKI depends largely on baseline renal function. The eGFR is a valid index to describe the level of renal function. Patients with an eGFR value below 60 mL/min are at high risk of CI-AKI. However, eGFR is not able to identify subclinical or latent forms of renal dysfunction. Therefore, a careful assessment of CI-AKI risk is essential, particularly before interventional procedures that may require high contrast medium volume (**Fig. 20.2**) (see Classic References, Mehran). Risk of CI-AKI can be stratified using a risk score model that includes patients' baseline and procedural characteristics.[21]

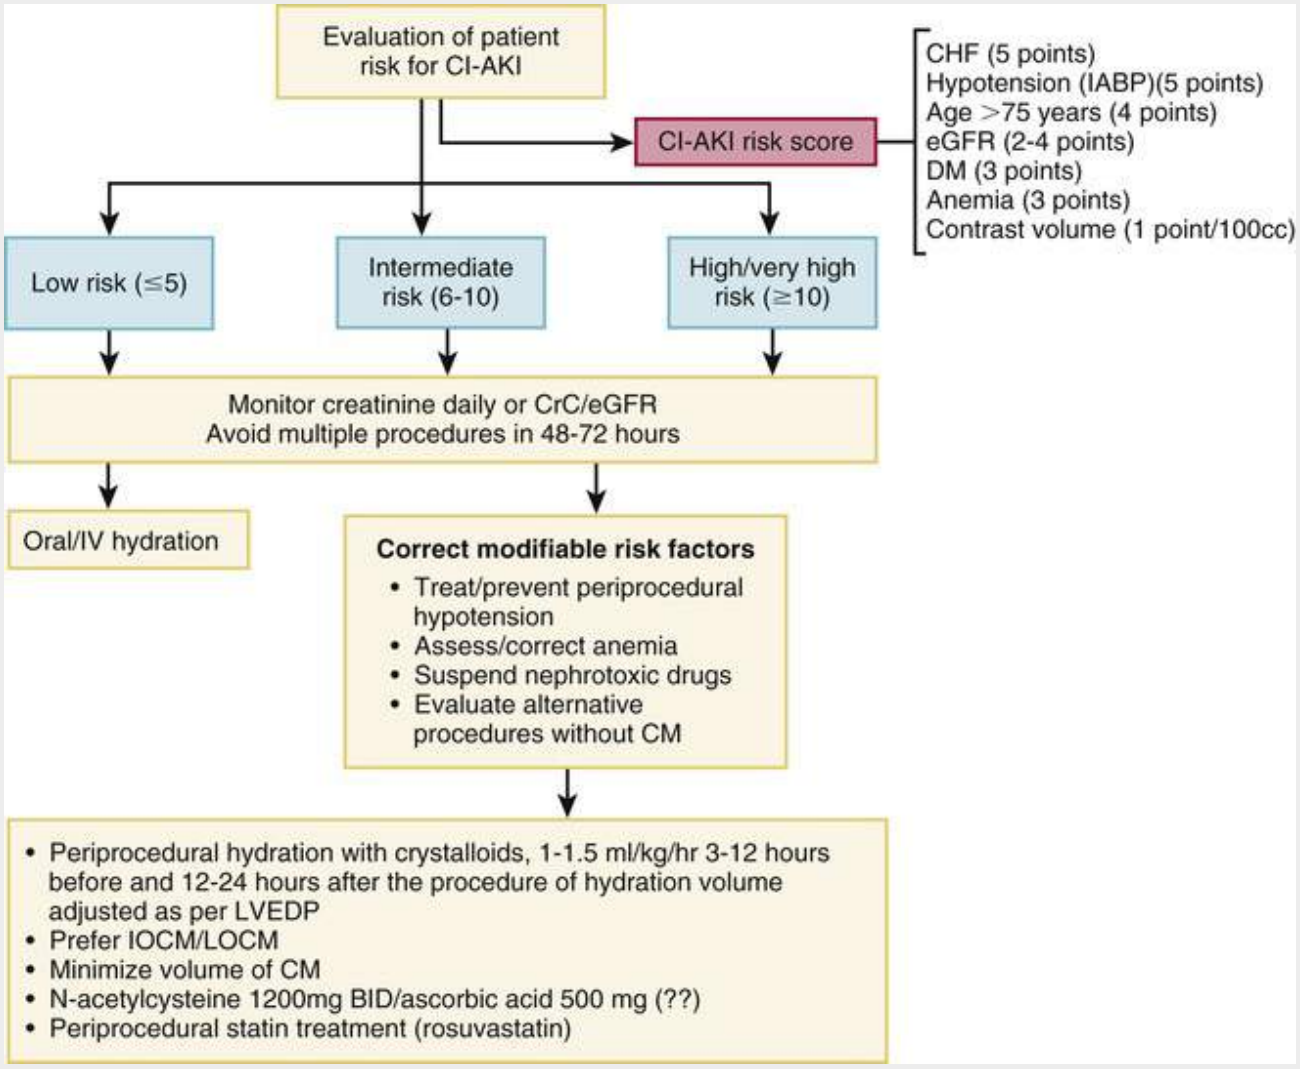

FIGURE 20.2 Risk score to determine the probability of contrast induced acute kidney injury. CHF, Congestive heart failure; CI-AKI, contrast-induced acute kidney injury; CM, contrast media; CrC, creatinine clearance; DM, diabetes mellitus; eGFR, estimated glomerular filtration rate; IOCM, iso-osmolar contrast media; IV, intravenous; LVEDP, left ventricular end-diastolic pressure; LOCM, low-osmolar contrast media; BID, twice daily.

In high-risk patients, prevention is crucial and consists of pharmacologic and nonpharmacologic measures. Individual risk/benefit ratios should be carefully estimated for each patient, and the utility of an alternative noninvasive diagnostic test should be evaluated. If the use of contrast medium is necessary for diagnostic purposes, the volume used should be minimized, and the use of monomeric low- or iso-osmolality contrast agents is recommended. Hydration plays a pivotal role in reducing the incidence of CI-AKI. Depending on the clinical condition (e.g., CHF), the Contrast-Induced Nephropathy (CIN) Consensus Working Panel recommendations state that an infusion of 1.0 to 1.5 mL/kg/hr of isotonic saline solution, from 3 to 12 hours before until 6 to 24 hours after the procedure, is suitable to minimize the incidence of CIN.[22] Recently, a clinical trial specifically investigated the efficacy and safety of a left ventricular (LV) end-diastolic pressure–guided hydration protocol with good results; thus filling pressure–guided fast hydration may be employed in the catheterization laboratory.[23] Moreover, to obtain effective hydration, devices have been developed that balance the volume of infusion and fluids lost through diuresis.[24] *N*-Acetylcysteine has been considered for the prevention of CI-AKI for years. In animal models of ischemia-reperfusion injury, the use of *N*-acetylcysteine significantly limited kidney damage mainly through its antioxidant properties.[25] However, the efficacy of *N*-acetylcysteine in humans in clinical studies remains unclear, given the high heterogeneity in study protocols and populations.[26] Similarly, some studies report that the use of isotonic sodium bicarbonate is associated with a higher

reduction in the incidence of CI-AKI than saline solution. These findings were attributed to a potential reduction in the production of reactive oxygen species in the renal parenchyma. However, recent meta-analyses did not show superiority of sodium bicarbonate over saline solution.[27,28] For this reason, both *N*-acetylcysteine and sodium bicarbonate have minimal roles in the latest guidelines on prevention (i.e., no benefit) and the routine prevention of CIN in patients undergoing percutaneous coronary angiography and interventions.

Risks Related to Radiation Exposure

Coronary catheterization may result in radiation-related injury, which although infrequent may be potentially serious. Radiation injury may be *deterministic* (i.e., dose dependent), which can present weeks after exposure, or *stochastic*, which is genetically determined and not dose dependent. Stochastic injury can result in cancer, pregnancy complications, and inheritable diseases. Deterministic injury may result in skin injury, hair loss, and lens injury. However, the most common location of radiation-induced lesions in cardiac catheterization is the skin of the back, and common patterns include erythema, telangiectasia, and plaques.[29] The sensitivity of the skin to radiation exposure is differentiated by site; areas at risk in decreasing order of sensitivity include anterior neck, antecubital and popliteal areas, flexor extremities, chest and abdomen, face, back, extensors, nape of the neck, scalp, palms, and soles.[30] Although uncommon in contemporary practice, early reports from coronary catheterization indicate deep and extensive skin rashes and burns at the site of radiation exposure, some requiring skin grafting.

PCI procedures may result in 10-fold higher radiation exposure compared to diagnostic catheterization (**see Chapter 62**). An average PCI results in 150 times more exposure than a chest radiograph and five times the annual radiation exposure received as environmental background radiation.[31] Measures used to assess patient dose include dose-area product (DAP, the absorbed dose multiplied by the area irradiated), air kerma (AK, *k*inetic *e*nergy *r*eleased per unit *ma*ss of air), and fluoroscopy time (FT), which are routinely measured and documented.[32] All procedures should be performed using the ALARA (as low as reasonably achievable) principle.[33] Exposure can be minimized in several ways: reduced FT and acquisition time, use of multiple angles rather than a single working camera position, reduced fluoroscopy dose, avoidance of high magnification, use of collimator beams and filters, avoidance of high angulation, and reduction in the flat-panel image detector as much as possible. For exposures of absorbed radiation greater than 5 Gy, patients should be advised to watch for areas of erythema; for those greater than 10 Gy, a medical physicist should be consulted to calculate the peak dose in 2 to 4 weeks; greater than 15 Gy is regarded as a hospital risk management event. Similarly, in the event that FT exceeds 60 minutes, physicians must be vigilant for late radiation effects.

From the perspective of occupational radiation exposure, operators should be cognizant of the need to wear protective personal equipment during catheterization procedures, including a lead apron, thyroid drape, lead eyeglasses, and dosimeters.[33] Table height and distance from the x-ray source are important, and radiation risk decreases as the inverse square of distance from the source. Operators should also optimally position lead shields and skirts and should be compliant with use of radiation dosimeters for monitoring exposure to the whole body (chest) and eye. Novel dosimeters providing real-time monitoring and alerts can serve to decrease operator radiation exposure.[34] Monitoring, reporting, and audit of radiation exposure can promote improved awareness and practice in the operator and catheterization laboratory staff.

Coronary Arteriography Technique

Patient Preparation

Patients should receive a comprehensive explanation of the diagnostic angiographic procedure and of the coronary intervention potentially required. Risks of angiography should be discussed in-depth and weighed against both the clinical benefit and the risks related to refusal of the procedure. Patients are required to provide written informed consent before coronary angiography. Women of childbearing age should be questioned on their pregnancy status and advised on the additional risks of radiation exposure for pregnant women. A thorough medical history, including comorbidities, current medications, and allergies, needs to be obtained before the procedure. In the event of an emergency procedure, as with a STEMI presentation, a brief evaluation of the patient history with particular attention to known CKD and known allergies to contrast media should be obtained if possible. In patients with prior coronary artery bypass graft (CABG) procedure, a report stating the type, arterial or venous graft(s), and position of the graft(s) should be attained if available to facilitate the cannulation and subsequent imaging of the grafts. Patients may receive mild sedation with a benzodiazepine before the procedure according to the hospital standard practice.[35] In case of hemodynamic instability or respiratory distress, anesthesiologist support might be necessary. In most patients, however, general anesthesia and deep sedation are unnecessary for coronary angiography. Conscious sedation with short-term agents such as midazolam or fentanyl is most common. Constant monitoring of the patient's ECG, heart rate, blood pressure, respiratory rate, and oxygen saturation is required periprocedurally. A venous access line should be readily available for the infusion of fluids or medications. Local anesthesia with topical anesthetic cream or subcutaneous injection of 1% lidocaine or mepivacaine (0.5 to 1 mL for radial access and 2 to 5 mL for femoral access) should be performed in all patients before puncturing the peripheral artery and introducing the sheath.[36] An adequate local anesthetic will not only make the patient more comfortable but, by reducing the pain during the arterial cannulation, also reduce the risk of peripheral artery spasm.

Access Sites

Possible access sites for coronary angiography are the femoral artery and the radial artery. Although the radial access approach is associated with fewer vascular and bleeding complications, femoral access remains the most commonly used in the United States. Femoral access allows for larger-diameter equipment that could be necessary in case of PCI. In addition, accessing from the femoral artery usually grants an easier advancement of the catheter to the aortic root due to the lack of tortuosity in the descending aorta. After disinfection and appropriate local anesthesia at the access site, the common femoral artery (CFA) is punctured with a base-metal needle approximately 1 cm below the inguinal line with a 45- to 60-degree angulation.[35] In obese patients, the ideal puncture site is sometimes difficult to determine. The head of the femur, visualized under fluoroscopy, can be used as a landmark (**see Chapter 19**, **Fig. 19.2**). Puncture should be performed with the needle leveled at half the head of the femur. Multiple punctures should be avoided to reduce the risk of bleeding and vascular damage. A J-tip flexible guide is inserted through the needle into the CFA. The needle is then removed and a sheath advanced around the wire into the artery (**see Fig. 19.3**). Once the sheath is fully advanced in the artery, the dilator and wire are removed, and the sheath is flushed with saline.[37] Usually, a 6 French (6F) sheath (French units: F = 0.33 mm) is used for coronary angiography and coronary interventions. Verification of the correct position of the sheath in the vessel can be ascertained simply by drawing blood from the sheath.

Radial access should always be considered first, before resorting to the femoral approach, especially for diagnostic coronary angiography.[38] The procedure for the sheath insertion is similar to that described

for the femoral artery. However, when using radial access, a modified Allen test should be performed on both hands (**see Chapter 19**). The modified Allen test is performed by applying pressure on both the ulnar and the radial artery of one wrist to occlude them while the patient keeps the hand elevated with the fist clenched for approximately 30 seconds. Once opened, the hand appears pale. The compression on the ulnar artery is then removed while pressure is maintained on the radial artery. If the ulnar artery supply to the hand is adequate, the color quickly returns to the hand and the test is normal. Conversely, if color does not return, the ulnar artery supply is insufficient, meaning that the radial artery supports the entire circulation of the hand. In this case the radial artery should not be punctured, because this may compromise the blood flow to the hand. This rule may be bypassed if an oximeter is placed in the thumb during radial artery occlusion, and resurgence of pulsation and oxygenation is documented after its initial disappearance ("Barbeau method").

When both radial arteries are acceptable access sites, the patient's right, closer to the operator, is preferred for technical reasons. However, the left subclavian artery may be less tortuous than the innominate artery. The ideal puncture site is 1 to 2 cm proximal to the radial styloid with the wrist slightly hyperextended. After local anesthesia, usually 0.5 to 1 mL of 1% lidocaine, the needle is advanced angled 30 to 45 degrees to the skin until a flashback of blood is visualized. A straight-tip wire is gently inserted through the needle. After removing the needle, a 5F or 6F sheath is inserted in the radial artery over the wire. A small incision 1 mm long can be made on the skin to facilitate advancement of the sheath. Because the radial artery is extremely vasoactive, the risk of spasm is high, especially in women; therefore, as soon as access is obtained, an intra-arterial spasmolytic agent such as nitroglycerin (100 to 200 µg) or verapamil (2.5 mg) diluted into 10 mL of saline should be administered.[35] A hydrophilic-coated sheath can further reduce the likelihood of spasm and regional pain. To prevent thromboembolic events and radial artery occlusion, weight-adjusted unfractionated heparin (UFH), 40 to 70 U/kg up to 5000 U, is administered either intravenously or intra-arterially.[39]

Radial access appears associated with fewer periprocedural events and should be preferred whenever possible. It should be noted, however, that the axillary-subclavian axis can be tortuous and calcific, particularly in elderly patients, and it can therefore be technically difficult to advance the catheter to the aortic root. Brachial access is very uncommon, but unlike radial access, avoids the small-caliber arteries in the forearm, and therefore may be required in the event that radial access is not available or fails. Brachial access can be obtained with a percutaneous or cutdown approach. On the other hand, there is no alternative blood supply to the forearm in case of closure.

Basic Technique

Coronary angiography is an invasive procedure based on the intravascular advancement of angiographic guidewires and catheters from a percutaneous access using the Seldinger technique. After a valved sheath is inserted into the access site artery (see Access Sites), a flexible metallic J-tipped guidewire is inserted through the sheath and advanced slowly under fluoroscopic imaging through the arterial axis until the aortic root is reached. A fluid-filled catheter is then advanced over the angiographic guidewire, while the wire itself is maintained in place. Once the catheter is in the aortic root, the wire is fully extracted from the sheath, and the catheter is flushed and connected to the contrast media injection apparatus. Under fluoroscopic imaging, and with the help of small injections of contrast, the coronary ostium is engaged with the tip of the catheter.[40] At this point, the x-ray tube is positioned appropriately (see projection section), and angiographic images are obtained while injecting contrast directly into the cannulated coronary artery.

Catheters for Diagnostic Procedures

There are several types of diagnostic catheters, characterized by differing lengths, diameters, and shapes. In general, catheters are composed of an external layer, which is not thrombogenic or lubricious, and by a lubricious inner layer. These two layers include a fine metallic core required to confer stability, improve maneuverability, and reduce the risks of kinking. Lengthwise, the catheter is divided into three parts: hub, body, and tip. Through a female Luer-Lok, the *hub* connects the catheter to the contrast injection system and facilitates the catheter grip and rotation with winged tips. The *body*, mostly strong and rigid, transmits to the tip the movements impressed on the hub by the operator. The *tip* can be divided, starting from the distal end, into three curves: primary, secondary, and tertiary, which allows the best possible fit to the aortic root curvature. The size of the catheter is another important characteristic. Compared to guiding catheters used for PCI (**see Chapter 62**), diagnostic catheters have a thicker wall, which considerably reduces their internal lumen. 5F catheters allow an optimal balancing between contrast flow and satisfactory catheter manipulation, particularly for the radial approach. Catheter length can vary from 80 to 110 cm (32 to 44 inches), depending on the anatomic characteristics and the access site (radial, brachial, or femoral). However, the standard length for adult left-heart catheterization by both the radial and the femoral approach is 100 cm (40 inches), while 80 cm is suitable for brachial access.

Among the diagnostic catheters, the most commonly used are the Judkins and the Amplatz catheters. *Judkins catheters* can be used both for the femoral and for the right/left radial approach. A preformed left Judkins (JL) presents a primary curve of 90 degrees and a secondary curve of 180 degrees, whereas the right Judkins (JR) presents a primary curve of 90 degrees and secondary curve of 30 degrees (**Fig. 20.3**). Since the JL is preformed, after removing the angiographic guide, it automatically engages the ostium of the left coronary artery (LCA). The JR, in contrast, once positioned in the right coronary sinus, requires a clockwise rotation to engage the ostium of the RCA from any vascular approach. In both JL and JR catheters, the distance between the primary and secondary curves (termed *arm*) is variable; for example, JL4 has a 4.2-cm length arm, JL5 and JL6 have 5.2- and 6.2-cm-long arms, respectively (**see Fig. 20.3**). Catheter selection depends on the approach (radial or femoral), the height of the patient, and the aortic diameter and curvature. For example, when using a femoral access, the JL4 is the most adaptable catheter for the LCA, whereas for the radial access, the JL3.5 catheter may be more suitable. Moreover, the presence of a dilated aortic root or the anatomy of particularly tall patients (>180 cm [72 inches]) may increase the length required between the primary and secondary curves and might require the selection of a catheter with a longer arm. In addition to their conventional use, JR catheters may be used for saphenous vein graft (SVG) and left internal mammary artery graft study through femoral and left radial approach.

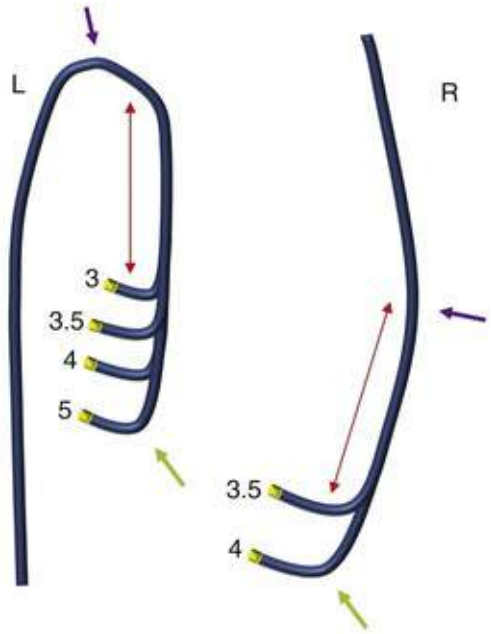

FIGURE 20.3 Judkins catheters. *Left* (L). Judkins for left coronary artery. *Right* (R), Judkins for right coronary artery. *Green arrows* indicate the primary curve. *Purple arrows* show the secondary curve. *Red arrows* indicate the distance between the primary and the secondary curve. To determine the correct catheter's tip, the operator should evaluate the approach (femoral or radial), the patient's height, and diameter of the aortic root. In particular, it would be helpful to add 0.5 cm for a femoral approach and for a dilated or horizontal aorta.

Amplatz catheters for the LCA (AL) and RCA (AR) represent a valid alternative to Judkins catheters (**Fig. 20.4**). The available lengths and sizes are the same as for the Judkins catheters, but the tip morphology of the left Amplatz (AL) catheter differs, allowing for easier coronary engagement in specific settings, such as short left main ostium, separate ostium of circumflex (Cx)–left anterior descending artery (LAD) branches, and RCA with anterior-high origin. Conversely, the right Amplatz (AR) catheter allows engagement of RCAs with inferior orientation. Amplatz catheters may also be used with confidence for the study of SVGs. *Multipurpose* (MP) *catheters* present a single bend (MPA 1 and 2 have a 45- to 60-degree primary curve, while MPB 1 and 2 have approximately an 80-degree primary curve) and may be used for the cannulation of coronary ostia that are difficult to reach with other catheters, as well as for engagement of SVGs. *Internal mammary artery* (IMA) *catheters* have a high angulated primary curve tip (80 degrees), to facilitate the engagement of the IMA either through the femoral or the radial approach. These catheters can also be used to engage the upward-pointing RCA (**Fig. 20.4**). It should be specified that the catheters just described are the ones most frequently used to perform diagnostic coronary angiography. Additional catheter types are available, although less frequently used, in case of specific coronary anatomic variables.

Selective Coronary Artery Cannulation

Left Coronary Artery.

The JL4.0 coronary catheter is used most often to engage the LCA (**Fig. 20.5**). The catheter is advanced over the guidewire until it reaches the aortic root. There, the catheter is rotated clockwise to direct it toward the left sinus of Valsalva. Once in position, the wire is removed, and the catheter regains its primary bent and should engage the ostium of the LCA. When the ascending aorta is dilated or the aortic arch is unfolded, advancement of the JL4.0 or JL5.0 might be necessary. If the tip of the JL catheter advances beyond the ostium of the LCA without engaging the ostium, the catheter can be advanced farther until the tip enters the left sinus and the catheter body assumes an acute angle. At that point, prompt withdrawal of the catheter should allow the tip to “pop” into the ostium of the LCA.

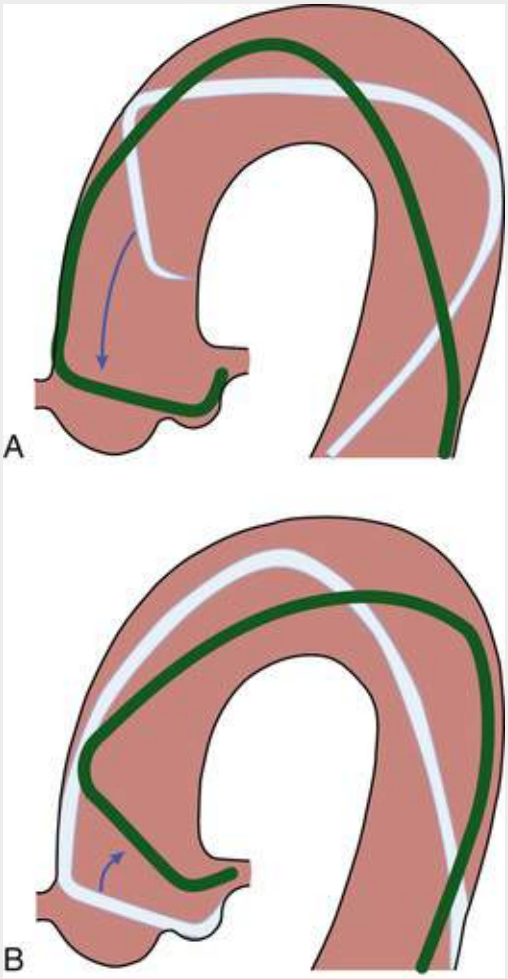

FIGURE 20.5 **A,** Push-pull technique for catheterization of the left coronary artery (LCA) with the Judkins left catheter. In the LAO view, the coronary catheter is positioned in the ascending aorta over a guidewire, and the guidewire is removed. The catheter is advanced so that the tip enters the left sinus of Valsalva. **B,** If the catheter does not selectively engage the ostium of the LCA, further slow advancement into the left sinus of Valsalva creates a temporary acute angle at the catheter. Prompt withdrawal of the catheter allows easy entry into the artery. (From Popma JJ, Kinlay S, Bhatt DL. Coronary angiography and intracoronary imaging. In Mann D, et al, editors. Braunwald's Heart Disease: A Textbook of Cardiovascular Medicine. 10th ed. Philadelphia: Elsevier Science; 2014.)

Right Coronary Artery.

The RCA is cannulated in the left anterior oblique (LAO) position (see later, Angiographic Projections). Once the JR or modified Amplatz catheter reaches the aortic root, it must be rotated clockwise to engage the vessel. The height of the catheter during the rotation may need to be adjusted by gently withdrawing the catheter to engage the ostium.

In patients with prior CABG, cannulation might be challenging because the locations of graft ostia are more variable, even when surgical clips or ostia markers are used. Whenever possible, the number, type, and course of the bypass grafts should be obtained before the procedure.

Saphenous Vein Grafts.

SVGs from the aorta to the distal RCA or posterior descending artery (PDA) originate from the right anterolateral aspect of the aorta approximately 5 cm (2 inches) superior to the sinotubular ridge. SVGs to the LAD artery (or diagonal branches) originate from the anterior portion of the aorta approximately 7 cm superior to the sinotubular ridge (**Fig. 20.6**). SVGs to the obtuse marginal branches arise from the left anterolateral aspect of the aorta 9 to 10 cm superior to the sinotubular ridge. In most patients, all SVGs can be engaged with a single catheter, such as a JR4.0 or a modified Amplatz right 1 or 2.

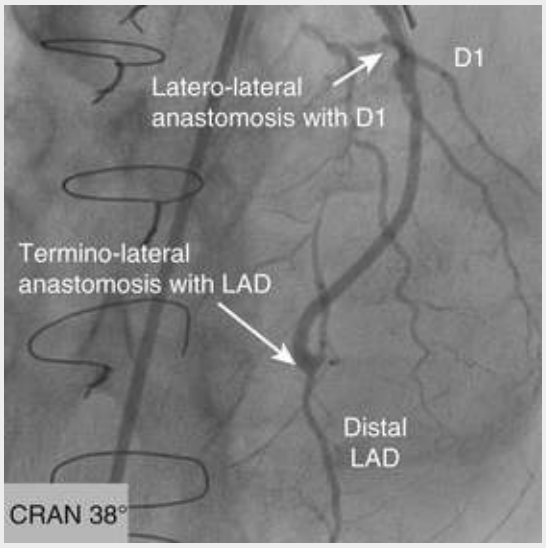

FIGURE 20.6 Sequential saphenous vein graft to the first diagonal branch (*D1*) and left anterior descending artery (*LAD*) with latero-lateral anastomosis to D1 and termino-lateral anastomosis to the distal LAD. CRAN, Cranial. (Courtesy Dr. Annapoorna Kini, Icahn School of Medicine at Mount Sinai, New York.)

Viewed in the LAO projection, the catheter should be rotated anteriorly from the leftward position as it is rotated in a clockwise direction. This movement should be repeated with the catheter at various heights in the ascending aorta, 5 to 10 cm above the sinotubular ridge, and with various degrees of rotation. Small test injections of contrast media can be used to verify that the catheter is in the SVG. If the graft is occluded, usually it is possible to visualize a "stump" during contrast injection. The surgical clips can be used to verify that all the grafts have been visualized. If one or more SVGs cannot be visualized, it can be useful to perform an ascending aortogram (preferably in biplane) to visualize all SVGs and their course to the coronary arteries. When visualizing an SVG, it is important to evaluate the ostium and the anastomotic site for irregularities or stenosis. It is also important to evaluate the flow distal to the anastomosis. *Sequential grafts* are those that supply two different epicardial branches in a side-to-side fashion (for the more proximal epicardial artery) and terminate in an end-to-side anastomosis (for the more distal epicardial artery). A Y graft is characterized by a proximal anastomosis in an end-to-side fashion to another saphenous vein or arterial graft, with two distal end-to-side anastomoses to the two epicardial grafts from these two grafts. It should be noted that with severe calcifications of the ascending aorta, the SVG could depart from the descending aorta to reach lateral wall branches.

Internal Mammary Artery Grafts.

The left IMA (LIMA) can be cannulated with a specially designed J-tip IMA catheter. The catheter is advanced into the aortic arch distal to the origin of the left subclavian artery, then rotated counterclockwise and gently withdrawn with the tip pointing in a cranial direction, allowing entry into the left subclavian artery. The right anterior oblique (RAO) or anteroposterior (AP) projections can be used to visualize the IMA (**Figs. 20.7 and 20.8**). For the right IMA (RIMA), first the innominate artery is entered with the guidewire in the LAO projection, then the IMA catheter is advanced to a point distal to the expected origin of the RIMA. The catheter is withdrawn slowly in the LAO view and rotated to cannulate the RIMA. Small injections of contrast are used to assess the position and the cannulation of the IMA. If the IMA cannot be selectively engaged and arteriography of the subclavian artery can be used, this usually allows for the opacification of all or most of the IMA, although weak (**Fig. 20.9**). The IMA can also be visualized with semiselective contrast injection; to avoid injury of the ostium, the catheter can simply be oriented toward the IMA without cannulating it. The correct orientation can be obtained by advancing a guidewire in the IMA to stabilize the position of the catheter during injection.

Radial Grafts.

Radial artery (RA) grafts represent the most popular arterial grafts after the LIMA and RIMA. Similar to SVGs, radial grafts require a double anastomosis, one on the aorta and one on the coronary vessel. Because of potential early spasm, RA grafts were abandoned in the 1970s and 1980s. In the 1990s, however, this procedure was rediscovered, and with specific surgical techniques and pharmacologic prophylaxis, it has safely been used with good short- and long-term results (**Fig. 20.10**).

Gastroepiploic Artery.

Rarely the right gastroepiploic artery (GEA) can be used for CABGs. To cannulate the GEA, first a

special catheter called the “cobra” is inserted into the common hepatic artery. Next, a hydrophilic-coated guidewire is advanced to the gastroduodenal artery and then to the right GEA. The cobra catheter is then exchanged for an MP or JR catheter, which is used for the selective cannulation of the GEA (**Fig. 20.11**).

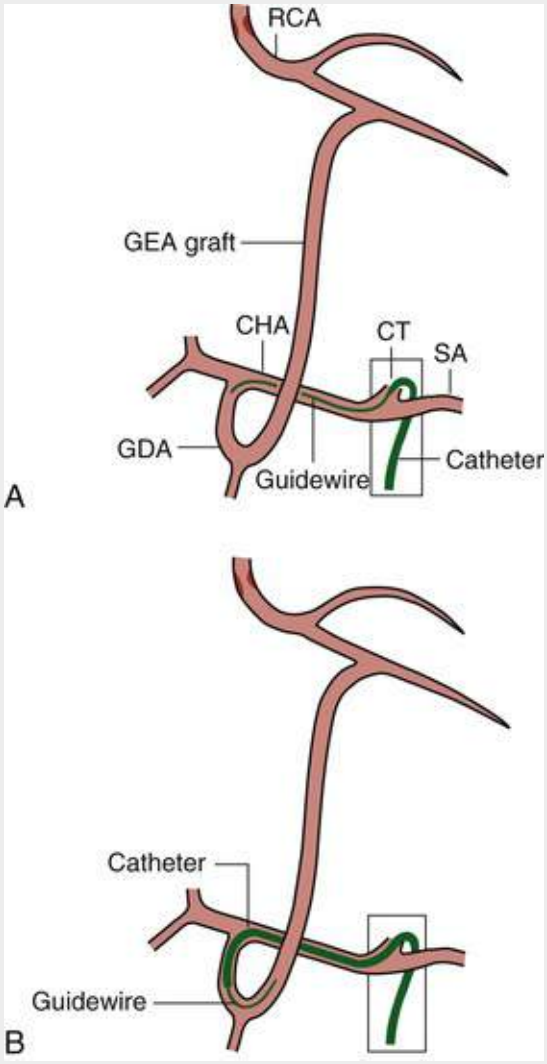

FIGURE 20.11 Catheterization of right gastroepiploic artery (*GEA*) graft. **A,** The celiac trunk (*CT*) is selectively engaged with a cobra catheter, and a guidewire is gently advanced to the gastroduodenal artery (*GDA*) and the GEA. **B,** The catheter is advanced over the guidewire for selective arteriography of the GEA graft. *CHA,* Common hepatic artery; *SA,* splenic artery. Philadelphia: Elsevier Science; 2014.)

Selection of Contrast Media

Since the introduction of intravascular contrast agents (ICAs) in the 1950s, clinical practice has become increasingly dependent on their use, particularly as the use of computed tomography (CT) and cardiac catheterization procedures has expanded exponentially in recent years. All currently used ICAs are classified on the basis of their physical and chemical structure, specifically, osmolality, iodine content, ionization in solution, and viscosity (**Table 20.2**). The most useful classification in clinical practice divides available ICAs into high-osmolar (HOCA), low-osmolar (LOCA), and iso-osmolar (IOCA) contrast agents. The HOCAs have an osmolality four to five times higher than the blood (300 Osm). LOCAs have an osmolality twice as high as blood. The latest-generation IOCAs have the same osmolality

as blood. Ionic high-osmolality ICAs were the first class of ICA used. However, the high osmolality and calcium-chelating proprieties often resulted in heart rhythm disorders (sinus bradycardia, AV blocks, QRS prolongation, long QT, ST-T, giant T wave inversion, and extremely rarely, VT and VF) and altered LV contractility. Therefore, in recent decades, new-generation ICAs have been developed, with low osmolality and neutral chemical characteristics that allow a significant reduction of adverse events.[41] In large cohort studies, the incidence of all types of adverse reactions to contrast was approximately 12% with a high-osmolality agent, compared to only 3% with a low-osmolality ICA (see Classic References, Katayama). For this reason, LOCAs and IOCAs are now considered the safest ICAs to use for vascular diagnostic procedures.

TABLE 20.2

Intravascular Iodinated Contrast Agents: Characteristics

	GENERIC NAME	OSMOLALITY RANGE (mOsm/kg H_2O)	VISCOSITY RANGE (cp or mPa.s) 37°C	IONICITY
High osmolarity	Diatrizoate/meglumine Diatrizoate/sodium	1500-2000	4.1-10.5	Ionic
	Iothalamate	600-1400	1.5-4	
Low osmolarity	Ioxaglate	600	7.5	
	Iodipamide	664	5.6	
	Iohexol	322-844	1.5-10.4	Nonionic
	Iopamidol	413-796	3.0-9.4	
	Iopromide	330-770	1.5-10	
	Ioversol	502-792	3-9	
	Ioxilan	610-721	5.1-8.1	
Iso-osmolarity	Iodixanol	270-320	6.3-11.8	

Modified from Manual on Contrast Media of the American College of Radiology (ACR) Committee on Drugs and Contrast Media. Version 10.2, 2016.

Automatic and Manual Injection of Contrast Media

Manual contrast injection with a manifold permits a constant modulation of the pressure of the injection and allows the operator to feel the resistance of the vessel to the injection. However, careful evaluation of the line should be performed before the injection to ensure the absence of air bubbles in the system. Manual injection was the only technique used to deliver contrast media until 10 years ago, when power injections were introduced. These automatic systems can detect air bubbles in the tubes and stop the injection accordingly. The maximum volume of contrast delivered, as well as the maximum pressure, can be preset to reduce the risk of iatrogenic artery dissection. Current systems also allow for operator touch–sensitive, variable–volume and pressure injections. For the RCA, 4 to 6 mL/sec is usually injected to optimally visualize the entire vessel, with a maximal pressure of 450 psi. For the LCA, a volume of 6 to 8 mL/sec is injected at a pressure of 450 to 600 psi.

The use of automatic injection systems is now preferred in most catheterization laboratories in Europe, whereas in the United States, 50% of sites still use manual injection. Automatic injections can significantly reduce the volume of contrast used for coronary procedures, and some studies report that they might reduce the risk of contrast-induced acute kidney injury.[42,43]

Adverse Reactions to Contrast Media and Prophylactic Therapy

Adverse reactions after injection of ICA may be acute or delayed and can further be classified as allergic

or allergic-like (physiologic). *Allergic reactions* can present with a variety of clinical symptoms, ranging from itching to skin rash, local edema, asthma, and full-blown anaphylactoid reaction. The pathophysiologic mechanisms hinge on the activation of different components of the immune system. *Allergic-like reactions* have a similar clinical presentation as the classic allergic response but are independent of immune system activation. Allergic-like reactions revolve around a physiologic response to contrast (e.g., nausea, vomiting, vasovagal reaction, hypertension, flushing).[44] The incidence of acute adverse reactions is related to the chemical and physical characteristics of ICAs (**Table 20.3**). In particular, as previously described, high-osmolar ICAs have approximately a 12% rate of acute adverse events, whereas that of low- or iso-osmolality ICAs is significantly lower (see Classic References, Katayama). In a cohort of 545 patients undergoing CT, the use of nonionic ICAs led to an allergic reaction rate of only 0.6%, of which only 23% were graded moderate-severe.[45]

TABLE 20.3

Classification of Acute Adverse Reactions After Injection of Intravascular Iodinated Contrast Agents

MILD*	MODERATE†	SEVERE‡
Allergic-Like		
Urticaria or pruritus (+) Cutaneous edema (+) Throat discomfort (“itching”) Nasal congestion Sneezing, conjunctivitis, rhinorrhea	Urticaria or pruritus (++) Diffuse erythema (++) Facial edema (++) Wheezing or bronchospasm (++) Throat discomfort (“tightness or hoarseness”)	Diffuse edema (+++) Facial edema and dyspnea (+++) Diffuse erythema and hypotension (+++) Wheezing or bronchospasm and hypoxia (+++) Anaphylactic shock
Physiologic

*Self-limited adverse effects without evidence of progression.

†More pronounced adverse effects that require medical therapy.

‡High risk of permanent morbidity and mortality if not adequately treated.

Modified from Manual on Contrast Media of the American College of Radiology (ACR) Committee on Drugs and Contrast Media. Version 10.2, 2016.

Temporally, acute reactions occur within seconds or minutes of contact with the ICA. Delayed reactions, on the other hand, may develop from 30 minutes up to 1 week after injection of ICA and usually present with cutaneous manifestations (**Table 20.4**). A prospective study of 539 patients by Loh and colleagues demonstrated that the percentage of delayed adverse events with the use of the dimeric low-molecular group (iohexol) is 14.3%, compared to 2.5% observed in the no-contrast group.[45a] Moreover, among the different types of ICA, nonionic dimeric agents show a higher percentage of delayed events than nonionic monomer agents. Because the rate of true allergic reaction to contrast is so low, prophylactic therapy is indicated only in patients with a history of allergic adverse events. In elective patients at risk for allergic reactions, in particular those with a history of anaphylactic reaction, prophylactic treatment must include prednisone, 50 mg by mouth (PO), or hydrocortisone, 200 mg intravenously (IV), at 13 hours, 7 hours, and 1 hour before ICA injection, plus diphenhydramine, 50 mg IV, intramuscularly (IM), or PO, 1 hour before ICA administration (see Classic References, Lasser). Methylprednisolone, 32 mg PO, 12 hours and 2 hours before ICA injection, plus an antihistamine can also be used. In addition, careful selection of ICA in addition to prophylactic therapy can help to further

reduce the risk of adverse reactions, which are very uncommon (0.2% to 1.6%). Reactions to contrast agents may be more difficult to manage in patients receiving beta-blocker therapy. Recurrence rates may approach 50% on repeat exposure to contrast agents, and prophylactic use of H_1 and H_2 histamine receptor–blocking agents and aspirin therapy has been recommended.

TABLE 20.4

Classification of Delayed Adverse Reactions After Injection of Intravascular Contrast Agents

MOST FREQUENT	RARE
Urticaria	Severe cutaneous reactions in patients with systemic lupus erythematosus (SLE)
Persistent rash	Cutaneous reactions in sun-exposed areas of body
Maculopapular exanthema	Inflammation and swelling of salivary glands (parotitis or mumps)
Exanthema pustulosis	Acute polyarthropathy
Urticaria or pruritus	Nausea or vomiting
Angioedema or pruritus	Fever
Pruritus alone	Drowsiness
	Headache
	Severe hypotension*
	Cardiopulmonary arrest*

*Extremely rare (only in part referable to administration of contrast agents).

Modified from Manual on Contrast Media of the American College of Radiology (ACR) Committee on Drugs and Contrast Media. Version 10.2, 2016.

Angiographic Projections

To identify and interpret the severity of coronary lesions, proper visualization of every segment of the main epicardial vessels and their branches is crucial. Although the coronary anatomy has a certain degree of variability, specific angulations of the x-ray tube are typically used during coronary angiography to ensure that vessel segments are not foreshortened or overlapping. The projections depend on the position of the x-ray tube and image intensifier. The AP view is obtained with the image intensifier in perpendicular position above the patient, with the x-ray beam traveling back to front. The intensifier can then be angled toward the patient's left or right side to obtain LAO and RAO views. The beam can be angulated cranially if the intensifier is tilted toward the head of the patient, and caudally if it is moved toward the patient's feet. The degree of angulation can be changed to prevent overlapping of vessels or obstruction of vessel segments caused by superimposition of implantable devices or other structures, such as spine bone or diaphragm. As a general rule, in LAO views, the LAD is visible on the right side of the spinal column. Conversely, in RAO projections, the LAD is on the left side of the spinal column. Cranial and caudal tilting is used to “open” overlapped segments. Caudal views are mostly used for the proximal segment of the LCA, whereas cranial views avoid foreshortening and allow for the evaluation of the mid- and distal portion of the vessel and its bifurcations. **Table 20.5** lists common projections for every coronary artery, and **Figs. 20.12 and 20.13** provide examples for the LCA and RCA, respectively.

TABLE 20.5

Standard Angiographic Projections

PROJECTION/DEGREES	ANATOMIC DESCRIPTION
Right Coronary Artery	
LAO 45	Vessel engagement projection Ostium and RCA along AV sulcus
LAO10-30, CRAN 30	PDA, PL branches, and RCA after crux
RAO 30	PDA ostium, PDA septal branches, right ventricular branches, acute margin branches
Left Coronary Artery	
Anteroposterior, CAUD 10	LMCA engagement projection
LAO 20-45, CAUD 30-45	"Spider projection": LMCA and proximal segment of LAD, Cx, and ramus (if present)
LAO 20-45, CRAN 30-60	Mid- and distal LAD and its branches, Cx PDA, and Cx PL branches if present
RAO 15-30, CAUD 10-30	All LAD and branches, Cx and OM branches
RAO 15-30, CRAN 10-30	Mid- and distal LAD and branches, mid-Cx and branches

Coronary Anatomy

The heart vasculature comprises three main epicardial arteries that divide into smaller, thinner branches that eventually form the arterioles. The arterioles have a muscular wall and are the main site of vascular resistance that can modulate the blood pressure reaching the capillary net downstream (**see Chapter 57**). This section reviews the coronary anatomy of the main epicardial vessels that can be visualized with coronary angiography.

The main epicardial vessels are the left main coronary artery (LMCA) and the RCA. The LMCA originates from the left sinus of Valsalva and divides into the LAD and the Cx arteries. Occasionally, a third branch can originate from the LMCA, the ramus intermedius (RI), usually attributed to the Cx artery.

The LAD artery runs along the anterior interventricular sulcus and provides circulation for the anterior and anterolateral wall of the left ventricle with diagonal vessels and the anterior two thirds of the interventricular septum with the septal branches. The number of diagonal and septal branches may vary greatly, and for the purpose of coronary description, they are simply numbered sequentially (D1, D2 … S1, S2, S3). Based on the length of the vessel, the LAD can be classified into type 1 if it does not reach the LV apex, type 2 if it reaches the LV apex, and type 3 if it reaches and wraps around the LV apex,

supplying also the posterior apex. The Cx artery courses along the left atrioventricular (AV) groove and provides branches for the left atrium, occasionally giving rise to the sinoatrial (SA) branch (40% of cases). The Cx also supplies the LV lateral and posterior walls with branches called *obtuse marginal* (OM) branches, which are numbered sequentially similar to the diagonal branches (**see Fig. 20.12**). There is high anatomic variability in the number of diagonal, septal, and OM branches present in the LCA.

The RCA originates from the right sinus of Valsalva and courses across the right AV groove. The proximal branches provided by the RCA are atrial branches for the right atrium, the SA node in 60% of cases, and the branch to the conus that supplies the right ventricular outflow tract. Once it reaches the acute margin of the ventricle, the RCA provides the acute margin branch. The RCA then continues to the crux cordis (where the AV groove intersects the posterior interventricular sulcus), where it branches into the PDA and the posterolateral (PL) branches (**see Fig. 20.13**). This anatomy is the most common and is termed *right coronary dominance*. Dominance can also be left or balanced, based on the origin of the PDA and the PL branches. Approximately 80% of the population displays a right dominance, meaning both the PDA and the PL branches are supplied by the RCA, while 10% of the population has a *left coronary dominance*, with PDA and PL branches deriving from the Cx artery. The remaining 10% display *codominance*, or *balanced coronary dominance*, with the PDA arising from the RCA and the PL branches arising from the Cx[1] (**Fig. 20.14**).

The subdivision of the coronary arteries into segments is crucial to describe the localization of lesions during angiography. **Table 20.6** lists the definitions of the coronary segments adapted from the SYNTAX Trial, with the corresponding CASS (coronary artery surgery study) number.

TABLE 20.6

Classification of Coronary Segments from SYNTAX Score

SEGMENT	DESCRIPTION	CASS NUMBER
Left main	From ostium of LCA until bifurcation into LAD and left Cx branches.	11
LAD proximal	Proximal to, and including, first major septal branch.	12
LAD middle	LAD immediately distal to origin of first septal branch and extending to the point where LAD forms an angle (RAO view). If this angle is not identifiable, this segment ends at one-half the distance from the first septal to the apex of the heart.	13
LAD distal	Terminal portion of LAD, beginning at end of previous segment and extending to or beyond apex	14
Major diagonal branches	LAD branches, sequentially numbered	15 first diagonal 16 second diagonal 29 third diagonal
Intermediate ramus	Branch from trifurcating left main other than proximal LAD or Cx; belongs to Cx territory.	28
Proximal Cx	Main stem of Cx from its origin from left main to and including origin of first OM branch.	18
Distal Cx	Stem of Cx distal to origin of most distal OM branch and running along posterior left atrioventricular grooves. Caliber may be small or artery absent.	19
OM branches	Cx branches, sequentially numbered	20 first OM 21 second OM 22 third OM
PL branches from Cx	PL branch originating from distal Cx	24 first PL 25 second PL 26 third PL
RCA proximal	From ostium to one-half the distance to acute margin of heart.	1
RCA mid	From end of first segment to acute margin of heart.	2
RCA distal	From acute margin of heart to origin of posterior descending artery.	3
Posterior descending	Branch running in the posterior interventricular sulcus	4 if from RCA 27 if from Cx
PL branches from RCA	Posterolateral branch originating from distal coronary artery distal to crux.	6 first PL 7 second PL 8 third PL

CASS, Coronary artery surgery study; *LAD,* left anterior descending artery; *RCA,* right coronary artery; *Cx,* circumflex artery; *RAO,* right anterior oblique; *OM,* obtuse marginal; *PL,* posterolateral.

Coronary Artery Anomalies

The prevalence of coronary artery anomalies (CAAs) in patients undergoing coronary angiography averages 1% to 5%[46] (**Table 20.7**). Despite being rare in the general population, CAAs are the second most common cause of sudden cardiac death (SCD) among young athletes.[47]

TABLE 20.7

Incidence of Coronary Anomalies in 1950 Angiograms

VARIABLE	NUMBER	FREQUENCY (%)
Coronary anomalies	110	5.64
Split RCA	24	1.23
Ectopic RCA (right cusp)	22	1.13
Ectopic RCA (left cusp)	18	0.92
Fistulas	17	0.87
Absent left main coronary artery	13	0.67
LCx arising from right cusp	13	0.67
LCA arising from right cusp	3	0.15
Low origin of RCA	2	0.1
Other anomalies	3	0.15

LCA, Left coronary artery; *RCA,* right coronary artery; *LCx,* left circumflex artery.

From Angelini P, editor. Coronary Artery Anomalies: A Comprehensive Approach. Philadelphia: Lippincott Williams & Wilkins; 1999, p 42.

There are many ways to classify CAAs. From a clinical standpoint, CAAs can be divided based on the presence of myocardial ischemia, into anomalies without ischemia, anomalies with episodic ischemia, and anomalies with obligatory ischemia (**Table 20.8**). Despite this important functional assessment, physicians often categorize CAAs based on anatomic characteristics. Use of CTCA and MRCA have increased the capability to detect and characterize anatomic abnormalities and help to determine optimal management of patients with a CAA. The most common anatomic classification of CAAs includes anomalies of ostium, anomalous origin of coronary artery, anomalous termination, congenital absence, and hypoplasia.[47]

TABLE 20.8

Classification of Coronary Anomalies Based on Ischemia

ISCHEMIA	CLASSIFICATION
Absence of ischemia	Most anomalies (split RCA, ectopic RCA from right cusp; ectopic RCA from left cusp)
Episodic ischemia	Anomalous origin of a coronary artery from the opposite sinus (ACAOS); coronary artery fistulas; myocardial bridge
Typical ischemia	Anomalous left coronary artery from the pulmonary artery (ALCAPA); coronary ostial atresia or severe stenosis

Congenital Atresia of Coronary Ostium.

Coronary ostial hypoplasia or atresia can occur as an isolated lesion or as a concomitant anomaly with other CAAs. The life expectancy of patients with coronary ostial hypoplasia or atresia depends on the presence of collateral circulation from other vessels that can supply the distal coronary bed.

Anomalous Origin of Coronary Artery.

Anomalous origin of coronary arteries is a common type of CAA. Coronary arteries with ectopic origin can arise either from the wrong sinus of Valsalva (e.g., the Cx artery arising from the right coronary sinus) (**Figs. 20.15 and 20.16**) or from a different structure, including the pulmonary artery (PA), a branch of another coronary artery, or even a ventricular chamber.[48] The course of the anomalous coronary arteries can be assessed by angiography in the RAO view. The LCA arising from the right aortic sinus usually follows one of these four courses: prepulmonic, retroaortic, interarterial, or transseptal (**Fig. 20.17**). The interarterial course of an anomalous LCA from the right sinus is associated with SCD during or shortly after exercise in young individuals. The hemodynamic mechanism underlying the risk of SCD remains unclear. Some authors hypothesize that distention of the aortic root and the pulmonary trunk

during exercise or stress might exacerbate the preexisting angulation of the anomalous coronary artery, resulting in compression of the coronary artery lumen. In other cases the vessel might have an aberrant course within the aortic wall that favors compression of the coronary artery. Similarly, origin of the RCA from the left aortic sinus with an interarterial course is associated with myocardial ischemia and SCD. Once this anomaly is diagnosed, CABG is recommended, although a stenting strategy has also been reported. A benign variation of the RCA origin is represented by the high anterior origin. This variation has no hemodynamic significance but might result in a challenging cannulation.

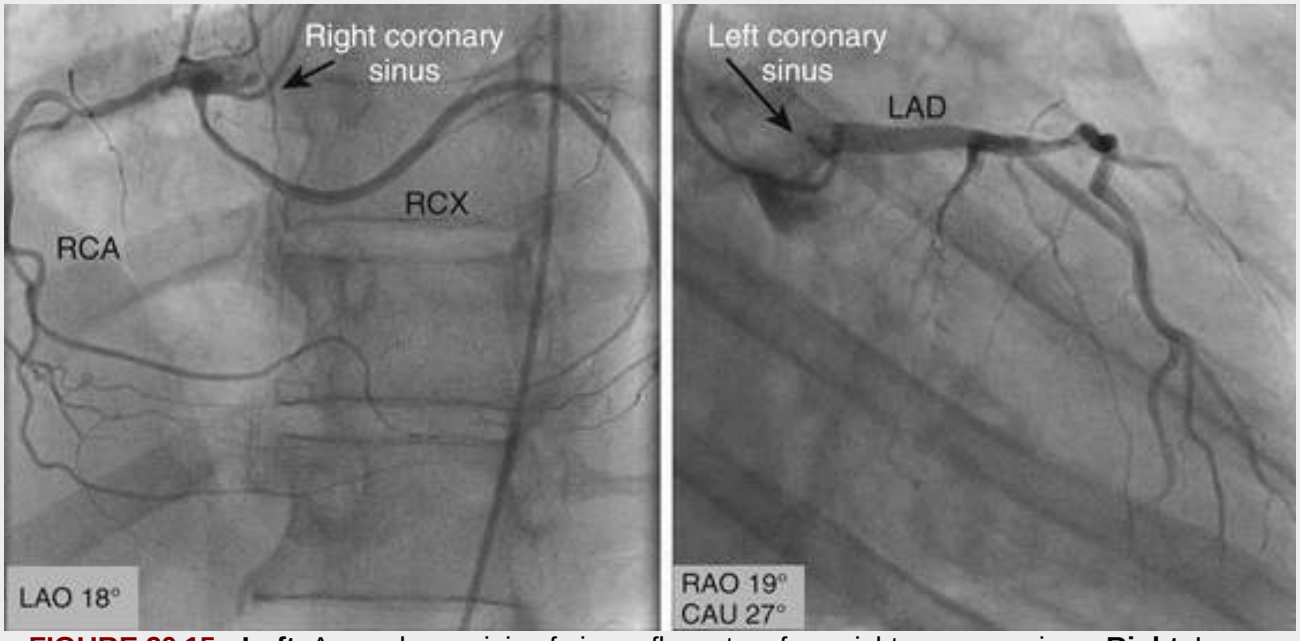

FIGURE 20.15 **Left,** Anomalous origin of circumflex artery from right coronary sinus. **Right,** Image shows that only the left anterior descending artery (LAD) arises from the left coronary sinus. *RCA,* Right coronary artery; *RCX,* right circumflex artery. FIGURE 20.16 Anomalous origin of right coronary artery (*RCA*) from left coronary sinus. The left main coronary artery (*LMCA*) has a separate ostium in the left coronary sinus and can be seen in the upper right corner. LAO, Left anterior oblique; CAU, caudal. (Courtesy Dr. Annapoorna Kini, Icahn School of Medicine at Mount Sinai, New York.)

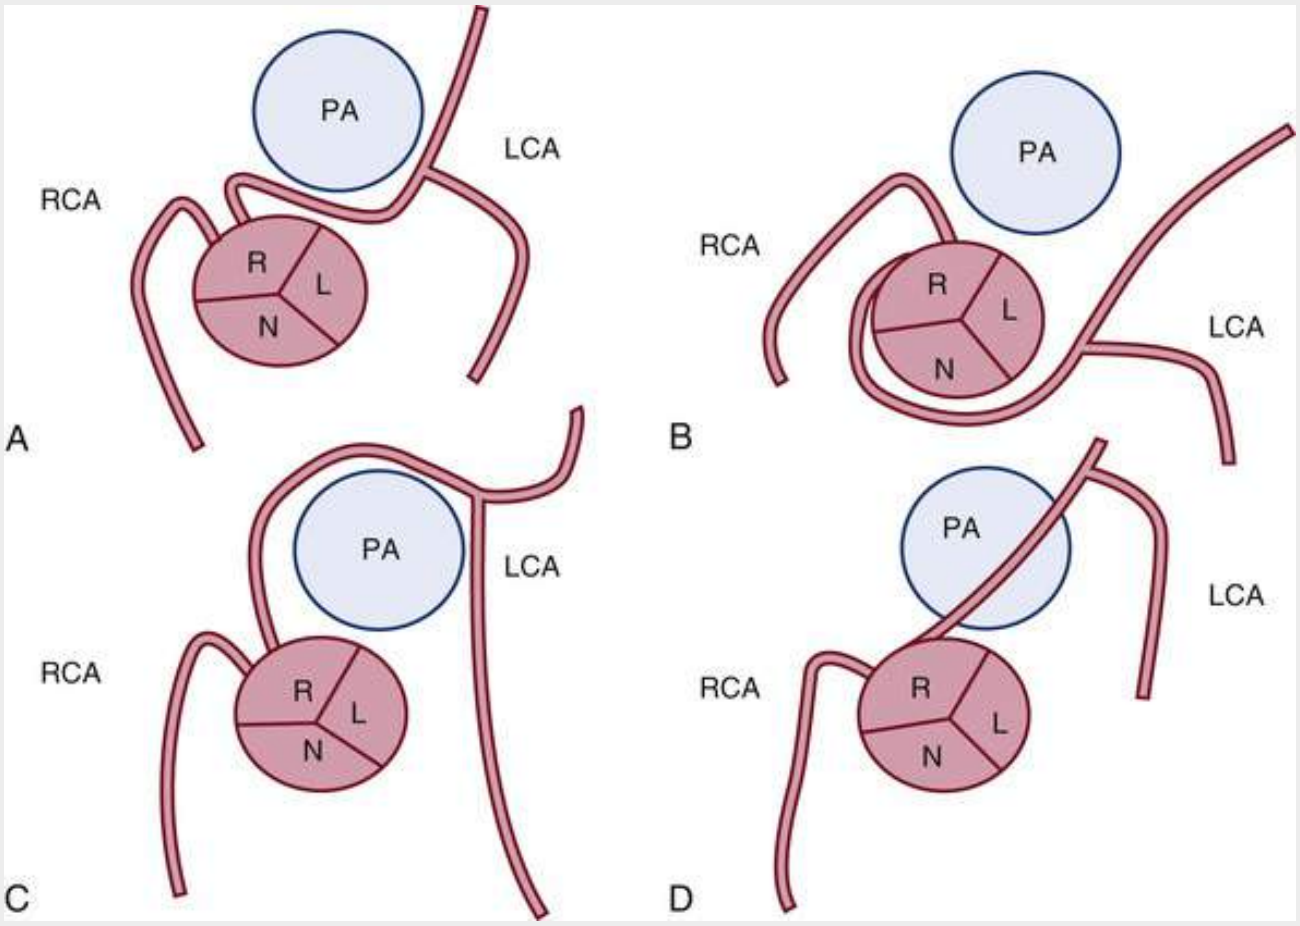

FIGURE 20.17 Four possible courses of the anomalous left coronary artery (*LCA*) arising from the right coronary sinus: **A,** interarterial; **B,** retroaortic; **C,** prepulmonic; **D,** transseptal. *PA,* Pulmonary artery; *RCA,* right coronary artery; *R,* right sinus of Valsalva; *L,* left sinus of Valsalva; *N,* noncoronary sinus.

Anomalous pulmonary origin of any coronary artery (APOCA) is a very rare occurrence (**Fig. 20.18**). If all three coronary arteries arise from the PA, prognosis is poor; patients with this anomaly usually die within the first month of life (see Classic References, Yamanaka). Anomalous origin of the LCA from PA (ALCAPA), also known as Bland-White-Garland syndrome, was reported for the first time in 1956 and represents the most common APOCA. Almost 90% of patients with this CAA die during the first year of life. Only very few, with extensive collateral circulation from the RCA, survive into adulthood. If diagnosed in time, the preferred treatment for APOCA is CABG.[49]

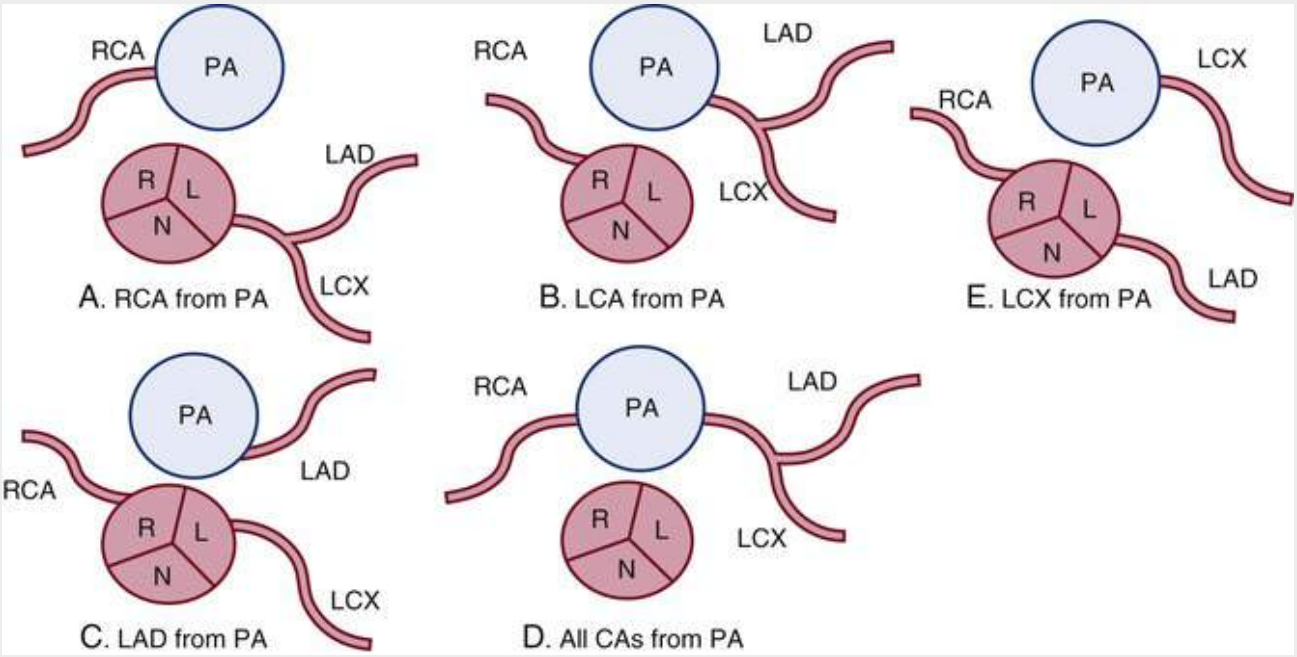

FIGURE 20.18 **A** to **E,** Anomalies of origin from pulmonary artery (*PA*). *RCA,* Right coronary artery; *LAD,* left anterior descending artery; *LCX,* left circumflex; *LCA,* left coronary artery; *CAs,* coronary arteries; *R,* right sinus of Valsalva; *L,* left sinus of Valsalva; *N,* noncoronary sinus.

Congenital Absence.

Lack of an LMCA is the most common form of congenital coronary absence, with a rate of 0.41% to 0.67% in the general population. In the absence of LMCA, the LAD and Cx arteries simply arise directly from the left sinus of Valsalva with separate origins. This anomaly is considered a benign condition and is an occasional finding during coronary angiography. The congenital absence of either the Cx or RCA have been reported and associated with a benign prognosis.[50]

Hypoplasia.

Hypoplasia of a coronary artery is defined as the maldevelopment of at least one of the major epicardial arteries or its branches. One, two, or all three coronary territories can be involved. Hypoplastic coronary arteries usually have a small diameter and a shortened course. A luminal diameter of less than 1.5 mm in a major epicardial vessel, with no nearby compensatory branches, has been proposed as the threshold for diagnosis. The prognosis of single-vessel hypoplasia of the Cx or RCA is relatively good, but SCD can occur in two-vessel hypoplasia.

Anomalous Termination.

Congenital coronary artery fistulas (CAFs) are rare anomalies, with an estimated incidence in the general population of approximately 0.002%. As an incidental finding, CAFs are reported in 0.3% to 0.8% of patients undergoing coronary angiography for any indication. CAFs are defined as abnormal direct communication between one or more coronary arteries with another major vessel or a chamber, such as the vena cava, left or right ventricle, pulmonary vein, or PA (**Fig. 20.19**).

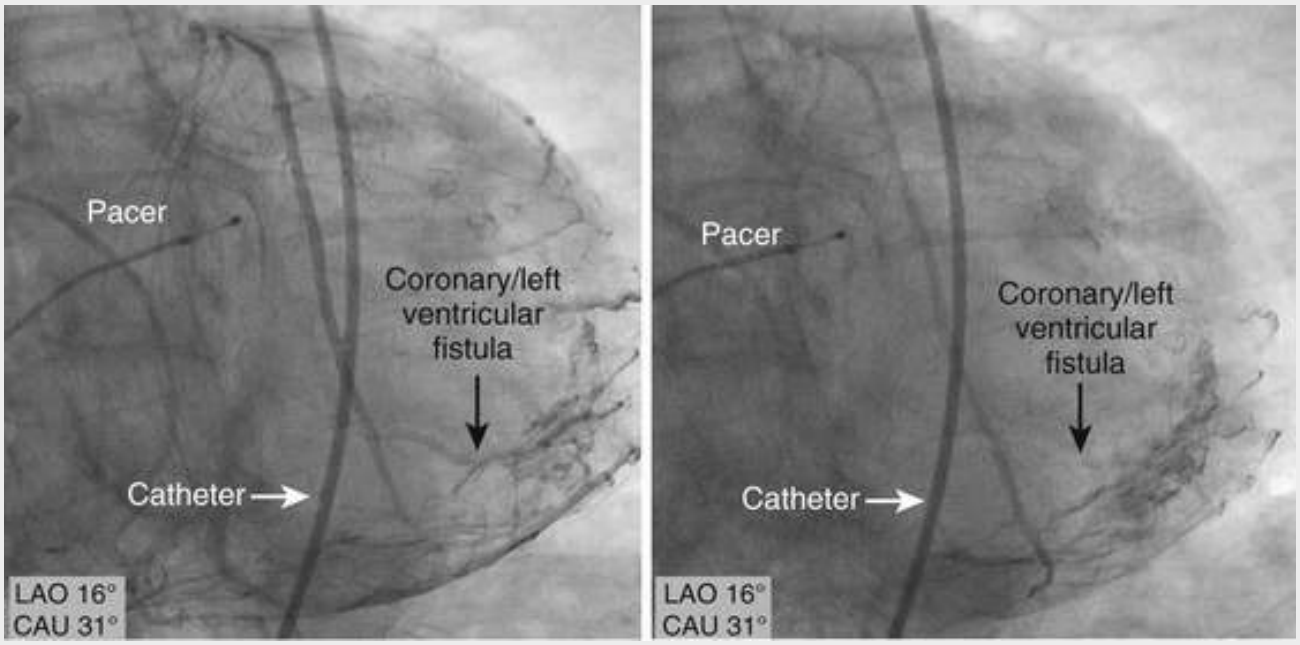

FIGURE 20.19 Coronary fistula with the left ventricle. LAO, Left anterior oblique; CAU, caudal. (Courtesy Dr. Annapoorna Kini, Icahn School of Medicine at Mount Sinai, New York.)

CAFs can originate from any of the major epicardial vessels and involve the RCA in 33% to 55%, the LAD in 35% to 49%, and the Cx in 17% to 18% of cases. Simultaneous involvement of both the left and the right coronary system exists in about 4% to 18% of CAFs.[51,52] Most of the fistulas drain into low-pressure structures, such as the right ventricle (40%), right atrium (26%), PA (17%), coronary sinus (7%), and superior vena cava (1%). Although possible, drainage of CAFs into left-sided chambers is less frequent (left atrium 5%, left ventricle 3%).[51-53]

Coronary angiography is the gold standard for the diagnosis of CAFs. However, in clinical practice, most CAFs are incidental findings during CTCA in low-risk patients. The clinical presentation of patients with CAF depends on size and volume of the shunt, location of the shunt, and concomitance with other cardiac disease. Approximately 50% of patients with CAF are asymptomatic. When present, common symptoms are dyspnea, fatigue, palpitation, and chest pain. The first manifestation of CAF can also include CHF, arrhythmias, SCD, and infective endocarditis. Symptomatic patients with large fistulas should be treated with surgical closure or interventional closure.

Pitfalls of Coronary Angiography

Improper interpretation of angiographic images can result from the use of inadequate projection views, CAAs, vessel foreshortening or superimposition of branches (**Fig. 20.20**), and deep engagement of the catheter into the vessel, potentially resulting in oversight of ostial lesions. In addition, obesity or instrument malfunctioning can lead to low image quality and erroneous image interpretation. Inadequate vessel opacification because of enhanced blood flow or competitive flow from a bypass graft might result in oversight of stenosis in collateral branches or in overestimation of the degree of thrombosis in a vessel. Also, when reading coronary angiograms, borderline lesions may require multiple views and potentially intracoronary imaging or evaluation of the fractional flow reserve (FFR) to adequately assess the severity of the lesion. **Fig. 20.21** shows an example of an eccentric lesion of the proximal LAD that is not visible in the LAO 34-degree, cranial 28-degree projection but becomes evident in the RAO 24-degree, caudal 21-degree projection. Moreover, a myocardial bridge or a coronary spasm can result in a minus defect in the coronary artery that can be misinterpreted as atherosclerotic disease, leading to unnecessary treatment

(see next section). In the case of ostial occlusion of a vessel, especially for primary or secondary branches of main epicardial vessels, it can be challenging to notice the missing vessel unless a collateral perfusion is present that allows for partial visualization of the downstream portion of the occluded vessel.[54]

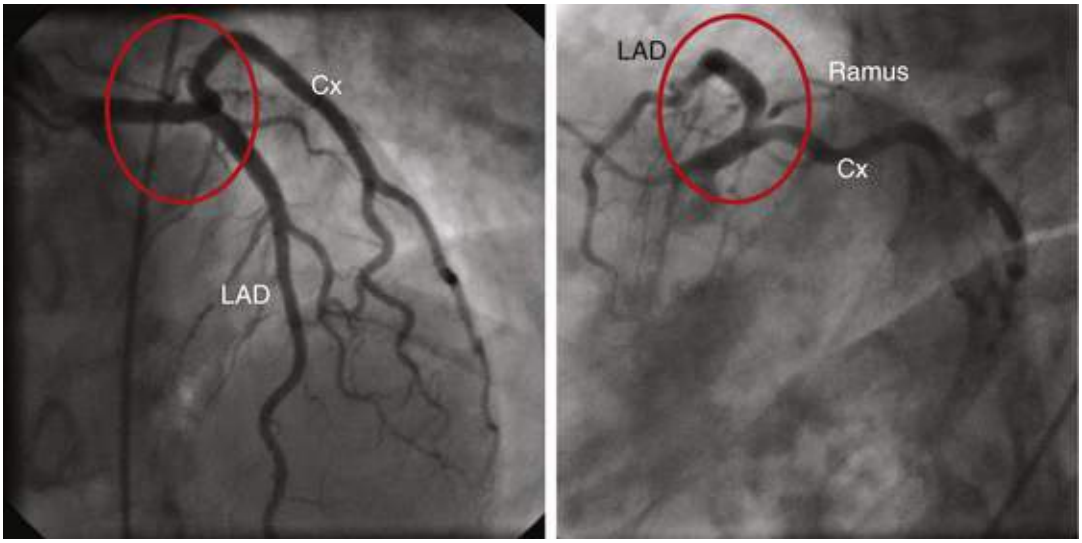

FIGURE 20.20 **Left,** Erroneous projection with overlapping of coronary vessels. **Right,** With a different projection, the trifurcation of the left main coronary artery becomes visible and can be evaluated for the presence of coronary stenosis. *LAD,* Left anterior descending artery; *Cx,* circumflex artery. (Courtesy Dr. Annapoorna Kini, Icahn School of Medicine at Mount Sinai, New York.)

Myocardial Bridging

Myocardial bridging is not a coronary lesion per se, although in the long term it can lead to local coronary

damage. It can also be mistaken for a coronary stenosis because bridging might cause filling defects. Myocardial bridging consists of a segment of an epicardial artery that descends into the myocardium for a variable distance (**Fig. 20.22**). It occurs in approximately 5% to 10% of patients and usually involves the LAD. As it runs in the myocardium, during systole the arterial segment is constricted by the muscle fibers and appears as a narrowing on the angiogram. However, these segments are usually easily identifiable because the narrowing disappears during diastole. Although bridging is not thought to be of any hemodynamic significance in most cases, myocardial bridging has been associated with angina, arrhythmia, depressed LV function, myocardial stunning, early death after cardiac transplantation, and SCD.[55] Treatment with beta blockers can be considered. Alternatively, surgical treatment can be attempted in selected cases.

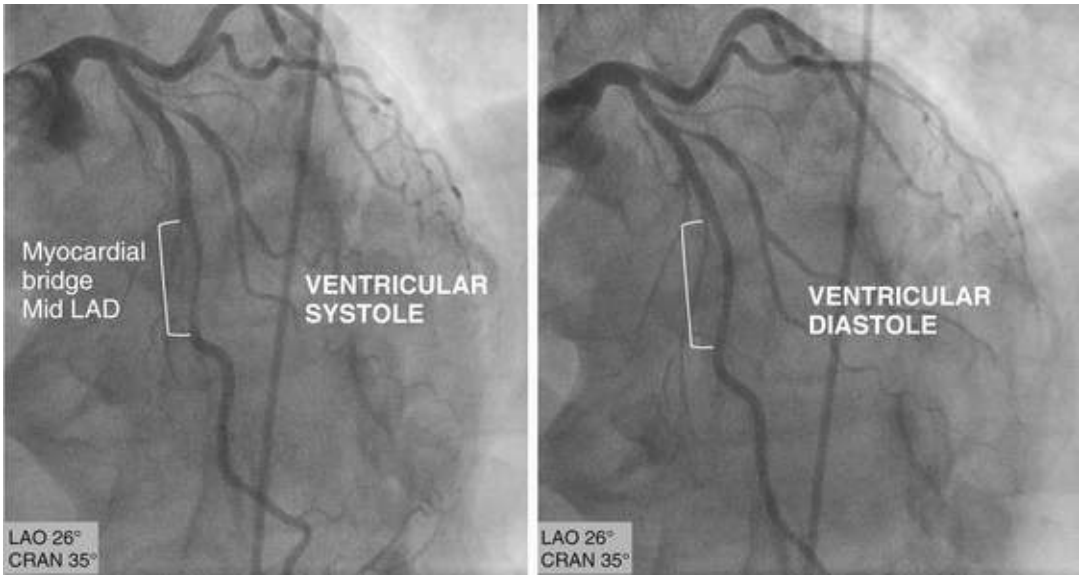

FIGURE 20.22 Myocardial bridge. **Left,** Narrowing of the middle left anterior descending artery (*LAD*) can be observed during the ventricular systolic phase. **Right,** The vessel diameter returns to normal during the ventricular diastolic phase. LAO, Left anterior oblique; CRAN, cranial. (Courtesy Dr. Annapoorna Kini, Icahn School of Medicine at Mount Sinai, New York.)

Coronary Artery Spasm

Coronary spasm is a dynamic reversible focal restriction or occlusion of a coronary artery caused by the constriction of the smooth muscle cells in the vessel wall (**Fig. 20.23**) (**see Chapter 57**). Coronary spasm, when prolonged, can cause Prinzmetal angina and lead to transitory ECG changes. Cigarette smoking, cocaine use, alcohol, intracoronary irradiation, and administration of catecholamines can promote coronary artery spasm. If a coronary spasm is suspected, a diagnosis can be made with several provocative tests, most often intravenous (IV) ergonovine maleate, IV acetylcholine, and hyperventilation. The physiologic response to ergonovine is a diffuse coronary vasoconstriction in all epicardial vessels. In patients with coronary spasm, however, ergonovine can induce focal coronary spasm often associated with chest pain and ECG changes. Intracoronary nitroglycerin is used to relieve the spasm. Acetylcholine (ACh) is a vasodilator acting on the muscarinic receptors of the vascular smooth muscle cells. Incremental doses of ACh (20, 30, and 50 µg) are injected directly into the coronary artery. In the presence of endothelial dysfunction, cells cannot produce NO in response to ACh, resulting in local vasoconstriction. Adverse reactions to ACh include hypotension, bradycardia, dyspnea, and flushing.

Also, hyperventilation during coronary angiography can elicit spasm, although it is a much less sensitive test compared to the others. If no spasm can be documented, the diagnosis relies instead on clinical features and the response to treatment with nitrates and calcium channel blockers.

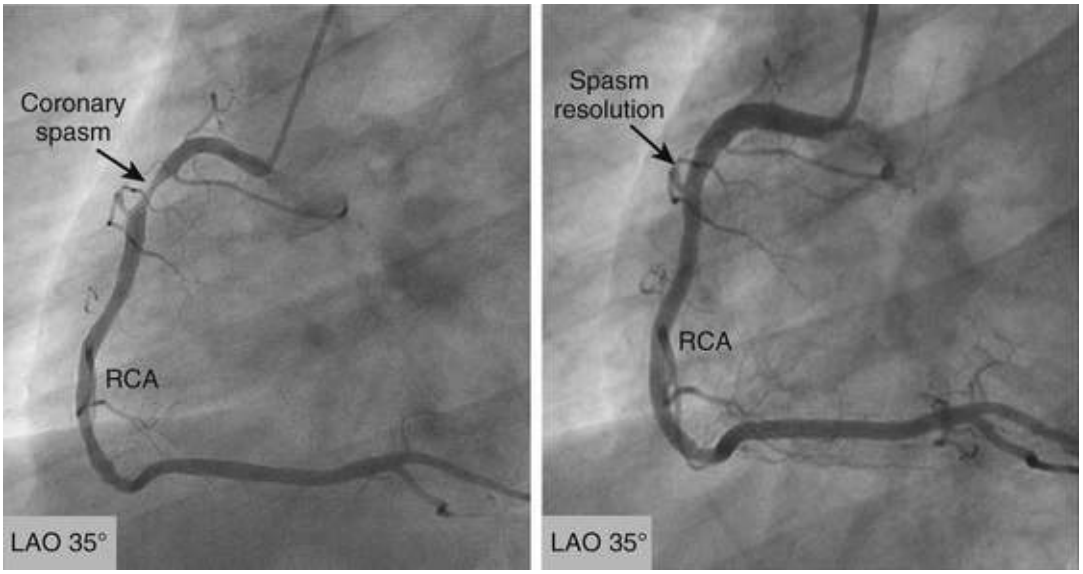

FIGURE 20.23 **Left,** Coronary spasm in the proximal segment of the right coronary artery (*RCA*). **Right,** Resolution of the spasm. LAO, Left anterior oblique. (Courtesy Dr. Annapoorna Kini, Icahn School of Medicine at Mount Sinai, New York.)

Angiogram Evaluation

When reading coronary angiograms, the entire extension of every coronary artery and its branches should be carefully evaluated in all the acquired views. First, the coronary dominance can be assessed. Next, the presence of abnormalities in the course of the coronary arteries should be investigated. The following elements should be part of the evaluation of diseased coronary vessels: (1) extension and localization of the lesion, (2) severity of the stenosis, (3) morphologic characteristics of the lesion, (4) evaluation of the downstream flow, (5) presence of collateral blood vessel circles, and (6) changes compared to previous angiograms, if available (**Fig. 20.24**).

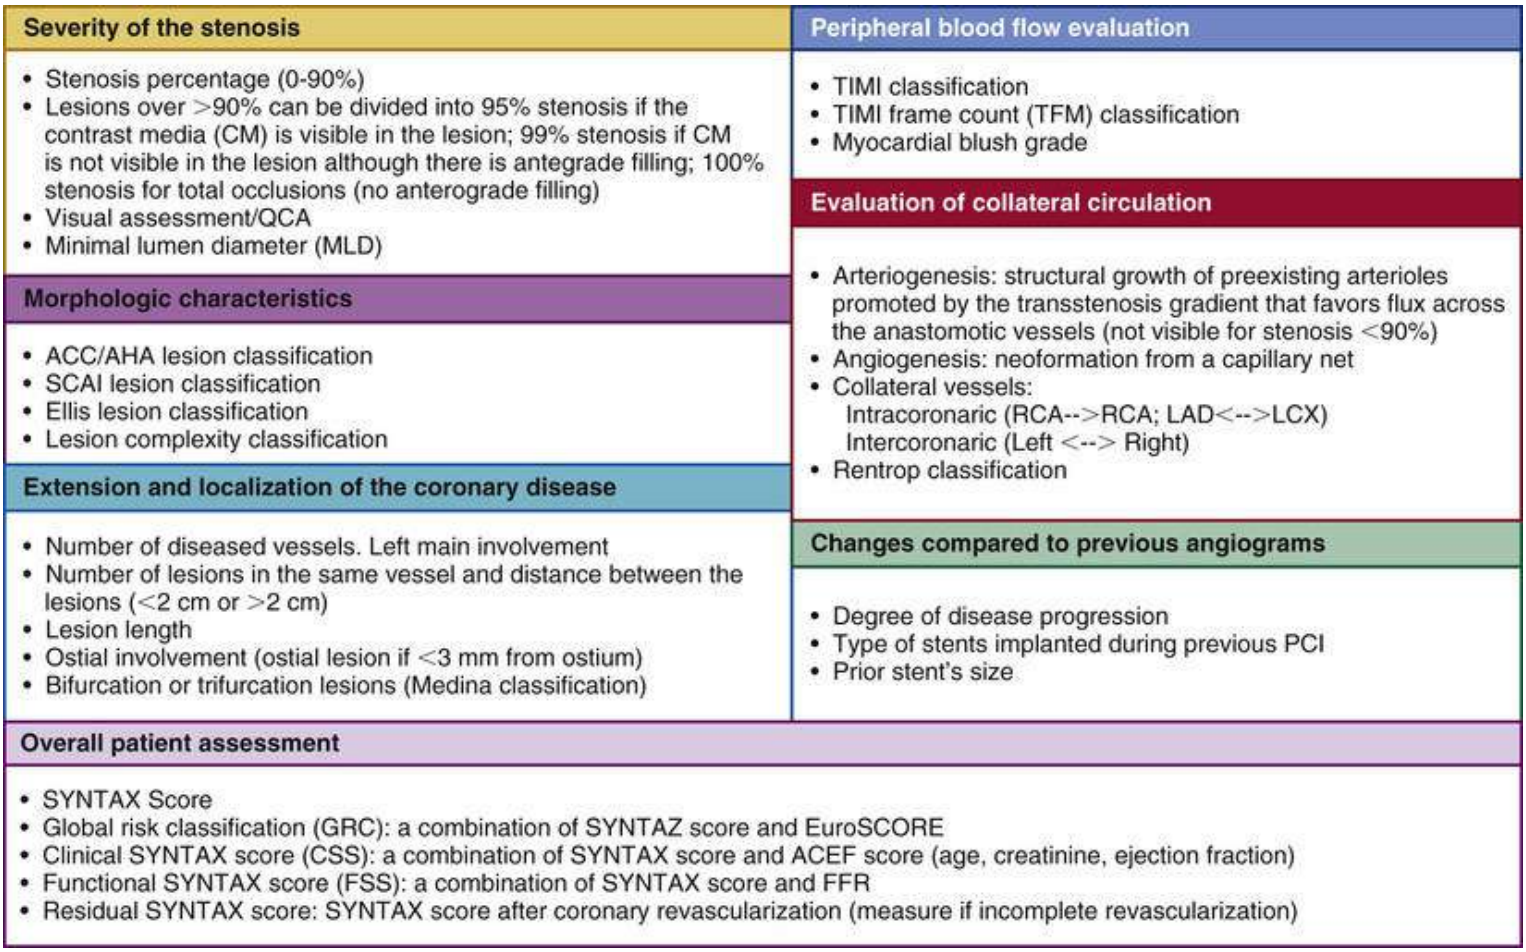

FIGURE 20.24 Evaluation of coronary stenosis.

Quantification of the Stenosis

A coronary stenosis is a reduction of the caliber of the vessel that is not caused by the progressive thinning of the vessel along its course but rather by pathologic local conditions. The degree of the stenosis can be evaluated by comparing the minimum diameter of the vessel at the level of the lesion to the diameter of the adjacent segment upstream of the stenosis. The degree of stenosis is usually underestimated compared to postmortem evaluation or intravascular ultrasound (IVUS) because the adjacent healthy lumen to which the stenosis is compared might present with vasospasm or diffuse atherosclerosis despite appearing normal on the angiogram. This often leads to underestimation of the stenosis. In addition, it is particularly difficult to evaluate long lesions since the arteries physiologically narrow during their course, and there might be a marked mismatch between the diameters of the normal segment upstream and downstream of a long stenosis.

Stenoses are defined as *minimal* if the narrowing is less than 50%, *moderate* between 50% and 70%, and *severe* or *significant* for a diameter reduction of 70% or more.[54] Evaluation of stenosis severity can be estimated visually by the interventional cardiologist reading the angiogram, or it can be measured with quantitative coronary angiography (QCA) methodologies based on the selection of the area of interest and vessel diameter measurements, which can be automatic, semiautomatic, or manual. Most programs can be calibrated using the diameter of the catheter and can automatically detect the edge of the vessel across its length and measure the minimum diameter of the stenosis and the length of the stenosis. Alternatively, rather than edge detection, densitometric methodology can be used. This technique avoids the errors of edge detection caused by geometric assumptions required for software calculations. Densitometry measures the stenosis based on the area containing ICA when the vessel is fully opaque. There is usually

good agreement between edge detection and densitometry techniques. QCA reduces interoperator variability of reading, which is estimated at ±20%.[56]

When evaluating a coronary lesion, the diameter and length of the stenosis are only two of many characteristics to consider. Also important are morphologic characteristics of the lesion, including the presence of thrombus, extent of calcification, and tortuosity of the vessel involved. The AHA has classified coronary artery lesions into three main types based on easily identifiable characteristics on the angiogram. This classification has predictive value for the success of a PCI procedure (**see Chapter 62**). Type A lesions have a procedural success rate of 92% and a low complication rate, type B lesions have a 72% success rate with a 10% rate of complications, and type C lesions have only a 61% success rate and a 21% rate of complications (**Table 20.9**). Additional classifications of lesion severity are the Society for Cardiovascular Angiography and Interventions (SCAI) and the Ellis systems.[57]

TABLE 20.9

AHA/ACC Lesion Classification

Type A	Length <10 mm Discrete Concentric readily accessible <45-degree angle Smooth contour	Little or no calcification Less than totally occluded Not ostial No major side branch involvement Absence of thrombus.
Type B B1 if only one characteristic is present B2 if two or more characteristics are present	Length 10-20 mm Eccentric Moderate tortuosity of proximal segment Irregular contour Presence of any thrombus grade	Moderate or heavy calcification Total occlusion <3 months old Ostial lesion Bifurcation lesion requiring two guidewires
Type C	Length >20 mm Diffuse Excessive tortuosity of proximal segment Total occlusion >3 months old and/or bridging collaterals' inability to protect major side branches Degenerated vein graft with friable lesions	

Evaluation of Microvascular Blood Flow

Evaluation of the downstream flow provides additional information not only on the severity of the stenosis, but also on the status of the microcirculation in the affected territory. It has been proved that often the microcirculation is impaired in the territory affected by epicardial vessel lesions. Prognostic information can be obtained from the degree of blood flow through the lesion. The most common classification is the Thrombolysis in Myocardial Ischemia/Infarction (TIMI) flow grade[35] (**Table 20.10**). In the presence of good blood flow in the coronary artery (TIMI 3) after PCI, patients can additionally be stratified using the TIMI frame count (TFC) score based on the number of angiographic frames necessary for the contrast to reach a standardized distal point in the vessel. The angiographic film should be acquired at 30 frames per second and contrast injection performed with a 6F catheter to measure TFC. The first frame is where the origin of the vessel appears fully opacified. The last frame is predefined for each coronary vessel: for the LAD and Cx arteries, it is the most distal bifurcation, whereas for the RCA, it is the emergence of the first PL branch. For the LAD, the apical segment is the milestone for the TFC. Because the LAD is usually longer than the other vessels, a correction factor needs to be used when calculating this score in the LAD by dividing TFC in the LAD by 1.7. Normal TFCs are 36 ±3 (or 21 ±2 if corrected) for the LAD, 22 ±4 for the Cx, and 20 ±3 for the RCA.[37] This score provides quantitative information on the status of the microcirculation in the infarcted areas and is a predictor of functional recovery and clinical outcomes after primary PCI. In fact, while most primary PCIs obtain patency of the epicardial flow and a TIMI flow grade 3, the tissue-level perfusion will determine the extent of the

myocardial damage or the muscle recovery. Similarly, the *myocardial blush* score provides a semiquantitative measure of peripheral perfusion (**Table 20.11**). It represents the arrival of the contrast in the capillaries and therefore can be appreciated only with angiographic acquisitions prolonged after the contrast has washed out of the main epicardial vessel. The myocardial blush grade is superior to TIMI flow grade for predicting postprocedural cardiac death and major adverse cardiac events (MACE).[58]

TABLE 20.10

Thrombolysis in Myocardial Ischemia/Infarction (TIMI) Flow Rate

TIMI 0 Flow	No penetration of contrast beyond the stenosis (100% stenosis, occlusion)
TIMI 1 Flow	Penetration of contrast beyond the stenosis but no perfusion of the distal vessel (99% stenosis, subtotal occlusion)
TIMI 2 Flow	Contrast reaches the distal vessel but at reduced rate of filling or clearing compared to other coronary arteries (partial perfusion)
TIMI 3 Flow	Contrast reached the distal vessel and clear at the same rate as the other coronary arteries

TABLE 20.11

Myocardial Blush Score

Grade 0	No myocardial blush or contrast density
Grade 1	Minimal myocardial blush or contrast density
Grade 2	Moderate myocardial blush but less than that obtained from the ipsilateral non–infarct-related coronary artery
Grade 3	Normal myocardial blush or contrast density comparable to that obtained during angiography of a contralateral or ipsilateral non–infarct-related artery

Collateral Vessel Circulation

The coronary arteries represent the end circulation of the heart, and thus there is very little redundancy in the vascularization of each myocardial territory. However, collateral vessels can form under specific circumstances. Collateral blood vessels are anastomotic connections between two segments of the same artery or between different native coronary arteries. They function as natural bypasses and represent an alternative source of blood supply for a coronary territory. Clearly, collateral circulation becomes very important in the event that the main vessel serving the territory becomes occluded. There are two main mechanisms by which collateral vessels can be formed: arteriogenesis and angiogenesis. *Arteriogenesis* is the growth of preexisting arterioles that transform into functional collateral arteries, as a muscular layer forms and viscoelastic and vasomotor properties are acquired. Arteriogenesis is promoted by the pressure gradient across the stenosis that favors the blood flow through the small, preexisting anastomotic vessels upstream of the stenosis. *Angiogenesis*, on the other hand, involves the de novo formation of vessels starting from primitive postcapillary venules. The process is favored by hypoxic stimuli such as local production of vascular endothelial growth factor (VEGF) and hypoxia-inducible factors (HIFs)[59] (**see Chapter 57**). The collateral vessel net can be intracoronary, if it connects different segments of the same coronary artery or the two LCAs, and intercoronary if it connects the RCA with one or both of the LCAs.

When evaluating coronary stenosis, it is important to take into account the presence of collateral vessels that may have formed over time. Collateral flow can allow visualization of an occluded vessel by retrograde opacification of the vessel downstream of the occlusion. Based on the presence of contrast in the collateral vessels and the degree of retrograde opacification of the epicardial vessel, collateral circulation can be classified with the Rentrop grade (see Classic References). Grade 0 represents no collateral circulation, grade 1 indicates presence of minor collateral vessels with no retrograde

visualization of the epicardial vessel, and grades 2 and 3 represent partial and complete retrograde opacification, respectively, of the epicardial vessel (**Figs. 20.25 and 20.26**).

Special Lesion Considerations

Chronic Total Occlusion

A chronic total occlusion (CTO) is the complete or almost-complete blockage of a coronary artery for 30 or more days. It can be an incidental finding in patients referred for diagnostic angiography. To visualize the vessel downstream to the CTO, a retrograde technique can be used by injecting the patent coronary artery; if collateral vessels are present between the two arteries, the vessel downstream of the CTO can

be visualized (see Rentrop classification for collateral vessels previously described). CTOs are considered very complex lesions and contribute greatly to the SYNTAX score (**see Chapters 61 and 62**); less than 50% of CTO lesions in the SYNTAX trial were successfully treated by PCI. A specific score, the J-CTO, has been developed to predict the probability of successful guidewire CTO crossing within 30 minutes; independent predictors were previously failed lesion, blunt stump type, vessel bending, presence of calcification, and occlusion length of 20 mm or more. For the purpose of CTO angioplasty, another way to visualize the vessel distal to the CTO is the preprocedural use of CTCA. Using co-registration software, the vessel portion that is "missing" in the coronary angiogram is integrated with the CT image, thus providing guidance for the advancement of the intracoronary guidewire.

Calcific Lesions

Atherosclerotic calcifications are an important predictor of successful PCI. Although invasive coronary angiography can detect calcific coronary lesions, it has a low sensitivity for calcium and can only detect moderate to severe calcifications[60] (**Figs. 20.27 and 20.28**). The gold standard for the evaluation of calcific lesions is CTCA (**see Chapter 18**). The extent of CAC correlates with the plaque burden (**Table 20.12**), and because of the high sensitivity of CT scan for calcium, this imaging modality can detect plaque burden at a very early stage As an alternative to CTCA, IVUS has been shown to have significantly higher sensitivity to detect coronary calcification than standard angiography, especially for milder calcifications.[60] Presence of a calcific arc greater than 180 degrees by IVUS is considered a severe calcification.[61]

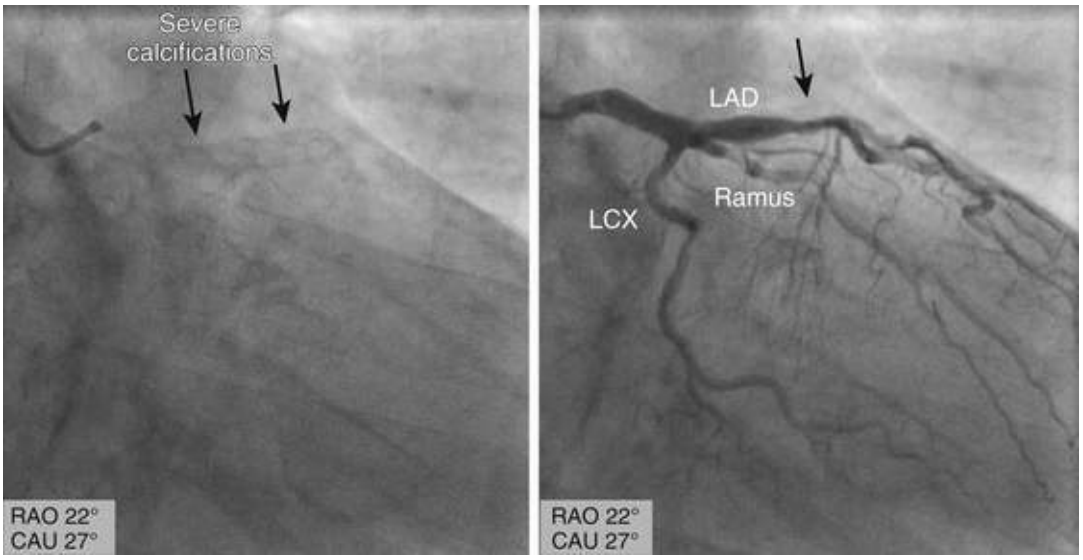

FIGURE 20.27 Severe calcifications in the proximal and middle left anterior descending artery (*LAD*). **Left,** Calcifications can be seen before contrast injection. **Right,** Marked irregularities of the vessel diameter in the segments with severe calcifications. *LCX,* Left circumflex artery. TABLE 20.12

Coronary Artery Calcium (CAC) Score

SCORE (AGASTON)	PLAQUE BURDEN	DESCRIPTION/PROBABILITY OF CORONARY ARTERY DISEASE
0	Nonidentified	Negative test: very low risk of having a cardiovascular event in the next 10 years (<5%).
1-10	Minimal	Minimal atherosclerosis is present. Findings are consistent with a low risk of having a cardiovascular event in the next 10 years (<10%)
11-100	Mild	Mild coronary atherosclerosis is present. Mild or minimal coronary stenosis is likely.
101-400	Moderate	Moderate calcium is detected in the coronary arteries. There is a moderate risk of having a cardiovascular event within 10 years.
>400	Extensive	High risk of having at least one significant coronary stenosis (>90%). Significant risk of having a cardiovascular event within the next 10 years.

The correct assessment of the calcium burden of a coronary lesion is important to determine the most appropriate treatment strategy. Highly calcific lesions are not compliant, and despite dilation before stent deployment, the risk of suboptimal stent apposition is high. Vessel dissection and distal embolization with aggressive vessel dilation before or after stent deployment are also possible complications. CABG might not be a valid alternative to PCI with extensive calcifications that do not allow for graft insertion on the native coronary artery, particularly in multivessel calcific disease. Atherectomy (rotational or orbital) may specifically treat calcific lesions during PCI (**see Chapter 62**).

Thrombotic Lesions

Presence of thrombus is usually associated with plaque rupture observed during acute coronary syndromes (**see Chapters 58 and 59**). However, patients with generalized prothrombotic states can develop thrombus in the absence of plaque rupture. Thrombi are associated with higher rates of periprocedural complications. Thrombus load has been graded with the TIMI score as follows:

Grade 0, no cineangiographic characteristics of thrombus present

Grade 1, images suggestive but not diagnostic for thrombus: reduced contrast density, haziness, and irregular lesion contour

Grade 2, small thrombus present that is one-half or less the vessel diameter

Grade 3, moderate-size thrombus present with greatest linear dimension more than one-half the vessel diameter but less than two vessel diameters (**Fig. 20.29**)

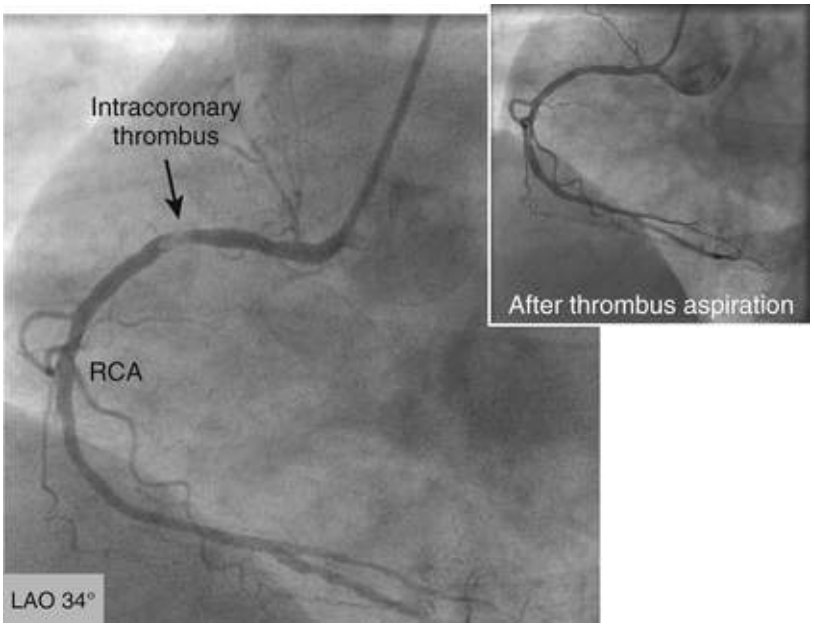

FIGURE 20.29 Grade 3 intracoronary thrombus in the proximal segment of the right coronary artery (*RCA*). **Right inset,** Absence of visible thrombus after aspiration. LAO, Left anterior oblique. (Courtesy Dr. Annapoorna Kini, Icahn School of Medicine at Mount Sinai, New York.)

Grade 4, large thrombus present with a largest dimension that is two vessel diameters or greater

Grade 5, recent total occlusion, which can involve some collateralization but usually does not involve extensive collateralization and tends to have a "beak" shape and a hazy edge or appearance of distinct thrombus

Grade 6, chronic total occlusion (CTO), which usually involves extensive collateralization, tends to have a distinct, blunt cutoff or edge, and will generally clot to the nearest proximal side branch.

Bifurcation Lesions

Bifurcation lesions account for approximately 15% of lesions requiring PCI. Bifurcation lesions are difficult to assess and treat because they may require intervention not only on the main vessel but on the side branch as well. Thus, these lesions are associated with increased complications during and after PCI. During coronary angiography, bifurcations are evaluated according to the Medina classification, a three-digit system based on the evaluation of three distinct vessel segments in the following order: main artery in the segment proximal to the bifurcation, main artery in the segment distal to the bifurcation, and the side branch. To each segment, the operator can assign 0 if no significant CAD or 1 if a significant stenosis is present.

Coronary Dissections

Coronary artery dissection can be a life-threatening complication during PCI or a spontaneous event. Iatrogenic dissections can be caused by the advancement of the guidewire into the coronary artery or by

plaque fracture after intracoronary balloon inflation. Based on their angiographic appearance, dissections can be classified (**Table 20.13 and Fig. 20.30**). Not all dissections require treatment. Type A and B dissections are usually considered benign and might not require intervention, whereas types C and F are often major dissections associated with morbidity and mortality. Whenever necessary, the management of coronary dissection is stent deployment.

TABLE 20.13

Classification of Coronary Dissections

Type A	Minor radiolucent areas within the coronary lumen during contrast injection with no persistence of the contrast after dye has cleared from the lumen
Type B	Dissections are parallel tract or double lumen separated by a radiolucent area during contrast injection with minimal or no persistence after dye clearance
Type C	Presence of contrast outside the coronary lumen ("extraluminal cap") with persistence of contrast after dye has cleared from the lumen
Type D	Spiral ("barbershop pole") luminal filling defects frequently with excessive contrast staining in the dissected false lumen
Type E	Dissection appears as new, persistent filling defects within the coronary lumen
Type F	Dissection that leads to total occlusion of the coronary lumen without distal antegrade flow

Modified from the National Heart, Lung and Blood Institute (NHLBI) classification system for intimal tears.

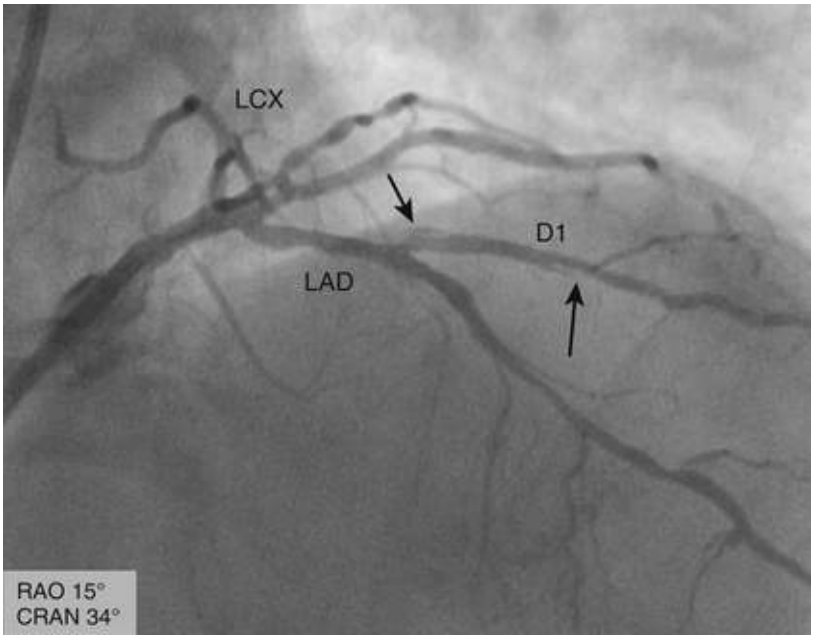

FIGURE 20.30 Type B coronary dissection. The *arrows* show two dissection sites in the diagonal branch. RAO, Right anterior oblique; CRAN, cranial. (Courtesy Dr. Annapoorna Kini, Icahn School of Medicine at Mount Sinai, New York.)

Spontaneous coronary artery dissections (SCADs) are rare. Their pathophysiology is not clear, but since they are more common in young women age 40 to 50 without any other cardiovascular risk factors, the etiology of SCAD has been associated with steroid hormones (**see Chapter 89**). In accordance with this theory, SCADs are more common within 2 weeks postpartum, when marked changes in hormonal levels are usually observed. Another possible explanation is the presence of undetected fibromuscular dysplasia (FMD), an arteriopathy that can involve different vascular districts, including renal arteries and coronary arteries (**see Chapter 64**). FMD can cause intramural hematomas that may result in SCADs. For example, in a study of 50 patients with SCAD, 86% were found to have FMD.[62]

Fractional Flow Reserve

Myocardial revascularization with PCI is recommended for coronary lesions with greater than 80% diameter stenosis. However, assessment of the hemodynamic significance of intermediate severe stenoses (those with diameter stenosis of 50% to 80%) might require more sophisticated methods to verify whether the lesion warrants an intervention. Application of FFR has been investigated intensively during the last decade (**see Chapters 57 and 62**).

FFR measures the pressure proximal to (aortic pressure) and distal to (guidewire pressure) a stenotic lesion during maximal hyperemia. Commercially available devices for detection of vessel physiology use 0.014-inch guidewires with a sensor on the tip (high-fidelity pressure transducer) to measure pressure, temperature, and flow. The application of FFR measurement is subject to certain technical necessities (**Table 20.14**). Coronary hyperemia can be induced by administration of adenosine (either IV or intracoronary). Each approach has its own limitations and benefits (**Table 20.15**). Several alternative drugs for induction of hyperemia are available, including papaverine (10 mg), nitroprusside (50 to 100 µg), adenosine triphosphate (ATP, 50 to 100 µg), or even contrast media.[89]

TABLE 20.14

Technical Approach for Fractional Flow Reserve (FFR) Measurement

1. Connect the FFR wire to systemic pressure analyzer. Calibration and zeroing should be performed outside the body.
2. It is necessary to use intravenous anticoagulation (heparin, 40 U/kg).
3. Advance the transducer into the guiding catheter until the transition zone is at the tip of the catheter. Pressure wire signal and guide pressure should be equalized before crossing the desired coronary lesion after flushing with saline.
4. Advance the FFR wire across the lesion (about 2 cm distal to the lesion).
5. Induce maximal hyperemia with adenosine (intravenous or intracoronary).
6. Estimate the pressure ratio proximal to distal of the lesion.
7. Finally, pull back the FFR wire into the guiding catheter to confirm equal pressure.

TABLE 20.15

Comparison of Intravenous and Intracoronary Adenosine Administration

	INTRAVENOUS	INTRACORONARY
Dose	140 µg/kg/min continuous infusion *or* Incremental dose until 160-180 µg/kg/min	Bolus injection of 20.30 µg/kg for RCA and 60-100 µg/kg for LCA
Effect peak	≤2 minutes after administration via central vein	<10 seconds
Effect duration	<2 minutes	<20 seconds
Side effect	AV block (rare) Bronchospasm (especially in patients with asthma) Decrease in blood pressure Increase in heart rate Angina-like symptoms and chest sensations	AV block, especially when administered in RCA
Benefit/limitation	Pullback is possible. Patient should avoid Valsalva maneuvers. Avoid kinking of punctured vein. In 8% of patients, only suboptimal hyperemia is inducible, resulting in implausible FFR values. Underestimation of values after caffeine or theophylline intake.	Does not allow pullback. In 10%-15% of patients, only suboptimal maximal hyperemia is possible. Underestimation of values after caffeine or theophylline intake.

AV, Atrioventricular; *FFR,* fractional flow reserve; *LCA,* left coronary artery; *RCA,* right coronary artery.

FFR is the ratio of maximal myocardial perfusion behind a stenotic lesion divided by maximal hyperemic flow in that same region in the hypothetical case that the lesion was not present. FFR is expressed as the reciprocal of normal maximal flow through a stenotic artery (**Fig. 20.31**). The normal value of FFR is unequivocally 1 for every coronary artery regardless of size. FFR values less than 0.80 in patients with stable CAD are considered hemodynamically significant and strongly correlate with inducible myocardial ischemia using noninvasive stress testing.

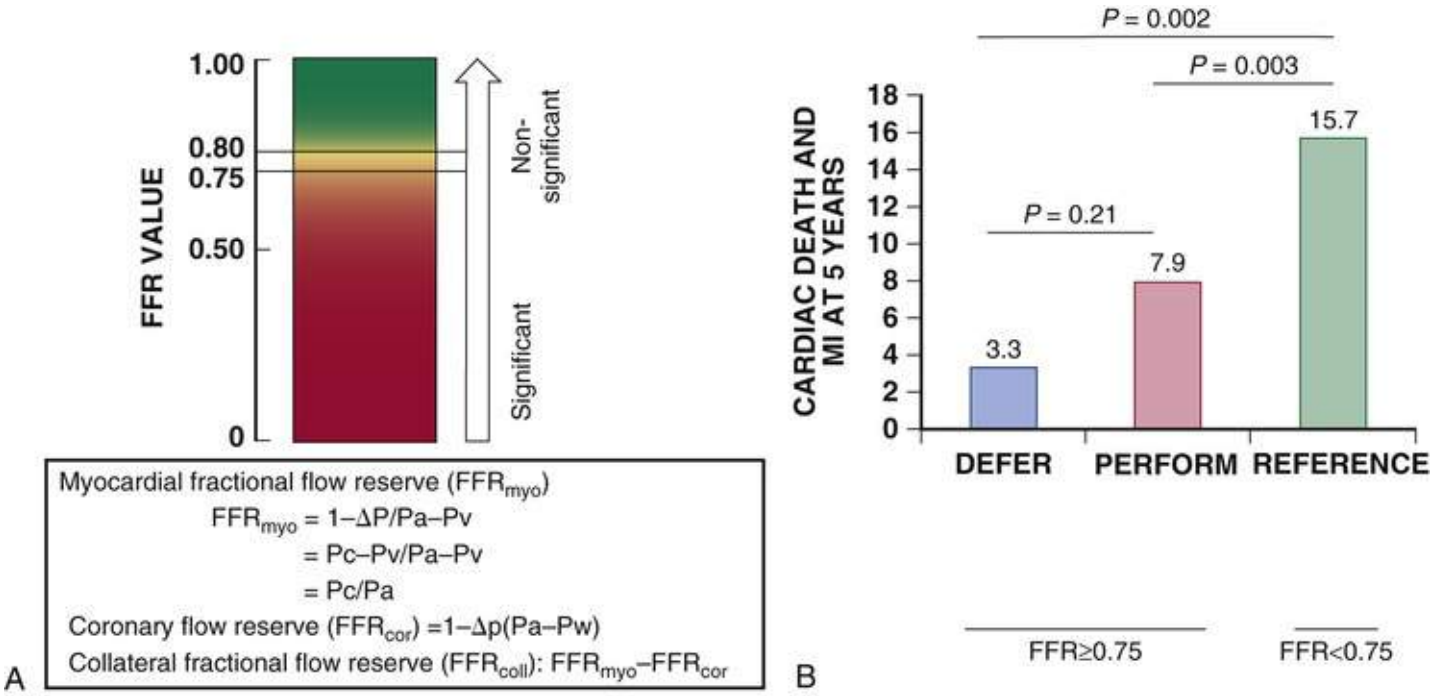

FIGURE 20.31 **A,** Calculation of fractional flow reserve (FFR) and normal and pathologic values for FFR. **B,** Cardiac death and myocardial infarction (*MI*) at follow-up of 5 years comparing defer vs. perform PCI in lesions with FFR ≥0.75 in comparison to reference group (FFR <0.75). (From Pijls NH, van Schaardenburgh P, Manoharan G, et al. Percutaneous coronary intervention of functionally nonsignificant stenosis: 5-year follow-up of the DEFER Study. J Am Coll Cardiol. 2007;49:2105-2111.)

In contrast to FFR, *coronary flow reserve* (CFR) measures the ability to increase resting flow to a normal maximal level (**see Chapter 57**). CFR estimates the capacity of major resistance components (epicardial vessel and supplied vascular bed). CFR, unlike FFR, is influenced by changes between basal and hyperemic blood flow, which in turn are influenced by heart rate, blood pressure, ventricular loading, and contractility. Therefore, CFR values should be interpreted with caution in particular patients (e.g., those with tachycardia, hypertension, LV hypertrophy, or heart failure). The most appropriate application of CFR is to identify coronary microvascular dysfunction.[63]

Several aspects during catheterization and measurement of FFR should be considered. The operator should avoid using catheters with side holes because a proximal pressure gradient will occur, thereby jeopardizing the measurement of distal gradient. Also, use of a larger guiding catheter might result in occlusion of the coronary ostium, leading to impairment of maximal flow. In numerous scenarios, a nonischemic FFR can be detected despite an apparently severe stenosis (**Table 20.16**).

TABLE 20.16

Reasons for Nonischemic Fractional Flow Reserve (FFR) Despite Apparently Severe Stenosis

Physiologic Reasons
Small perfusion territory
Myocardial infarction scar
Little viable tissue
Small vessel
Abundant collaterals
Severely diseased microcirculation
Interpretational Reasons
Other culprit lesion
Diffuse disease, not focal stenosis
Chest pain of noncardiac origin
Technical Reasons
Insufficient hyperemia
Guiding catheter too large, resulting in ostial occlusion
Electrical drift
True False-Negative FFR
Transmural myocardial infarction (small viable tissue area)
Severe left ventricular hypertrophy (imperfect hyperemia due to myocardial hypertrophy)
Exercise-induced spasm (resolution of lesion with hyperemia)

From Koolen JJ, Pijls NH. Coronary pressure never lies. Cath Cardiovasc Interv 2008;72:248-56.

Clinical Application

International clinical guidelines recommend the use of FFR in several clinical settings (**Table 20.17**) (**see Chapter 62**). Several CAD lesion subsets and clinical manifestation necessitate the measurement of FFR.

TABLE 20.17

International Guideline Recommendations for Measurement of Fractional Flow Reserve (FFR)

2011 ACCF/AHA/SCAI Guideline for Percutaneous Coronary Intervention (PCI)
FFR is reasonable to assess angiographic intermediate coronary lesions (50%-70% diameter stenosis) and can be useful for guiding revascularization decisions in patients with stable ischemic heart disease (SIHD). (Class IIA, level of evidence A)
2012 ACCF/AHA/ACP/AATS/PCNA/SCAI/STS Guideline*
Measurement of FFR to determine whether PCI of a specific coronary lesion is warranted.
2014 European Society of Cardiology†
FFR to identify hemodynamically relevant coronary lesion(s) in stable patients when evidence of ischemia is not available. (Class I, level of evidence A) FFR-guided PCI in patients with multivessel disease (Class IIA, level of evidence B)

Developed with the special contribution of the European Association of Percutaneous Cardiovascular Interventions (EAPCI). Eur Heart J 2014;35:2541-2619.

Intermediate or Severe Lesions.

In almost 50% of angiographies, intermediate or severe lesions (defined as stenosis greater than 50% but less than 80%) are present. The Deferral vs. Performance of Percutaneous Coronary Intervention of

Functionally Non-Significant Coronary Stenosis (DEFER) Study investigated 325 patients undergoing PCI in three groups: FFR ≥0.75, FFR <0.75 treated with PCI, and FFR <75 with medical therapy[64] (**see Fig. 20.31B**). The prognosis of lesions with FFR >75 was excellent regardless of whether PCI was performed, whereas lesions with FFR <75 had the worst prognosis.

Multivessel Disease PCI.

The FAME (Fractional Flow Reserve vs. Angiography for Multivessel Evaluation) Trial compared a physiologic-guided PCI approach (FFR-PCI) to a conventional angiographic-guided PCI in 1005 patients with multivessel CAD. In FFR-PCI patients, PCI was performed if FFR was ≤0.80. At 1 year, there was a significantly lower rate of MACE (a composite of death, nonfatal MI, and revascularization) in the FFR-guided PCI group.[65] Similarly, the FAME 2 (Fractional Flow Reserve–Guided PCI versus Medical Therapy in Stable Coronary Disease) Trial investigated patients in whom at least one stenosis was functionally significant (FFR ≤0.80) and randomly assigned them to FFR-guided PCI plus the best available medical therapy (PCI group) or optimal medical therapy alone (medical therapy group).[66] The trial was halted prematurely because of an excess of MACE (composite of death, myocardial infarction, and urgent revascularization) in the medical therapy group compared to the PCI group.[66] Hence, FFR ≤0.80 is the currently used cutoff for clinical purposes.

Left Main Stenosis.

Stenosis of the LMCA is associated with a high rate of false angiographic interpretation. Estimation of LMCA stenosis, in combination with the SYNTAX Score assigned to the coronary arteriogram as a whole, might lead to referral of the patient to a CABG procedure. Therefore, application of FFR is critical for decision making. Alternatively, IVUS or optical coherence tomography (OCT) can be used.

Ostial and Side Branch Lesions.

Lesions with side branch involvement may result in a “jailed” side branch after PCI. Estimating the need for PCI of the involved side branch is crucial eventually to reduce the need for risky and more complex interventions of the side and main branches. FFR may be used in the side branch to assess its significance for possible treatment. Functional SYNTAX Score might be used in lesions with nonsignificant FFR.

Saphenous Vein Graft Lesions.

In SVGs the FFR is the sum of competing flow in the native vessel, the SVG itself, and collateral circulation induced by longstanding occlusion of the native artery. Therefore the FFR will represent a net response indicating potential ischemia in that region. Small studies reported a high incidence of graft closure when placed on arteries with a preoperative FFR greater than 0.80.[67] Similar evidence was provided for arterial conduits from a retrospective evaluation.[68]

Acute Coronary Syndromes.

Measurement of FFR in patients with acute MI may lead to false-negative results because of a transient microcirculatory dysfunction in the infarcted area.

Multiple Lesions in One Vessel.

Serial lesions in one vessel constitute a challenge for estimation of an accurate FFR. Approximately expressed, if the distance between two consecutive lesions is more than six times the vessel diameter, each lesion can be considered independently. Otherwise, the FFR measured distal to the last lesion gives a sum of the flow across these serial lesions. In clinical practice, a pullback recording can be applied to identify the specific regions of a vessel with the highest pressure gradient. After treatment of these lesions, a reassessment should be done to estimate whether the gradient is residually high or not.

Postprocedural FFR Measurement.

Measurement of FFR after PCI might identify residual stenosis of a lesion requiring further intervention. In a study including 750 patients treated with PCI who underwent FFR immediately after stent implantation, positive post-PCI FFR was independently associated with adverse events at 6 months (**Fig. 20.32**). Noninvasive methods to determine FFR are under investigation.

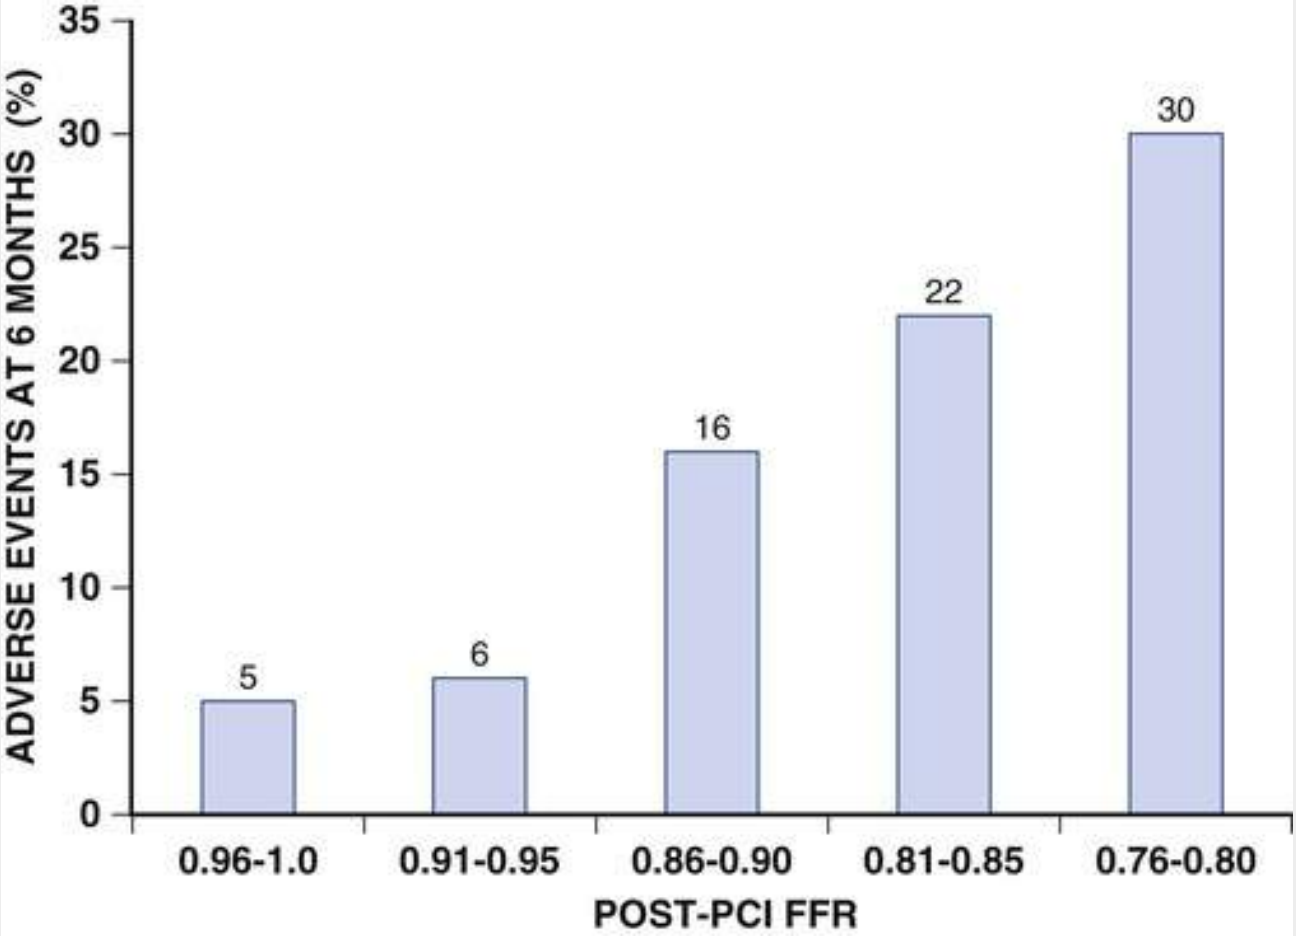

FIGURE 20.32 Increase in adverse events with lower post–percutaneous coronary intervention (PCI) fractional flow reserve (FFR). (From American Heart Association; Pijls NH, Klauss V, Siebert U, et al. Coronary pressure measurement after stenting predicts adverse events at follow-up: a multicenter registry. Circulation. 2002;105:2950-4.)

Instantaneous Wave-Free Ratio

FFR requires maximal arteriolar vasodilation by administering a pharmacologic agent, most often adenosine. However, many physicians are reluctant to use adenosine because of patient-related discomfort and contraindications. Therefore, several catheterization laboratories have adopted the instantaneous wave-free ratio (iFR), a new physiologic index for assessment of the hemodynamic severity of a coronary stenosis.[69] Recently, randomized trials have demonstrated that the use of iFR compared with FFR is more feasible and reliable.[69-73]

The pressure gradient across a stenosis is related to the coronary flow velocity and microcirculatory resistance. To evaluate the severity of a stenosis, one must know constant coronary flow velocity and minimum microcirculatory resistance. During the wave-free period, the proximal-originating compression wave and microcirculatory-originating compression wave are quiescent, while microcirculatory resistance is the lowest and most stable throughout the cardiac cycle. Coronary pressure and flow are

linearly related.[69] Using conventional pressure guidewires, the process of measuring iFR is similar to that of FFR, except it does not require vasodilators. Measurement of iFR is based on a specific period in diastole called the *wave-free period,* during which resistance at rest is stable. This resting state occurs spontaneously in each cardiac cycle, without hyperemic stimulation, beginning 25% into diastole and ending 5 milliseconds before the end of diastole, representing almost 75% of diastole during which evaluation of pressure can be made[69] (**Fig. 20.33**). iFR is calculated as the mean pressure distal to the stenosis during the diastolic wave-free period divided by the mean aortic pressure during the diastolic wave-free period.

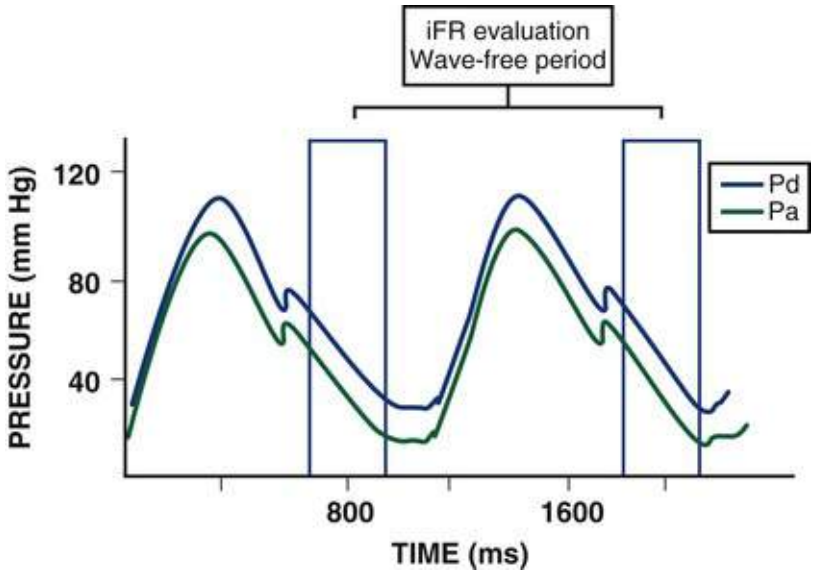

FIGURE 20.33 Illustration of wave-free period in the cardiac cycle. Instantaneous wave-free ratio (iFR) value of wave-free period in the cardiac cycle is demonstrated by the pressure distal to the stenosis lesion (Pd) divided by aortic pressure (Pa).

Comparison with Fractional Flow Reserve

In the first clinical study, iFR showed a good correlation with FFR ($r = 0.9$; $P < 0.001$) and also showed excellent diagnostic performance. Several studies recently reported various degrees of agreement between iFR and FFR, ranging from 80% to 90% depending on the severity of the investigated lesion. To match an FFR of 0.80 or less, the best iFR cutoff seems to be 0.89 to 0.90.[70-72]

Recently, iFR versus FFR approaches were compared in a randomized fashion.[73,74] The iFR strategy correlated with more deferral of PCI and overall similar ischemic outcomes to FFR. Further research on cost-effectiveness is ongoing.

Coronary Intravascular Imaging

The diffusion of techniques for intravascular imaging has advanced the understanding of coronary atherosclerotic disease and has provided additional information to angiography for the guidance of intracoronary stenting. IVUS and OCT are the main imaging modalities currently available in the catheterization laboratory for intravascular imaging.

Intravascular Ultrasound

An invasive coronary angiogram is a luminogram with poor specificity. Vascular imaging such as IVUS and OCT can facilitate detailed assessment and characterization of CAD and aid optimization of revascularization with stent implantation. Although OCT provides better definition of the vascular endothelium and fibrous cap of atheromas,[75] IVUS has higher vessel wall penetration that ensures a more detailed characterization of the atheroma core.

Principles.

IVUS employs an intracoronary catheter with a transducer at the tip, which generates sound waves by converting electrical energy into acoustic energy.[76] The waves are reflected off arterial vessel walls, returned to the transducer, and subsequently converted into a working image for qualitative and quantitative evaluation. Contemporary IVUS catheters include transducers emitting sound waves at frequencies of 20 to 45 MHz, which provide high penetration (5 to 10 mm) for accurate assessment of vessel size and plaque burden. However, the low resolution (70 to 200 μ; 100-μ micron axial resolution parallel to radius and 200-μ lateral resolution perpendicular to radius) of gray-scale IVUS results in imperfect plaque characterization.[77] Virtual histology IVUS (VH-IVUS) overcomes the drawback of gray-scale IVUS and allows detailed interpretation of plaque morphology in the different stages of phenotypic plaque evolution, namely, pathologic intimal thickening, fibrotic plaque, thick- and thin-cap fibroatheroma, and fibrocalcific plaque.[78] VH-IVUS also clearly demonstrates necrotic core, dense calcium, and areas of plaque rupture. Comparatively, OCT using light wave technology permits a higher resolution of 5 to 10 μ, although with low penetration for optimal assessment of plaque morphology, as well as differentiation between thrombus and plaque.[79] Finally, near-infrared spectroscopy (NIRS) technology promotes understanding of coronary plaque lipid burden and may be used in conjunction with IVUS or OCT.[80]

Technology.

There are two types of IVUS systems: single-element transducers and phased array transducers with multiple crystals arranged around the end of the delivery catheter.[76] A single-element transducer uses one element that generates and receives sound waves; a phased array system uses multiple transducers, which can be pulsed separately. The single-element type of catheter is commercially available with a transducer frequency of 40 to 45 MHz and a crossing profile of 2.9F to 3.2F compatible with 5F and 6F guides. Two such catheters are the Revolution (Volcano, California) and the Opticross (Boston Scientific). In contrast, the Eagle Eye Platinum catheter (Volcano) employs a phased array transducer with 20-MHz frequency and 2.9F crossing profile compatible with 5F guides. This catheter combines gray-scale and radiofrequency VH-IVUS assessment. The working length of the catheter is 150 cm (60 inches), and the proximal end is connected to the IVUS console for image reconstruction, which may be operated within the catheterization laboratory by radiation scientists. A console connected to the angiography table permits the operator to obtain measurements online during the procedure.

Indications for Use.

Current ACC/AHA guidelines[81] recommend IVUS use for assessment of indeterminate lesions in the LMCA (class IIA, level of evidence B) and non-LMCA (IIB, B) coronary arteries to determine the need for revascularization. IVUS is also recommended for optimization of stent implantation, particularly in the LMCA (IIA, B). Indeed, the use of IVUS in observational data has been associated with implantation

of larger and longer stents and higher pressures for postprocedural dilation.[82] After PCI, IVUS is recommended for the investigation of stent failure, to determine the mechanism of both in-stent restenosis (IIA, C) and stent thrombosis (IIB, C). Some investigators have also advocated IVUS use for the assessment and diagnosis of SCAD to visualize the tissue flap, true and false lumens, and intramural hematoma, thereby facilitating more accurate diagnoses.[83]

Procedure

Similar to a standard PCI procedure, IVUS examination is performed through a coronary guide catheter system over a 0.0014-inch guidewire using standard techniques with adequate anticoagulation for thrombus prevention. The crossing profile of the IVUS catheter varies from 2.9F to 3.2F, which is compatible with a 5F to 6F guide catheter. It is conventional to give a bolus dose of intracoronary nitroglycerin to prevent arterial spasm and allow better imaging assessment.[29] Once at the desired location distal to the lesion, pullback of the catheter is initiated, which may be automated or manual, with a typical pullback rate of 0.5 mm/sec. IVUS-related complications are rare and usually self-resolving. The risk of coronary dissection or perforation with IVUS use is estimated at 1.6%.[84] Complications with IVUS catheter use may be related to size of the vessel and force used to advance the catheter.

Interpretation

IVUS identifies three layers in normal vessel architecture, including the intima, media, and adventitia (**Fig. 20.34**). The *intima* is an echogenic, bright inner layer. The *media* is a hypoechoic, homogeneous area between the intima and adventitia composed of smooth muscle cells, collagen, elastic tissue, and proteoglycans. The *adventitia* is the outer reflective layer.[76] In the presence of atherosclerosis, there is evidence of medial thinning and deposition of plaque in the intima. This is typically noted to be heterogeneous due to variable impedance of the different plaque components (**Fig. 20.35**). Thrombus in the lumen may appear similar to plaque and cannot be clearly differentiated on gray-scale IVUS in the absence of a distinct interface between thrombus and plaque. Occasionally, IVUS may indicate the presence of blood flow through luminal thrombus. VH-IVUS identifies different plaque morphologies in a color-coded manner, and necrotic core, dense calcification, and fibrous and fibrofatty areas are all clearly noted.[78]

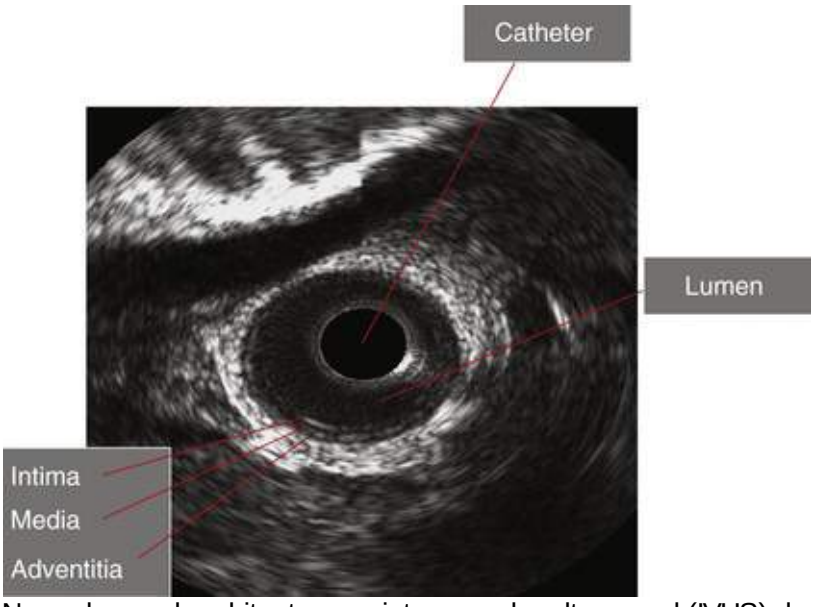

FIGURE 20.34 Normal vessel architecture on intravascular ultrasound (IVUS) demonstrating three layers: intima, media, and adventitia. (Courtesy Dr. Annapoorna Kini, Icahn School of Medicine at Mount Sinai, New York.)

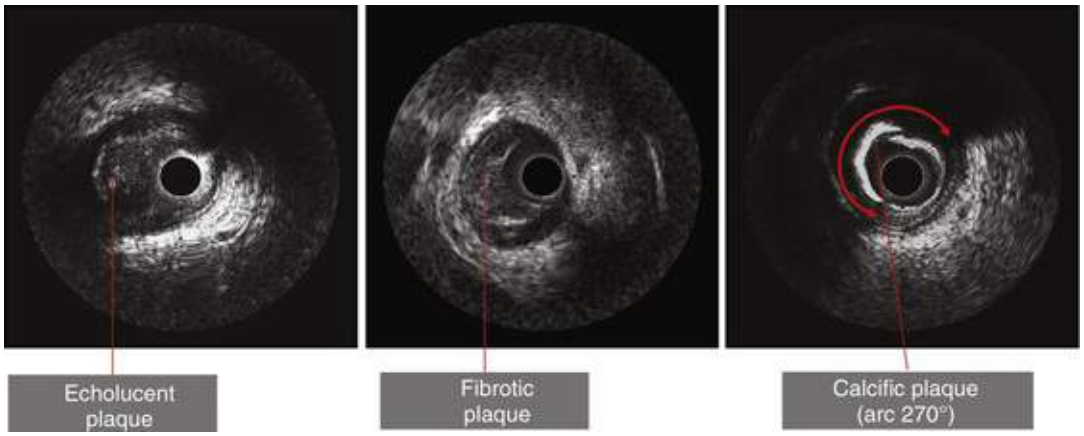

FIGURE 20.35 Heterogeneous nature of different plaque components caused by variable impedance on IVUS. (Courtesy Dr. Annapoorna Kini, Icahn School of Medicine at Mount Sinai, New York.)

A coronary dissection may be diagnosed on IVUS with documentation of tissue flap, true and false lumens, and intramural hematoma.[85] Implanted coronary stents can be assessed using IVUS for both expansion and apposition. A gap between the stent struts and the vessel wall indicates malapposition; the greater the distance between the stent strut and the vessel wall, the worse the malapposition. Stent underexpansion and malapposition are correlated with long-term adverse outcomes, including stent thrombosis. Real-time assessment of stent apposition and the need for post-dilation can be made online to allow specific management during PCI. Post-PCI neointimal hyperplasia caused by in-stent restenosis can be assessed using IVUS and appears as a hypoechoic area within the stent.[76]

In addition to immediate qualitative assessment of images for nature and extent of CAD, automated software analysis is available for both online and offline quantitative measurement of plaque burden and vessel size. Several validated measurements may be taken for evaluation of minimum lumen area, minimum lumen diameter, external elastic membrane (EEM) area, EEM diameter, plaque and media area (EEM area– lumen area), and plaque burden (plaque and media area/EEM area)[77] (**Fig. 20.36**). General criteria for significant obstructive disease include minimum lumen area less than 6 mm^2 in the LMCA or

less than 4 mm^2 in the proximal LAD and other major vessels.[87]

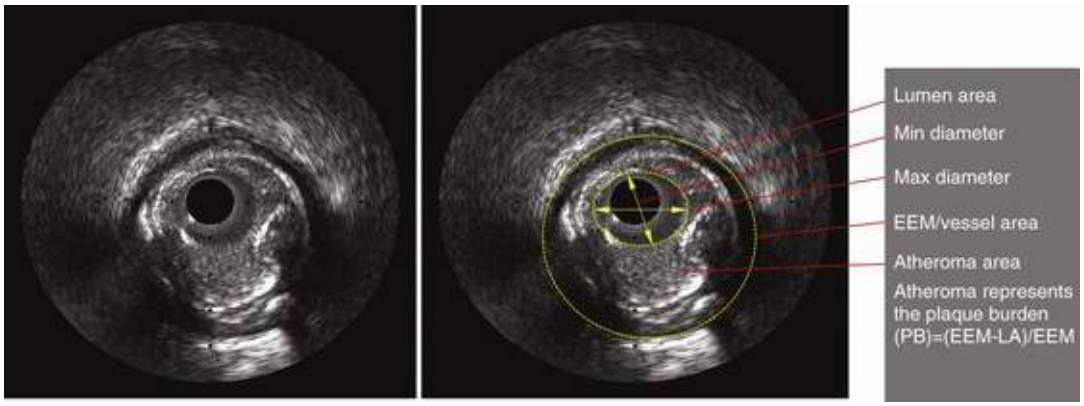

FIGURE 20.36 IVUS quantitative measurements for evaluation of lumen diameter and lumen area (LA), external elastic membrane (EEM) area, and plaque burden (PB). (Courtesy Dr. Annapoorna Kini, Icahn School of Medicine at Mount Sinai, New York.)

For VH-IVUS, the gray-scale IVUS images recorded during pullback are combined with raw radiofrequency data captured on top of the R wave and reconstructed in a color-coded map by the IVUS-VH data recorder. The color-coded map identifies necrotic core (red), dense calcium (white), fibrofatty tissue (light green), and fibrous tissue (dark green). Thin-cap fibroatheroma on VH-IVUS is diagnosed in the presence of a greater than 30-degree arc of necrotic core abutting the lumen in three consecutive slices.[77]

Clinical Data

Several observational datasets have shown long-term benefit from IVUS use for PCI attributed to greater minimum stent area and lower MACE. In the Assessment of Dual Antiplatelet Therapy with Drug-Eluting Stents (ADAPT-DES) Study, IVUS was used in 39% of cases and was associated with longer stents, larger stent diameters, and higher inflation pressures in 74% of IVUS-guided cases.[82] IVUS-guided PCI was also associated with lower MACE, stent thrombosis, and target lesion revascularization after propensity-adjusted multivariable analysis. The MATRIX (Comprehensive Assessment of Sirolimus-Eluting Stents in Complex Lesions) registry compared patients undergoing IVUS guided versus non-IVUS guided PCI. Both short- and long-term outcomes were significantly reduced with IVUS use.[86] Similarly, a meta-analysis has shown that IVUS is associated with lower MACE, mortality, MI, stent thrombosis, and target lesion revascularization than angiography-guided PCI.[88] Nevertheless, these outcomes are from observational, not randomized data. Several randomized trials have been rather small in size and negative for routine use of IVUS imaging to improve PCI "hard outcomes."

In the Providing Regional Observations to Study Predictors of Events in the Coronary Tree (PROSPECT) study, almost 700 patients presenting with ACS underwent three-vessel coronary angiography and IVUS after PCI. The study showed that non–culprit lesion–related MACE (composite of all-cause death, cardiac arrest, MI, or rehospitalization due to unstable or progressive angina) was associated with plaque burden of 70% or more, minimum lumen area of 4 mm^2 or less, and thin-cap fibroatheroma less than 65 μ.[84] However, at 3 years, MACE was equally related to culprit and nonculprit vessel lesions. Use of intracoronary imaging may facilitate early detection and treatment of vulnerable plaque in nonculprit lesions and decrease long-term MACE.

An important limitation of IVUS interpretation is the need for coaxial catheter position during image

acquisition.[89] The low resolution prevents clear differentiation between thrombus and plaque burden. In regard to applicability to the workflow of a busy catheterization laboratory, routine IVUS use is perceived to be expensive, time-consuming, and limited by operator skill. Further, IVUS does not allow visualization of the plaque lipid content, which might have important prognostic repercussions. To overcome this limitation, near-infrared spectroscopy (NIRS) can be used.

Plaque Lipid Core Detection

The NIRS catheter emits near-infrared waves with a wavelength of 0.8 to 2.5 µ. Based on differences in absorption pattern of the light, different components of plaque and lipid are demonstrated in a map or chemogram of lipid deposition along the coronary artery.[90] The TVC Insight Catheter (Infraredx, Massachusetts) combines NIRS and IVUS (40 MHz), with a crossing profile of 3.2F compatible with 6F guide catheter systems. The TVC composite system allows superimposed imaging from NIRS-IVUS, which can provide information on vessel size, plaque burden, and areas of lipid-rich plaque.[91]

Hybrid catheters are also available, combining FFR-IVUS and IVUS-OCT to provide complementary data from these dual technologies. NIRS can be used before PCI to identify lipid-rich plaques that might be at risk of periprocedural myonecrosis and distal embolization, to evaluate the necessity of distal protection filters.[92] The Coronary Assessment by Near-infrared of Atherosclerotic Rupture-prone Yellow (CANARY) Trial was a randomized clinical study on 57 patients undergoing coronary angiography and NIRS-IVUS imaging. Patients were randomized to angioplasty with or without a distal embolic protection device. The results showed that lipid-rich plaques identified by NIRS are associated with higher rates of periprocedural MI. However, the use of a distal protection filter did not prevent myonecrosis after PCI at lipid-rich plaques.[93]

Optical Coherence Tomography

Cardiovascular OCT is a catheter-based imaging technique that uses light and its reflection to create images of the coronary wall. Initially developed to perform imaging of the retina, OCT technology rapidly expanded to various biomedical and clinical applications.

Principles.

OCT is based on a fiberoptic wire with a rotating lens that emits near-infrared light (approximately 1300 nm) and records the light reflected from the analyzed tissue. One of the most valuable properties of OCT is its high resolution, up to 10 µ for axial resolution and 20 µ for lateral resolution. Although resolution is high, tissue penetration ranges from 1.0 to 3.5 mm.

The images created by OCT are derived from the delay that results from the light traveling to the target tissue and back to the lens. Images are generated by measuring the echo time delay and the intensity of reflected light. The speed of light does not allow direct measurement of the echo time delay, so a technique known as *interferometry* has been developed to analyze the reflected light signal. With this technique the light reflected from target tissue is measured by correlating it with light that has traveled a known reference distance. Cross-sectional images of the vessel are created by obtaining multiple axial scans as the fiberoptic wire is simultaneously rotating and pulled back rapidly along the vessel.

Two types of OCT imaging systems have been developed: *time-domain* OCT (TD-OCT) and Fourier-domain OCT, also known as *frequency-domain* OCT (FD-OCT). Using a novel wavelength-swept laser

as a light source, FD-OCT imaging systems provide superior signal-to-noise ratio and allow significantly faster imaging speed compared to the earlier time-domain technology. Recent FD-OCT imaging systems are capable of acquiring images at a rate of 180 frames/sec at a pullback speed of up to 36 mm/sec. One single pullback allows imaging of up to 75 mm of the vessel.

Early OCT technology required a complete displacement of blood from the viewing field to generate high-quality images. An over-the-wire low-pressure occlusion balloon catheter with distal flush ports to infuse saline or Ringer lactate can be used to remove erythrocytes from the viewing field. However, the accelerated pullback speed provided by FD-OCT no longer requires occlusion of the vessel, with a shift toward a nonocclusive approach with flushing of contrast.

Clinical Applications

OCT can be used to guide diagnosis during coronary angiography as well as procedure planning and assessment of PCI, as indicated in an initial clinical study.[94]

Normal Vessel Wall

In a healthy vessel, OCT visualizes the coronary artery wall as a layered structure (**Fig. 20.37**). The intima appears as a thin, highly reflective, and signal-rich layer, while the media occurs as a dark, low-reflective band. The latter is delimited by the internal elastic lamina, an adluminal signal-rich line, and the external elastic lamina, an abluminal signal-rich line. The adventitia appears as a signal-rich, heterogeneously textured outer layer.

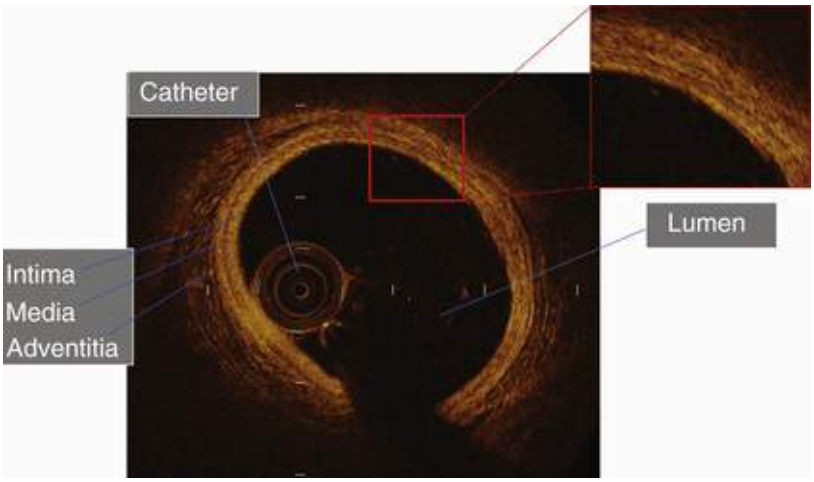

FIGURE 20.37 Optical coherence tomography (OCT) of a healthy vessel: The coronary artery wall is visualized as a layered structure. (Courtesy Dr. Annapoorna Kini, Icahn School of Medicine at Mount Sinai, New York.)

Stable Coronary Artery Disease

In patients with stable CAD, OCT imaging is used for quantitative assessment of the lesion by measuring the minimal lumen area (MLA). For the identification of hemodynamically severe coronary stenosis, OCT was shown to have only moderate diagnostic efficiency, when using the “gold standard” FFR as a reference, and similar accuracy compared to IVUS.[95]

Plaque Morphology

OCT provides the possibility to distinguish between fibrotic, lipid-rich, and calcified lesions (**Table 20.18**). High-risk features of plaques, including a thin fibrous cap, large lipid core, and increased macrophage infiltration, can be detected by OCT.[96]

TABLE 20.18

General Characteristics of Tissue Types by Optical Coherence Tomography (OCT)

TISSUE TYPE	BACKSCATTERING	ATTENUATION	GENERAL ASPECTS
Calcium	+	+	Sharp borders, low signal, with heterogeneous regions
Lipid	++	+++	Irregular borders, superficial high signal followed by very low signal
Fibrotic	++	+	Homogeneous bright tissue
Red thrombus	+++	+++	Superficial signal rich, low penetration, signal-free shadowing
White thrombus	+++	+	Signal rich, more penetration than for red thrombus
Media layer	+	+	Low signal region, limited by two signal-rich lines (IEL/EEL)
IEL/EEL	+++	+	High signal lines (20 μ)

IEL/EEL, Internal/external elastic lamina; +, low; ++, moderate; +++, high.

Acute Coronary Syndrome

In patients with ACS, OCT has not only high sensitivity to detect intraluminal thrombus, but also the capability of discriminating between red and white thrombus (**Fig. 20.38**). Furthermore, OCT has higher sensitivity in detecting fibrous cap rupture (**Fig. 20.39**) and fibrous cap erosion compared to IVUS.[97] The capability of OCT to discriminate the underlying mechanism of ACS has direct impact on further treatment strategy. In SCAD (**Fig. 20.40**), one of the non-CAD related causes that can be detected by OCT, unnecessary stent implantation can be avoided.

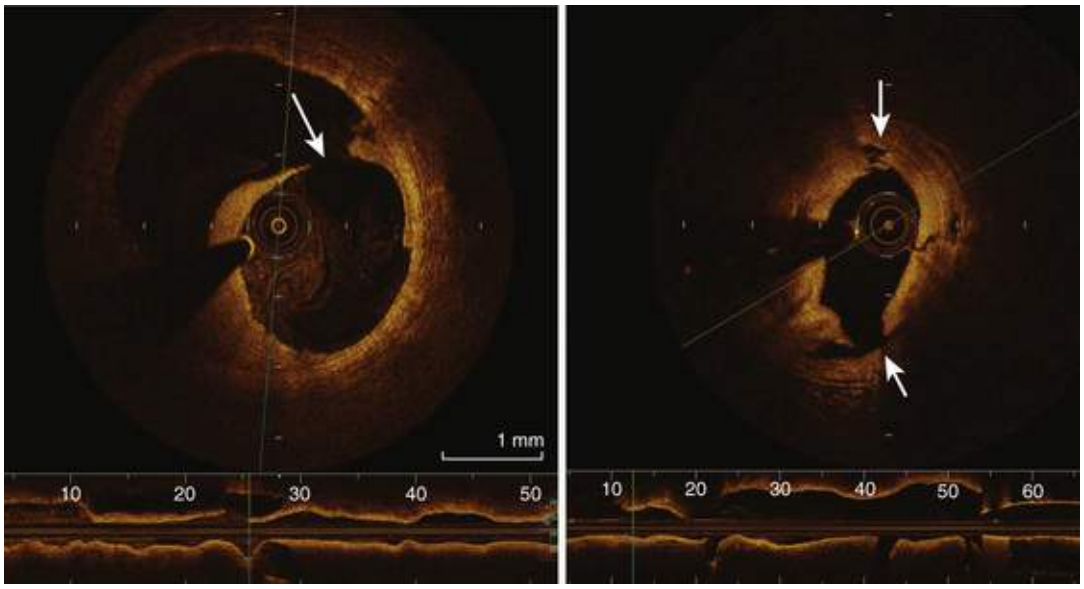

FIGURE 20.40 OCT of a dissected vessel. **Left,** Spontaneous coronary artery dissection (SCAD). **Right,** Dissection after balloon predilation. *Arrows* indicate the sites of rupture. (Courtesy Dr. Annapoorna Kini, Icahn School of Medicine at Mount Sinai, New York.)

Procedure Planning and Lesion Preparation

In procedural planning for PCI, OCT is a valuable tool for assessing the landing zone and especially for measuring calcium thickness. Concentric but thin calcium allows the use of regular or scoring balloons, whereas thicker concentric calcium may require atherectomy[98] (**Fig. 20.41**). OCT imaging can guide adequate lesion preparation, which is crucial for optimal stent deployment, but it can also be helpful for stent selection. Stent diameter, as well as length, can be chosen according to measurements of the reference vessel diameter both proximal and distal to the target lesion, as well as the lesion length. The fast-pullback acquisition of images makes FD-OCT less susceptible to artifacts resulting from heart motion, and therefore an optimal tool for accurate measurement of lesion length.

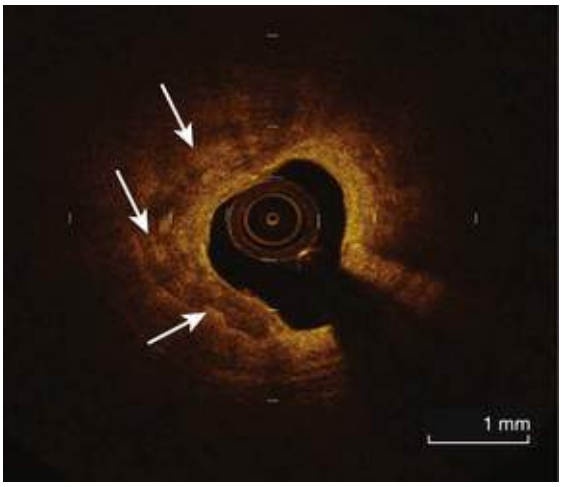

FIGURE 20.41 OCT of a severely calcified lesion. *Arrows* indicate some of the calcifications. (Courtesy Dr. Annapoorna Kini, Icahn School of Medicine at Mount Sinai, New York.)

Assessment After Percutaneous Coronary Intervention

Post-PCI OCT offers the possibility to detect postprocedural complications (**Fig. 20.40**) and to provide information on the potential need for further procedural steps. OCT is used for ensuring appropriate stent expansion and evaluating apposition of the stent with the vessel wall (**Fig. 20.42**). Stent underexpansion, associated with small minimal stent area measured by OCT, was shown to be an independent predictor of device-oriented clinical endpoints, including cardiac death, target vessel–related MI, target lesion revascularization, and stent thrombosis.[99] By allowing the determination of the distance of each stent strut from the vessel wall, OCT is capable of detecting the percentage of malapposed stent struts, which were shown to be associated with delayed neointimal coverage.[100] The presence of uncovered stent struts detected by OCT was proposed as an independent predictor of late stent thrombosis in drug-eluting stents.[101] In particular, for bioresorbable scaffolds, the rate of stent thrombosis seems to increase significantly in malapposition. Therefore, use of OCT is strongly recommended after deployment of such a stent. *Stent edge dissection* (SED) is another post-PCI complication that is detectable by OCT which has been shown to be associated with adverse clinical outcomes.[102] However, the vast majority of SEDs diagnosed by OCT heal without further treatment, and additional stenting should be reserved for the presence of intramural hematoma, as recently suggested.[98] Deployment of stent edges within the normal vessel wall and appropriate selection of stent diameter may help to avoid SED.[102] Compared to SED, tissue protrusion is a less investigated post-PCI complication. Irregular tissue protrusion was shown to be associated with device-related clinical endpoints, which were primarily driven by target lesion revascularization.[99] However, the further management of tissue protrusion detected by OCT is not yet clear.

PART IV
Heart Failure

OUTLINE

21

Approach to the Patient with Heart Failure

James L. Januzzi Jr, Douglas L. Mann

Definition and Epidemiology

Heart failure (HF) is a complex clinical syndrome resulting from structural and functional impairment of ventricular filling or ejection of blood. Although the clinical syndrome of HF may result from abnormalities or disorders involving all aspects of cardiac structure and function, most patients have impairment of myocardial function, ranging from normal ventricular size and function to marked dilation and reduced function. Symptoms of HF frequently depend on the presence of elevated left- or right-sided heart filling pressures, but the term “congestive heart failure” is no longer preferred, because many patients do not have overt congestion at evaluation, and their symptoms may be caused by other factors, such as reduced cardiac output.

The global incidence and prevalence rates of HF are approaching epidemic proportions, as evidenced by the relentless increase in the number of HF hospitalizations, the growing number of HF deaths, and the spiraling costs associated with the care of HF patients. The overall prevalence of HF is thought to be increasing, in part because current therapies for cardiac disorders (e.g., myocardial infarction, valvular heart disease, arrhythmias) are allowing patients to survive longer. Worldwide, HF affects almost 23 million people. In the United States the most recent epidemiologic data suggest that 5.7 million Americans have HF, and it is estimated that by 2030 the prevalence will increase 25% from current estimates.[1] Estimated prevalence of symptomatic HF in the general European population is similar to that in the United States and ranges from 0.4% to 2%.[2]

The prevalence of HF rises exponentially with age and affects 4% to 8% of people older than 65 (**Fig. 21.1A**). Although the relative incidence of HF is lower in women than men for all age groups, women constitute at least half the cases of HF because of their longer life expectancy, and the overall prevalence of HF is greater in women than men age 80 or older.[3] The U.S. National Institutes of Health (NIH)–funded Multi-Ethnic Study of Atherosclerosis (MESA) showed that blacks had the highest risk for development of HF, followed by Hispanic, white, and Chinese Americans[4] (**Fig. 21.1B**). In North America and Europe, lifetime risk of developing HF is approximately one in five for a 40-year-old. Risk factors for HF include ischemic heart disease, incident or prevalent myocardial infarction, myocarditis, valvular heart disease, tachycardia, diabetes mellitus, structural heart disease related to congenital heart disease, sleep apnea, excessive drug or alcohol use, and obesity. A significant percentage (30% to 40%) of nonischemic HF is thought to be caused by genetic factors (**see Chapter 7**). In addition, certain medications may increase the risk for HF, including nonsteroidal anti-inflammatory drugs (NSAIDs) and cancer chemotherapy.

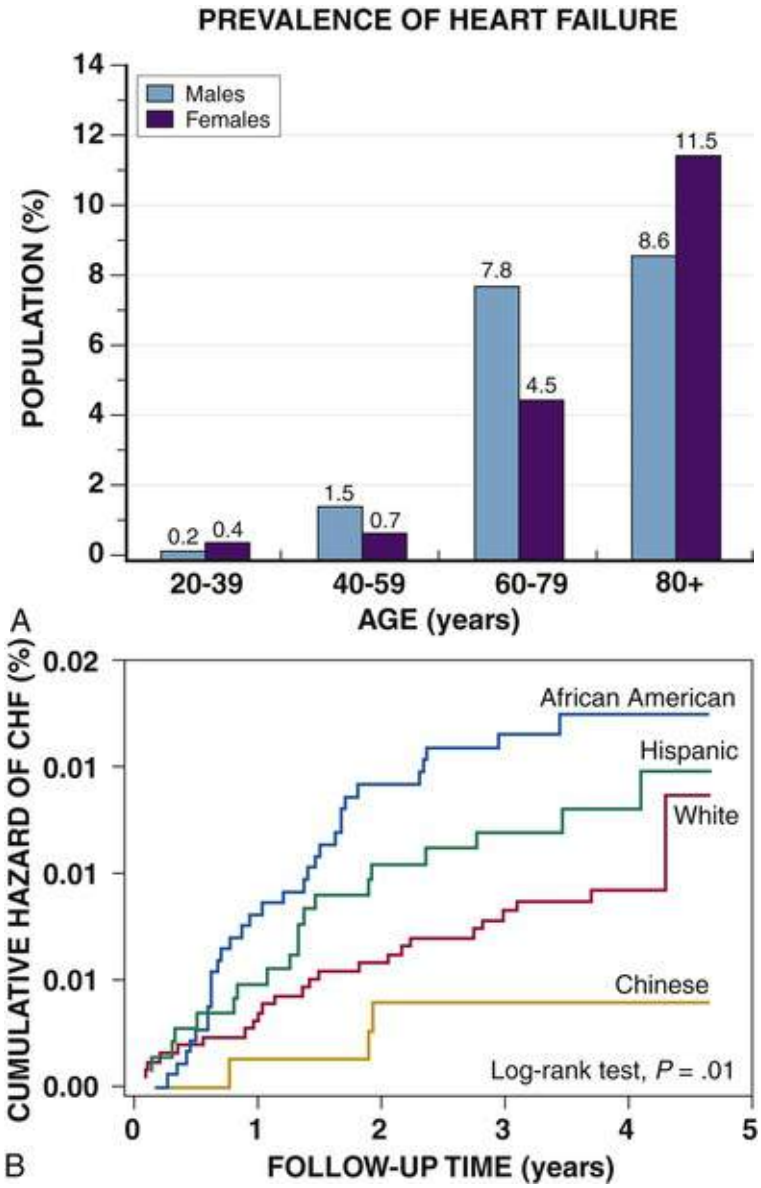

FIGURE 21.1 Prevalence and outcomes of heart failure (HF) in the United States. **A,** Prevalence of HF by sex and age (National Health and Nutrition Examination Survey: 2007–2010). **B,** Neslon-Aalen plots of cumulative hazard ratios for the development of congestive heart failure (CHF) by racial or ethnic group, in the Multi-Ethnic Study of Atherosclerosis (MESA) study. (**A,** Modified from Go AS, Mozaffarian D, Roger VL, et al. Heart disease and stroke statistics—2013 update: a report from the American Heart Association. Circulation 2013;127:e6-245; **B,** From Bahrami H, Kronmal R, Bluemke DA, et al. Differences in the incidence of congestive heart failure by ethnicity: the Multi-Ethnic Study of Atherosclerosis. Arch Intern Med 2008;168:2138-45.)

The distribution of ejection fraction (EF) across unselected populations of HF patients is bimodal, with peaks centered around 35% and 55%.[3] Approximately half of patients have HF with preserved EF (HFpEF; **Chapter 26**), and the balance have HF with reduced EF[3] (HFrEF; **Chapter 25**). HFpEF is generally defined as a left ventricular EF of 50% or greater, whereas HFrEF is generally defined as an EF less than 40%. Treatment strategies for treating HF are based on these two categories, so these distinctions are critical. Recent interest has focused on those with HF and an EF between 40% and 50%[5]; these patients do not yet have consensus regarding their best management, because they are often excluded from clinical trials. The prevalence of HFpEF increases dramatically with age and is much more common in women than in men at any age.[4] The prevalence of HFpEF appears to be increasing, perhaps as a function of the aging population and increased recognition of HFpEF. These data further emphasize that HFpEF is an important cause of the HF syndrome.

Classification of Heart Failure

Patients with HF are classified according to symptomatology and the stage of the disease. The American College of Cardiology and American Heart Association (ACC/AHA) HF staging approach emphasizes the importance of development and progression of disease,[6] whereas the New York Heart Association (NYHA) functional classification focuses more on exercise tolerance in those with established HF (**Table 21.1**). Although considerably subjective, the NYHA functional classification is widely used. Use of both systems in conjunction provides a reasonable framework for clinician communication and patient prognostication. The NYHA classification is also used to determine eligibility for certain therapies (e.g., mineralocorticoid receptor antagonists, cardiac resynchronization).

TABLE 21.1

American College of Cardiology/American Heart Association (ACC/AHA) Stages of Heart Failure (HF) Compared to the New York Heart Association (NYHA) Functional Classification

ACC/AHA STAGES		NYHA FUNCTIONAL CLASSIFICATION	
A	At high risk for HF but without structural heart disease or symptoms of HF.	None	
B	Structural heart disease but without signs or symptoms of HF.	I	No limitation of physical activity. Ordinary physical activity does not cause symptoms of HF.
C	Structural heart disease with prior or current symptoms of HF.	I	No limitation of physical activity. Ordinary physical activity does not cause symptoms of HF.
		II	Slight limitation of physical activity. Comfortable at rest, but ordinary physical activity results in symptoms of HF.
		III	Marked limitation of physical activity. Comfortable at rest, but less than ordinary activity causes symptoms of HF.
D	Refractory HF requiring specialized interventions.	IV	Unable to carry on any physical activity without symptoms of HF, or symptoms of HF at rest.

When the diagnosis of HF is suspected, the goals of the clinical assessment is to determine whether HF is present, define the underlying etiology and the type of heart failure (HFrEF versus HFpEF), assess the severity of HF, and identify comorbidities that can influence the clinical course and response to treatment. Although the diagnosis of HF can be straightforward when the patient presents with a constellation of the classic signs and symptoms in the appropriate clinical setting (**Tables 21.2** and **21.3**), no sign or symptom alone can define the presence or severity of HF. Furthermore, detection of diagnostic physical findings of HF is imprecise, often requiring other diagnostic tools. Thus, as depicted in **Fig. 21.2**, the clinical assessment of HF most often depends on information that is gleaned from a variety of sources, including the history (both past and present), physical examination, laboratory tests, cardiac imaging, and functional studies.

TABLE 21.2

Using the Medical History to Assess the Heart Failure Patient

Symptoms Associated with HF Include:
Fatigue
Shortness of breath at rest or during exercise
Dyspnea
Tachypnea
Cough
Diminished exercise capacity
Orthopnea
Paroxysmal nocturnal dyspnea
Nocturia
Weight gain/weight loss
Edema (of extremities, scrotum, or elsewhere)
Increasing abdominal girth or bloating
Abdominal pain (particularly if confined to right upper quadrant)
Loss of appetite or early satiety
Cheyne-Stokes respirations (often reported by family rather than patient)
Somnolence or diminished mental acuity
Historical Information Helpful in Determining if Symptoms Are Caused by HF
A past history of HF
Cardiac disease (e.g., coronary artery disease, valvular or congenital disease, previous myocardial infarction)
Risk factors for heart failure (e.g., diabetes, hypertension, obesity)
Systemic illnesses that can involve the heart (e.g., amyloidosis, sarcoidosis, inherited neuromuscular diseases)
Recent viral illness or history of HIV infection or Chagas disease
Family history of HF or sudden cardiac death
Environmental and/or medical exposure to cardiotoxic substances
Substance abuse
Noncardiac illnesses that could affect the heart indirectly, including high-output states (e.g., anemia, hyperthyroidism, arteriovenous fistulas)

TABLE 21.3

Physical Findings of Heart Failure

Tachycardia
Extra beats or irregular rhythm
Narrow pulse pressure or thready pulse*
Pulses alternans*
Tachypnea
Cool and/or mottled extremities*
Elevated jugular venous pressure
Dullness and diminished breath sounds at one or both lung bases
Rales, rhonchi, and/or wheezes
Apical impulse displaced leftward and/or inferiorly
Sustained apical impulse
Parasternal lift
Third and/or fourth heart sound (either palpable and/or audible)
Tricuspid or mitral regurgitant murmur
Hepatomegaly (often accompanied by right upper quadrant discomfort)
Ascites
Presacral edema
Anasarca*
Pedal edema
Chronic venous stasis changes

*Indicative of more severe disease.

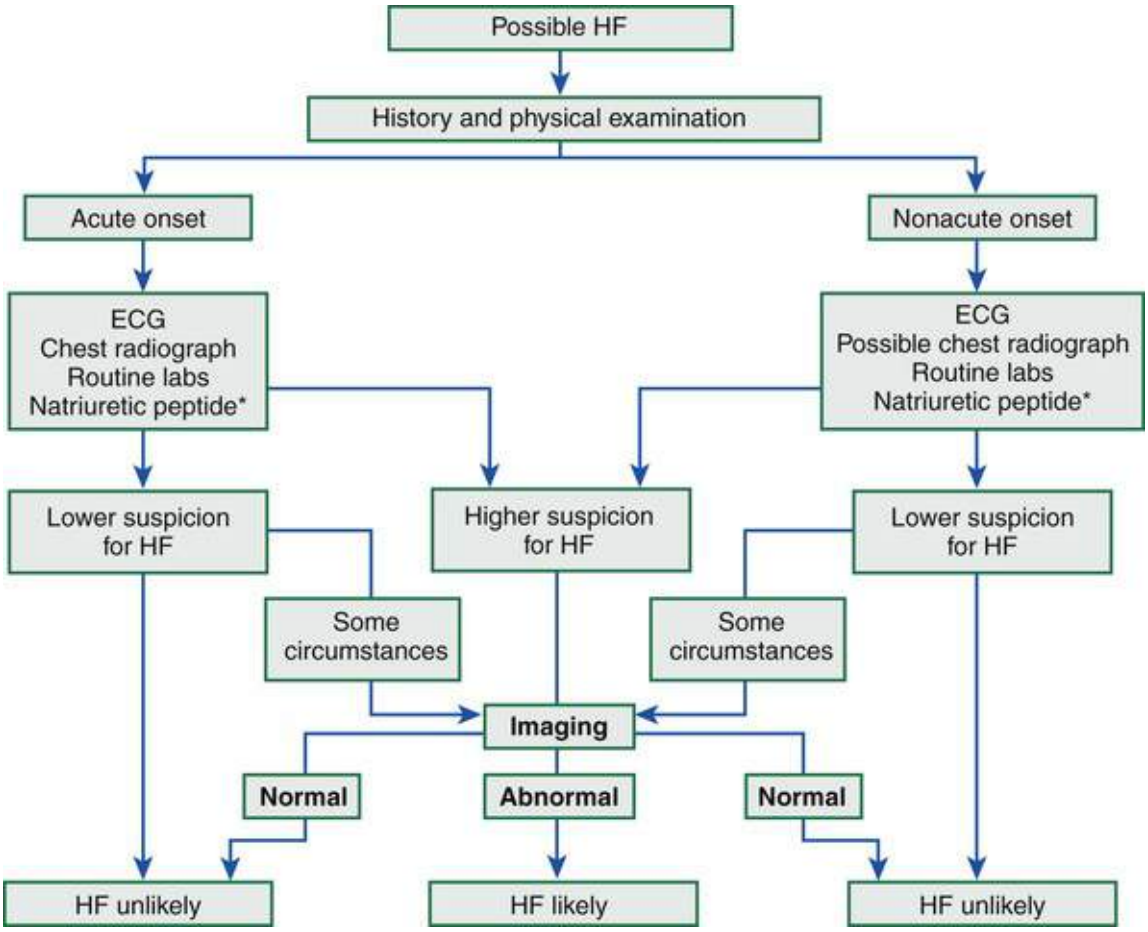

FIGURE 21.2 Flow chart for the evaluation of patients with HF. Appropriate cutoff values for natriuretic peptide testing (*asterisk*) to identify or exclude HF are provided in **ETable 21.1**. The diagnosis of HF is made using a combination of clinical judgment and initial and subsequent testing. Following thorough history and physical examination together with initial diagnostic testing, imaging (e.g., with echocardiography) may still be necessary in ambiguous cases to identify definitively or to exclude the diagnosis.

The Medical History and Physical Examination

A complete medical history and carefully focused physical examination are the foundation of the assessment in HF patients, providing important information regarding etiology of HF, identifying possible exacerbating factors, and lending pivotal data for proper management (**see Chapter 10**). The information obtained guides the further direction of the patient's evaluation and enables the clinician to make the most judicious use of additional tests. Further, the history helps to evaluate incongruent results that may emerge during the diagnostic process, and it can obviate the need for needless further testing.

Heart Failure Symptoms and Signs

Patients with HF may complain of a vast array of symptoms, the most common of which are listed in **Table 21.2**. None of these is entirely sensitive or specific for identifying the presence of severe congestion (**Table 21.4**), but some are more reliable than others for this indication. Importantly, none is specific to HFpEF versus HFrEF.

TABLE 21.4

Sensitivity and Specificity of History and Physical Examination (H&P) Components for Diagnosis of Elevated Filling Pressures in Patients with Heart Failure*

H&P FINDING	FREQUENCY	SENSITIVITY	SPECIFICITY	PREDICTIVE VALUE		LR		OR (95% CI)
				Positive	Negative	Positive	Negative	
Rales (≥1/3 lung fields)	26/192	15	89	69	38	1.32	1.04	1.4 (0.6, 3.4)
S3	123/192	62	32	61	33	0.92	0.85	0.8 (0.4, 1.5)
Ascites (moderate/massive)	31/192	21	92	81	40	2.44	1.15	2.8 (1.1, 7.3)
Edema (≥2+)	73/192	41	66	67	40	1.20	1.11	1.3 (0.7, 2.5)
Orthopnea (≥2 pillows)	157/192	86	25	66	51	1.15	1.80	2.1 (1, 4.4)
Hepatomegaly (>4 fingerbreadths)	23/191	15	93	78	39	2.13	1.09	2.3 (0.8, 6.6)
Hepatojugular reflux	147/186	83	27	65	49	1.13	1.54	1.7 (0.9, 3.5)
JVP ≥12 mm Hg	101/186	65	64	75	52	1.79	1.82	3.3 (1.8, 6.1)
JVP <8 mm Hg	18/186	4.3	81	28	33	0.23	0.85	0.2

*Values expressed as percentages unless otherwise indicated; *LR,* likelihood ratio; *OR,* odds ratio; *CI,* confidence interval.

Worsening *dyspnea* is a cardinal symptom of HF and is typically related to increases in cardiac filling pressures, but also may represent restricted cardiac output.[7] The absence of worsening dyspnea, however, does not necessarily exclude the diagnosis of HF, since patients may accommodate symptoms by substantially modifying their lifestyle. Probing more deeply into the current level of activity may uncover a decline in exercise capacity that is not immediately apparent. Dyspnea at rest is often mentioned by patients hospitalized with HF and has a high diagnostic sensitivity and significant prognostic ramifications in this population. However, it is also cited by patients with many other medical conditions, so that the specificity and positive predictive value (PPV) of dyspnea at rest alone are low. Patients may sleep with their heads elevated to relieve dyspnea while recumbent (orthopnea); additionally, dyspnea while lying on the left side (trepopnea) may occur. *Paroxysmal nocturnal dyspnea,* shortness of breath developing while recumbent, is one of the most highly reliable indicators of HF.

Cheyne-Stokes respiration (also referred to as periodic or cyclic respiration) is common in advanced HF and is usually associated with low cardiac output and sleep-disordered breathing (**see also Chapters 25 and 87**). The presence of Cheyne-Stokes respiration is generally indicative of an adverse prognosis.[8] Nocturnal cough is a frequently overlooked symptom of HF.

These symptoms all typically reflect pulmonary congestion, whereas a history of weight gain, increasing abdominal girth, early satiety, and the onset of edema in dependent organs (extremities or scrotum) indicate right-sided heart congestion. However, nonspecific, right upper quadrant pain caused by congestion of the liver is common in patients with significant right-sided HF and may be incorrectly attributed to other conditions.

Another cardinal symptom of HF is *fatigue,* generally held to be reflective of reduction in cardiac output as well as abnormal skeletal muscle metabolic responses to exercise.[9] Other causes of fatigue in HF may include major depression, anemia, renal dysfunction, endocrinologic abnormalities, and side effects to medications. Unintended weight loss, often leading to cachexia, may be prominent and is a major prognostic indicator.[10]

Other Historical Information

Information about a patient's past and current medical problems and a multigenerational family history as well as social history provides the background on which symptoms are interpreted and a management plan is designed. The presence of hypertension, coronary artery disease, and diabetes is particularly

helpful since these conditions account for approximately 90% of the population attributable risk for HF in the United States.[11]

The medical history should also focus on the drugs taken by the patient. Agents associated with incident HF include cancer chemotherapy,[12] diabetes drugs (e.g., thiazolidinediones), ergot-based antimigraine drugs, appetite suppressants, certain antidepressants and antipsychotic agents (notably including clozapine), decongestants such as pseudoephedrine (due to its ability to trigger severe hypertension), and anti-inflammatory agents such as the antimalarial hydroxychloroquine (infrequently associated with infiltrative cardiomyopathy) and NSAIDs. The NSAIDs are well-recognized to lead to HF through their ability to worsen renal function, trigger hypertension, and lead to fluid retention, particularly in elderly patients. Although selective and nonselective cyclooxygenase (COX) 2 inhibitors can provoke HF, the use of celecoxib has not been associated with increased risk of HF.

A history of use of herbal remedies and dietary supplements should be obtained. Environmental or toxic exposures, including alcohol or drug abuse, should be carefully sought. A multigenerational family history should be taken for prior HF or sudden cardiac death. Information about the presence of comorbidities (as described later) is essential in devising management plans. Although most etiologies of HF are cardiac, it is worth remembering that some systemic illnesses (e.g., anemia, hyperthyroidism) can cause this syndrome without direct cardiac involvement (**see Chapter 92**).

Physical Examination

The physical findings listed in **Table 21.2** complement information from the medical history in defining the presence and severity of HF. The signs of HF have been extensively described, and much as with the history of patients with heart failure, components of the physical examination have variable sensitivity and specificity for the diagnosis[13] (**see Table 21.4**), in part because of the subtlety of some physical findings, as well as variability in the physical diagnostic skills of the examiner. No physical finding in HF is absolutely pathognomonic for HFpEF versus HFrEF.[13]

An evaluation for the presence and severity of HF should include consideration of the patient's general appearance, measurement of vital signs in the seated and standing position, examination of the heart and pulses, and assessment of other organs for evidence of congestion, hypoperfusion, or indications of comorbid conditions. The patient's general appearance conveys vital information. The examiner should assess the patient's body habitus and state of alertness, as well as whether the patient is comfortable, short of breath, coughing, or in pain. The skin examination may show pallor or cyanosis resulting from underperfusion, stigmata of alcohol abuse (e.g., spider angiomata, palmar erythema), erythema nodosum from sarcoidosis, bronzing from hemachromatosis, or easy bruising from amyloidosis. Additional findings supporting amyloidosis include deltoid muscle infiltration (leading to the “shoulder pad sign”), tongue hypertrophy, and bilateral thenar wasting from carpal tunnel syndrome. The details of inspection and palpation of the heart are discussed in **Chapter 10**. By observing or palpating the apical impulse, the examiner can rapidly determine heart size and quality of the point of maximal impulse. In cases of severe HF, a palpable impulse corresponding to a third heart sound may be present. Cardiac auscultation is a crucial part of HF evaluation.

A characteristic holosystolic murmur of mitral regurgitation is heard in many HF patients. Tricuspid regurgitation, which is also common, can be differentiated from mitral regurgitation by the location of the

murmur at the left sternal border, an increased intensity of the murmur during inspiration, and the presence of prominent “V” waves in the jugular venous waveform. Both mitral and tricuspid regurgitation murmurs may become softer as volume overload is treated, and a reduction in ventricular size (with corresponding reduction in annular diameter) improves valve coaptation and competency. Aortic stenosis is an important cause of HF because its presence greatly alters management. The presentation of aortic stenosis may be subtle, however, since the intensity of the murmur depends on blood flow across the valve, which may be reduced as HF develops. The presence of a third heart sound is a crucially important finding and suggests increased ventricular filling volume; while difficult to identify, a third heart sound is highly specific for heart failure and carries a substantial prognostic meaning. A fourth heart sound usually indicates reduced ventricular compliance. In advanced HF the third and fourth heart sounds may be superimposed, resulting in a summation gallop.

A key objective of the examination in HF patients is to detect and quantify the presence of volume retention, with or without pulmonary and systemic congestion. As with symptoms, evidence of congestion does not always indicate with certainty that HF is present, and the absence of manifest congestion does not definitively exclude the diagnosis. Patients with HFpEF and HFrEF do not generally show significant differences in frequency or significance of the stigmata of volume overload.[14]

The most definitive method for assessing a patient's volume status by physical examination is by the measurement of jugular venous pressure (JVP). An elevated JVP has good sensitivity (70%) and specificity (79%) for elevated left-sided filling pressure[13] (**see Table 21.4**). The sensitivity and specificity of the JVP in detecting congestion can be considerably improved by exerting pressure on the right upper quadrant of the abdomen while assessing venous pulsations in the neck (hepatojugular reflux). Changes in JVP with therapy usually parallel changes in left-sided filling pressure. Limitations of JVP assessment include difficulties in its evaluation because of body habitus as well as significant interobserver variability in its estimation. Increase in the JVP may lag behind left-sided heart filling pressures, or it may not rise at all if pulmonary artery pressure is increased to the extent that right ventricular failure or tricuspid regurgitation occur. Conversely, the JVP may be elevated without an increase in left ventricular filling pressures in patients with pulmonary arterial hypertension, in those with isolated right ventricular pressure, or when isolated severe tricuspid regurgitation is present.

Although pulmonary congestion is exceedingly common in HF, physical findings indicating its presence are variable, and many are nonspecific. Dullness to percussion and diminished breath sounds at one or both lung bases suggest the presence of a pleural effusion. Bilateral pleural effusions are most common, but when an effusion is present unilaterally, it is usually right sided, with only approximately 10% occurring exclusively on the left side. Leakage of fluid from pulmonary capillaries into the alveoli can be manifest as rales or rhonchi, and wheezing may result from reactive bronchoconstriction. Pulmonary rales caused by HF are usually fine in nature and extend from the base upward, whereas those from other causes (e.g., pulmonary fibrosis) tend to be coarser. Importantly, rales or rhonchi may be absent in congested patients with advanced HF; this may reflect compensatory increases in local lymphatic drainage. “Cardiac asthma” is caused by the physical presence of fluid in the bronchial wall as well as secondary bronchospasm.[15] It can result in an incorrect diagnosis of “obstructive airways disease exacerbation,” with consequent mistriage and incorrect therapy with bronchodilators; such mismanagement may be associated with increased risk for mortality.[16]

Lower extremity edema is a common finding in volume-overloaded HF patients but may be the result of venous insufficiency (particularly after saphenous veins have been harvested for coronary artery bypass grafts) or as a side effect of medications (e.g., calcium channel blockers). Careful inspection of the JVP

helps improve the specificity of pedal edema for HF.

Detecting reduced cardiac output and systemic hypoperfusion are key components of the examination. Patients with poor systemic perfusion usually have low systolic and narrow pulse pressures as well as weak and thready pulses, but this relationship is not exact. Many patients with systolic blood pressure in the range of 80 mm Hg (or even lower) may have adequate perfusion, whereas others with reduced cardiac output may maintain blood pressure in the normal range at the expense of tissue perfusion by greatly increasing systemic vascular resistance. Findings suggesting reduced cardiac output include poor mentation, reduced urine output, mottled skin, and cool extremities. Of these, cool extremities are the most broadly useful.

Assessment for systemic congestion taken together with evaluation for reduced cardiac output may be useful to categorize patients into "dry/warm" (uncongested with normal perfusion), "wet/warm" (congested with normal perfusion, the most common combination found in decompensated heart failure), "dry/cold" (uncongested but hypoperfused), and "wet/cold" (cardiogenic shock),[17] as discussed in **Chapter 24**. These categories not only are prognostic, but also inform treatment decision making (**Fig. 21.3**).

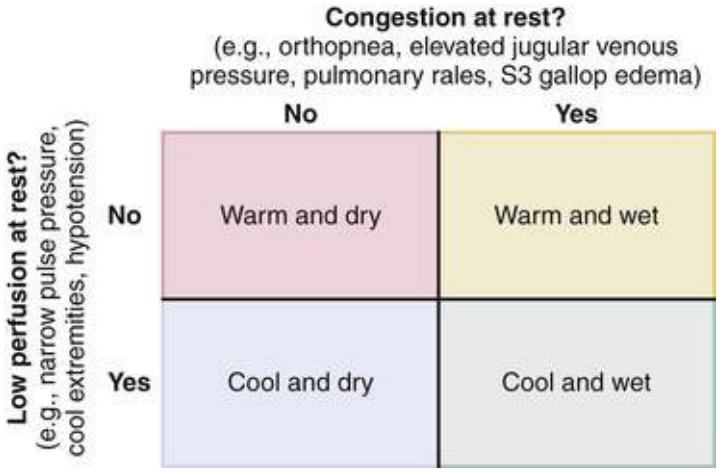

FIGURE 21.3 Schema for categorizing patients with HF on the basis of perfusion (warm versus cold) and presence of congestion (dry versus wet). The four categories of HF identified in this schema have different treatment strategies. (Based on data from Nohria A, Tsang SW, Fang JC, et al. Clinical assessment identifies hemodynamic profiles that predict outcomes in patients admitted with heart failure. J Am Coll Cardiol 2003;41:1797.)

Routine Laboratory Assessment

A suggested algorithm for the diagnostic evaluation of HF is presented in **Fig. 21.2**. The laboratory testing and imaging modalities described here provide important information for the diagnosis and management of patients with suspected or proven HF.

Chest Radiography

Despite advances in other imaging technologies, the chest x-ray film remains a useful component of the assessment, particularly when the clinical presentation is ambiguous. Results of chest radiography are additive to clinical variables from history and physical examination and similarly complement the results of biomarker testing. Accordingly, chest radiography should be a routine part of the early evaluation of

patients presenting with symptoms suggestive of acutely decompensated HF (**see Chapter 15**).

The classic chest x-ray pattern in patients with pulmonary edema is a “butterfly” pattern of interstitial and alveolar opacities bilaterally fanning out to the periphery of the lungs. Many patients, however, present with subtler findings, in which increased interstitial markings, including *Kerley B lines* (thin horizontal linear opacities extending to the pleural surface caused by accumulation of fluid in the interstitial space), peribronchial cuffing, and evidence of prominent upper lobe vasculature (indicating pulmonary venous hypertension) are the most prominent findings. Pleural effusions and fluid in the right minor fissure may also be seen. In many cases, particularly in patients with advanced heart failure, the chest radiograph may be entirely clear, despite significant symptoms of dyspnea; the negative predictive value (NPV) of chest radiography is too low to definitively exclude HF.[18]

Electrocardiography

The electrocardiogram (ECG) is a standard part of the initial evaluation of a patient with suspected HF. It may provide important clues regarding incident heart failure while assisting in understanding when previously diagnosed patients experience an episode of decompensation. In HF patients the ECG is infrequently normal, but it may only show nonspecific findings; thus, similar to the chest radiograph, the PPV of the ECG greatly surpasses the NPV in this setting (**see Chapter 12**).

Sinus tachycardia caused by sympathetic nervous system activation is seen with advanced HF or during episodes of acute decompensation. In addition to increasing the likelihood for the diagnosis, an elevated heart rate is also a prognostic finding in HF. The presence of atrial arrhythmia on the ECG as well as the ventricular response may provide clues as to the cause of HF, as well as explain why a patient may have developed decompensated symptoms; identifying atrial arrhythmia with a rapid ventricular response also provides a target for therapeutic interventions. Increased ventricular ectopy identifies a patient at risk for sudden death, particularly when the EF is very low (e.g., <30%).

The presence of increased QRS voltage may suggest left ventricular hypertrophy. In the absence of a prior history of hypertension, such a finding might be caused by valvular heart disease or by hypertrophic cardiomyopathy, particularly if bizarre repolarization patterns are noted. If right ventricular hypertrophy is present, primary or secondary pulmonary hypertension should be considered. Low QRS voltage suggests the presence of an infiltrative disease or pericardial effusion. The presence of Q waves suggests that HF may be caused by ischemic heart disease, and new or reversible ST changes identify the presence of acute coronary ischemia, even when chest pain is absent. Indeed, since acute coronary ischemia is a leading cause of acutely decompensated HF, a 12-lead ECG should be immediately obtained in this patient, to exclude acute myocardial infarction (AMI).

The intervals on the ECG may provide important information on causes of HF as well as for treatment strategy. Prolongation of the PR interval is common in patients in this setting and may result from intrinsic conduction disease, but it may also be seen in patients with infiltrative cardiomyopathy such as amyloidosis. With the advent of cardiac resynchronization therapy (CRT; **see Chapter 27**), evaluation of the QRS complex has become a critical part of the clinical assessment, providing important information on the cause of HF and regarding the therapeutic approach. The QT interval is often prolonged in patients

with HF and may be caused by electrolyte abnormalities, myocardial disease, and effects of common drugs, such as antiarrhythmics. A lengthened QT interval may identify patients at risk for torsades de pointes and is thus an important variable to consider when using therapeutic agents with effects on ventricular repolarization.

Measurement of Blood Chemistry and Hematologic Variables

Patients with new-onset HF and those with acute decompensation of chronic HF should have a panel of electrolytes, blood urea nitrogen (BUN), serum creatinine, hepatic enzymes, fasting lipid profile, thyroid-stimulating hormone, transferrin saturation, uric acid, complete blood count, and urinalysis. As discussed later, the natriuretic peptides may be exceedingly useful for diagnosis as well as for prognostication. A test for HIV or further screening for hemachromatosis is reasonable in select patients, and diagnostic tests for rheumatologic diseases, amyloidosis, or pheochromocytoma are reasonable when suspicion exists for these diseases.

Abnormalities of sodium are common in HF patients, particularly during periods of acute decompensation, and have substantial prognostic meaning. Studies have shown that hyponatremia (defined as serum sodium values <135 mmol/L) may be found in up to 25% of patients with acute HF, and hyponatremia may also be seen in patients with indolently worsening HF without obvious decompensation.[19] Low sodium concentrations in HF may result from worsening volume retention or may be related to the use of diuretics, including thiazides. Hyponatremia is associated with impaired cognitive and neuromuscular function, and when present and persistent, low sodium is strongly prognostic for longer hospital stay, as well as a high risk for mortality.[20] Despite this fact, strategies to correct serum sodium levels have not been shown clearly to improve the clinical course[21] (**see Chapter 24**). Hypernatremia, although uncommon, is also prognostic for mortality in patients with HF. Hypokalemia occurs frequently in HF patients who are treated with diuretics. In addition to increasing the risk of cardiac arrhythmias, low potassium may also lead to leg cramps and muscle weakness. Conversely, hyperkalemia is less common but is most often caused by effects of medications such as angiotensin-converting enzyme (ACE) inhibitors or mineralocorticoid inhibition.

Abnormalities of renal function are common in HF patients and result from renal congestion, inadequate cardiac output, or comorbid conditions.[22] In addition, HF therapies such as diuretics and ACE inhibitors or angiotensin receptor blockers can increase BUN and creatinine. In this regard, abnormalities of renal function may have substantial effects on the ability to treat HF patients aggressively. Furthermore, abnormal renal function represents one of the more powerful prognostic variables gleaned from routine laboratory testing in HF patients. For these reasons, assessment of renal function should be performed as part of the initial evaluation of HF, then periodically repeated during follow-up.

In patients hospitalized with acutely decompensated HF, registry data suggest that 60% to 70% have a reduced estimated glomerular filtration rate.[23] In such patients the initial BUN and serum creatinine concentrations are independently predictive of death.[24] After admission, approximately 30% of patients with acute HF may also develop an increase in serum creatinine by 0.3 mg/dL or greater, which is similarly prognostic for mortality.[22,23] The causes of this “cardiorenal” syndrome are complex but include the severity of right-sided heart congestion, increased intra-abdominal pressure, and renal hypoperfusion

from inadequate cardiac output. On the other hand, worsening renal function may also occur from aggressive decongestion strategies; such a decline in renal function has been linked to improved (rather than worse) prognosis because it presumably indicates a more thorough treatment for congestion, the trigger for acute HF hospitalization.[25] Accordingly, when faced with worsening renal function, the clinician must perform a careful examination to assess volume status and tissue perfusion and decide on appropriate therapies to manage the situation. Lastly, improvement in renal function may follow therapies that reduce the severity of congestion; such a finding is still associated with poor long-term prognosis.

Diabetes mellitus is common in HF patients, and hyperglycemia has emerged as a possible risk factor for adverse outcome in affected patients. Since diuretics can cause gout, measuring uric acid levels can help in patient management; elevated serum uric acid levels have been noted to be prognostic, and therapies to lower their concentration are now being studied to improve HF outcomes. Abnormalities in aspartate transaminase (AST), alanine transaminase (ALT), alkaline phosphatase (ALP), bilirubin, or lactate dehydrogenase (LDH) may occur in HF patients because of either hemodynamic derangements leading to hepatic congestion or medications, and it is important to follow levels periodically. An unexpected increase in prothrombin time (PT) in patients receiving warfarin therapy may be an early harbinger of decompensation since it may reflect impaired synthetic capacity of a congested liver. Albumin levels are an indication of the patient's nutritional status and may be depressed because of poor appetite or impaired absorption across an engorged bowel wall; hypoalbuminemia is prognostic for mortality in acute and chronic HF.

Hematologic abnormalities are exceedingly common in HF, affecting almost 40% of affected patients. Low hemoglobin levels have been associated with more severe HF symptoms, reduced exercise capacity and quality of life, and increased mortality.[26] Although anemia may be a consequence of chronic disease in HF patients, a low hemoglobin level should trigger an evaluation to detect treatable causes, particularly iron deficiency. Increasing attention has also been given to the red blood cell distribution width as a prognostic variable in both acutely decompensated and chronic HF.[27] The white blood cell count with differential is helpful in detecting the presence of an infection responsible for destabilizing a previously well-compensated patient and could provide a clue that HF has an uncommon cause, such as eosinophilic infiltration of the myocardium.

Biomarkers

Beyond standard laboratory testing, the measurement of newer biomarkers has emerged over the past decade as an important adjunct to the initial and subsequent evaluation of patients with suspected or proven HF. Biomarkers are now routinely used to distinguish HF from other conditions, establish severity of the diagnosis, and provide useful prognostic information in HF patients. There is also considerable interest in determining the ability of biomarkers to guide therapy, in both acute and chronic settings. As shown in **Table 21.5**, Braunwald[28] has proposed that HF biomarkers be divided into six distinct categories, with an additional category reserved for biomarkers not yet classified.

TABLE 21.5

Biomarkers Used in Assessing Patients with Heart Failure

Inflammation[*†‡]
C-reactive protein
Tumor necrosis factor
Fas (APO-1)
Interleukins 1, 6, and 18
Oxidative Stress[*†§]
Oxidized low-density lipoproteins
Myeloperoxidase
Urinary biopyrrins
Urinary and plasma isoprostanes
Plasma malondialdehyde
Extracellular Matrix Remodeling[*§]
Matrix metalloproteinases
Tissue inhibitors of metalloproteinases
Collagen propeptides
Propeptide procollagen type I
Plasma procollagen type III
Neurohormones[*†§]
Norepinephrine
Renin
Angiotensin II
Aldosterone
Arginine vasopressin
Endothelin
Myocyte Injury[*†§]
Cardiac-specific troponins I and T
Myosin light-chain kinase I
Heart-type fatty acid protein
Creatine kinase MB fraction
Myocyte Stress[†‡§¶]
B-type and N-terminal pro–B-type natriuretic peptide
Midregional proadrenomedullin
ST2
New Biomarkers[†]
Chromogranin
Galectin 3
Osteoprotegerin
Adiponectin
Growth differentiation factor-15

[*]Biomarkers in this category aid in elucidating the pathogenesis of HF.

[†]Biomarkers in this category provide prognostic information and enhance risk stratification.

[‡]Biomarkers in this category can be used to identify patients at risk for HF.

[§]Biomarkers in this category are potential targets of therapy.

[¶]Biomarkers in this category are useful in the diagnosis of HF and in monitoring therapy.

As articulated,[29] clinically useful biomarkers of HF should be easily measured with high analytic precision, should reflect important processes involved in HF presence and progression, should not recapitulate clinical information already available at the bedside, and must provide clinically useful information for caregivers to establish or reject a diagnosis more swiftly and reliably, to estimate prognosis more accurately, or to inform more successful therapeutic strategies. Only the natriuretic peptides have met these requirements, although other promising biomarkers exist for use in HF assessment.

Natriuretic Peptides

The natriuretic peptides are useful biomarkers for HF diagnosis, estimation of HF severity and prognosis, and possibly for management of HF as well. The most frequently measured natriuretic peptides are B-type natriuretic peptide (BNP) and its amino-terminal (N-terminal) cleavage propeptide equivalent, NT-proBNP. These two biomarkers are released from cardiomyocytes in response to stretch, and highly

precise assays exist for their detection in blood (**see Chapter 23**). Given the preponderance of myocardium in the ventricles, BNP and NT-proBNP are held to reflect ventricular stretch and synthesized in response to wall stress. Atrial natriuretic peptide (ANP) is another member of this class and is synthesized and secreted from atrial tissue. A midregional (MR) pro-ANP assay is now available and appears to deliver comparable results to BNP and NT-proBNP in HF,[30] although data remain limited.

Because of the differences in their clearance, BNP and NT-proBNP have considerably different half-lives (BNP: 20 minutes; NT-proBNP: 90 minutes), and thus they circulate with very different concentrations. Both natriuretic peptides have become an important part of the HF assessment; however, as with any diagnostic test, clinicians must always remember the broad array of structural and functional reasons for BNP or NT-proBNP release to interpret these values correctly.[31] Natriuretic peptide levels tend to increase progressively with worsening NYHA functional class and tend to be higher in HFrEF than HFpEF, despite independent contributions of diastolic function to their concentrations. Patients with acute HF more often have higher values for BNP and NT-proBNP than stable patients with chronic HF, although this is not a universal finding. Knowledge of an individual's natriuretic peptide value when stable may be useful to better interpret a change in symptoms when it occurs.

When using BNP or NT-proBNP, the clinician should remember that beyond left ventricular systolic and diastolic dysfunction, concentrations of both peptides are higher in patients with valvular heart disease, pulmonary hypertension, ischemic heart disease, atrial arrhythmias, and even pericardial processes such as constriction.[31] Additionally, numerous relevant medical covariates with effects on natriuretic peptide values must also be kept in mind. For example, both BNP and NT-proBNP concentrations increase with age, thought to identify accumulating structural heart disease in older patients. Both natriuretic peptides are higher in patients with renal failure, partially reflective of slower clearance, but also similarly identifying heart disease in these patients with prevalent cardiovascular risk factors. Elevated natriuretic peptide values can also be seen in hyperdynamic states, including sepsis. Patients who have right ventricular dysfunction as a result of pulmonary embolus may have elevated natriuretic peptide concentrations. It is also important to recognize that angiotensin receptor neprilysin inhibitors (ARNIs; **see Chapter 25**) will lead to elevated levels of BNP but will not affect the circulating levels of NT-proBNP. Obesity is strongly linked to lower-than-expected BNP or NT-proBNP values, despite comparable or higher wall stress in heavier patients. Given the common effect on BNP, NT-proBNP, and MR-proANP, this is not likely to be a clearance effect (because each is cleared differently), but rather more likely to represent suppression of natriuretic peptide gene expression or post-translational modification.

Results of BNP or NT-proBNP, although useful, should always be interpreted in the context of sound clinical judgment and integrated with results of history, physical examination, and other testing. These important biomarkers strongly supplement clinical judgment but should not replace it. Keeping this in mind, the natriuretic peptides have been shown to be quite useful to identify and exclude acutely decompensated HF in the emergency department, as well as more indolent HF in the outpatient setting. Suggested cutoff values for use of natriuretic peptides are shown in **ETable 21.1**.[32]

ETABLE 21.1

Suggested Cutoff Values for Clinical Applications of Natriuretic Peptides

PEPTIDE	CUTOFF VALUE	SENSITIVITY (%)	SPECIFICITY (%)	PPV (%)	NPV (%)
To Exclude Acutely Decompensated Heart Failure					
BNP	<30-50 pg/mL	97	*	*	96
NT-proBNP	<300 pg/mL	99	*	*	99
MR-proANP	<57 pmol/L	98	*	*	97
To Identify Acutely Decompensated Heart Failure					
Single Cut-Point Strategy					
BNP	≥100 pg/mL	90	76	79	89
NT-proBNP	≥900 pg/mL	90	85	76	94
MR-proANP	≥127 pmol/mL	87	79	67	93
Multiple Cut-Point Strategy					
BNP, "gray zone" approach	< 100 pg/mL to exclude	90	73	75	90
	100-400 pg/mL, "gray zone"	*	*	*	8
	>400 pg/mL, to rule in	63	91	86	74
NT-proBNP, "age-stratified" approach	≥450 pg/mL for age <50 yr	90	84	88	66
	≥900 pg/mL for age 50-75 yr				
	≥1800 pg/mL for age >75 yr				
MR-proANP, "age-stratified" approach	≥104 pmol/L for age <65 yr	82	86	75	91
	≥214 pmol/L for age ≥65 yr				
Outpatient Application					
BNP	<20 pg/mL (asymptomatic) or <40 pg/mL (symptomatic)	*	*	*	96
NT-proBNP, "age stratified" approaches	<125 pg/mL for age <75 yr	*	*	*	98
	<450 pg/mL for age ≥75 yr *or*	*	*	*	91
	<50 pg/mL for age <50 yr	*	*	*	98
	<75 pg/mL for age 50-75 yr	*	*	*	98
	<250 pg/mL for age >75 yr	*	*	*	93
MR-proANP	Unknown	Unknown	Unknown	Unknown	

*Not applicable.

PPV, Positive predictive value; *NPV,* negative predictive value.

Pivotal data for BNP and NT-proBNP testing to diagnose acute HF came from the Breathing Not Properly study and the ProBNP Investigation of Dyspnea in the Emergency Department (PRIDE) study, respectively. In the Breathing Not Properly, a BNP concentration of 100 pg/mL was highly accurate for the diagnosis of acutely decompensated HF; in PRIDE an NT-proBNP cutoff value of 900 pg/mL provided comparable performance to a BNP of 100 pg/mL. Subsequently, the International Collaborative of NT-proBNP (ICON) investigators subsequently showed that age stratification improved PPV of NT-proBNP in acutely dyspneic patients. An NT-proBNP concentration less than 300 pg/mL was also useful to exclude acutely decompensated HF.[31]

Knowledge of natriuretic peptide levels in the emergency department (ED) is associated with more rapid diagnosis, lower admission rate, shorter length of hospital stay and reduced cost. As clinical uncertainty in acute dyspnea is associated with worse prognosis, it is reassuring to note that natriuretic peptide testing is particularly useful in this complex situation.

For patients with less acute presentations of dyspnea in settings other than the ED, values of BNP or NT-proBNP are most often considerably lower. When used for evaluation of the dyspneic ambulatory patient, therefore, the optimized cutoff values from ED studies should not be used; lower values are mandatory and optimized for their NPV to exclude (rather than identify) HF[32] (**ETable 21.1**). Age stratification again improves diagnostic accuracy in this setting, because older patients are expected to have generally higher concentrations of BNP or NT-proBNP in the absence of clinical HF. If a patient is found to have values higher than such cutoffs, further diagnostic testing (e.g. echocardiography) is likely

needed. Causes of falsely low BNP or NT-proBNP in the outpatient setting are comparable to those found with acute dyspnea.

Natriuretic peptide levels provide useful prognostic information across all ACC/AHA stages of HF, even when adjusted for important variables from history, physical examination, echocardiography, or even cardiopulmonary exercise testing. One natriuretic peptide measurement is prognostically meaningful, but serial follow-up measurements add incrementally important prognostic information. For example, in patients with acute HF, those who do not show a robust reduction in BNP or NT-proBNP by the time of hospital discharge tend to have considerably higher rates of morbidity and mortality.[33] It has thus been suggested that a BNP or NT-proBNP decrease of 30% or more by hospital discharge is desirable. Similarly, in ambulatory HF patients, chronically elevated or rising natriuretic peptide values identify a particularly high-risk population. HF therapies may lower BNP and NT-proBNP concentrations, and when this finding occurs, prognosis is improved.

Other Biomarkers

Other promising biomarkers for use in patients with HF have been identified, and some are clinically available (see **Table 21.5**). In general, newer biomarkers for HF have been developed to supplement the natriuretic peptides for prognostication. Although most have not yet achieved the prerequisite data to justify their widespread use, a few promising biomarkers bear mention.

Soluble concentrations of *ST2*, a member of the interleukin receptor family, have been shown to be strongly linked to progressive HF and death in patients across the four ACC/AHA stages of HF.[34] Originally identified in a basic science model of mechanotransduction, ST2 plays a pivotal role in the formation of fibrosis in the heart; elevated concentrations of ST2 are thus associated with progressive cardiovascular dysfunction, remodeling, and risk of death. Soluble ST2 concentrations are additive to natriuretic peptides for prognostication, are useful in both HFrEF and HFpEF, and are similarly dynamic to natriuretic peptides in their changes after HF therapies. In patients with both acutely decompensated and chronic heart failure, a chronically elevated or rising ST2 value strongly predicts adverse outcome. Notably, among apparently normal patients in a population-based analysis, ST2 values predicted future HF, beyond other biomarkers such as BNP as well as echocardiographic parameters.[35] This implies that the biochemical changes of ventricular remodeling may be detectable well before conventional biomarkers or imaging are abnormal. Recent data suggest ST2 concentrations also indicate vascular remodeling and may therefore predict future arterial hypertension. Whether this mediates risk for future HF is uncertain.

Galectin 3 is another novel biomarker of tissue fibrosis. It is produced by activated macrophages involved in response to tissue injury and is strongly associated with increased myocardial collagen formation. When measured clinically, elevated galectin 3 values not only predict adverse outcomes in HF patients with both HFrEF and HFpEF, but also predict onset of HF in apparently normal patients, similar to ST2.[34]

The myofibrillar proteins *troponin T and I* are indicators of cardiomyocyte injury and may be elevated in HF patients in the absence of an acute coronary syndrome or even significant coronary artery disease (CAD). With the emergence of highly sensitive troponin assays, even more patients may be found to have elevated concentrations of these important predictors of risk.[36] Although an elevated troponin value does

not specifically identify myocardial necrosis caused by CAD per se, given the importance of AMI in the triggering of acute HF, a troponin should always be measured in this setting, but interpreted with caution. Elevated troponin concentrations in community-based normal individuals are prognostic for onset of HF (particularly if rising in serial measurement). Troponin is independently predictive of increased mortality risk across the HF spectrum.

Other novel biomarkers are emerging and may have a role in the comprehensive evaluation of the patient with HF. Many of these novel markers reflect systemic stress or disarray of organs outside the heart. For example, the midregional fragment of proadrenomedullin is a biomarker reflective of vascular and systemic stress and is powerfully prognostic for short-term adverse outcome[30] (**see Chapter 23**). Similarly, growth differentiation factor-15, another marker of cardiovascular stress, not only strongly predicts outcomes in established HF, but also may be prognostic for new-onset HF in apparently well persons.[35] The C-terminal fragment of provasopressin (also known as copeptin) provides an indirect means by which to measure the biologically unstable parent hormone from which it is derived; values of copeptin are prognostic in HF but are not directly associated with serum sodium values in this setting. Lastly, novel biomarkers of renal dysfunction are emerging as strong predictors of cardiovascular risk beyond the standard measures of BUN and serum creatinine. Cystatin C, a ubiquitous protein found in all nucleated cells whose clearance is directly related to glomerular filtration, and beta trace protein are two renal function markers whose values are tightly related to outcomes in HF. Neutrophil gelatinase-associated lipocalin, *N*-acetyl-β-D-glucosaminidase, and kidney injury molecule-1 are promising biomarkers of acute renal injury whose values rise well before renal function is perceived to be worsening and impart important prognostic information in HF patients.[37]

Ultimately, for the comprehensive evaluation of HF, it seems likely that a combination or panel of biomarkers will prove to be the most useful way of assessing prognosis.

Risk Scoring for Prognosis

During initial and subsequent evaluation of the patient with HF, the clinician should routinely assess the potential for adverse outcome. Besides biomarker testing, a number of validated methods for risk stratification in HF exist, including a variety of multivariable clinical risk scores for use in both ambulatory and hospitalized patients. One well-validated risk score, the Seattle Heart Failure model, is available in an Internet-based application (www.seattleheartfailuremodel.org) and has been shown to provide robust information regarding risk of mortality in ambulatory HF patients.[38] For patients hospitalized with acute symptoms, the model developed by the Acute Decompensated Heart Failure National Registry (ADHERE) incorporates three routinely measured variables on hospital admission (systolic blood pressure, BUN, and serum creatinine) and partitions patients into categories with a 10-fold difference in risk (2.1% to 21.9%).[38] Importantly, clinical risk scores have not performed as well in estimating risk of hospital readmission. For this purpose, biomarkers may be of more use before discharge, particularly when measured after treatment.

Right-Heart Catheterization

Measurement of intracardiac pressures and hemodynamics as part of the diagnostic workup or for guiding therapy is less frequently performed now than in the past, since biomarkers and noninvasive imaging

techniques provide much of the information that was previously available only by heart catheterization. Nonetheless, right-heart catheterization affords unequivocal assessment of hemodynamics and filling pressures, so it is particularly useful when uncertainty exists about the cause of a patient's symptoms and in situations where precise measurements are required to guide therapy or decision making (e.g., selection of patients for heart transplantation). Right-heart catheterization also is of value (and should be considered) in those with HF complicated by clinically significant hypotension, systemic hypoperfusion, dependence on inotropic infusions, or persistently severe symptoms despite adjustment of recommended therapies (**see Chapter 19**).

An invasive assessment with right-heart catheterization is important to assess the pulmonary vascular resistance, a necessary part of the evaluation for heart transplantation. When pulmonary artery pressures are found to be elevated, response to pulmonary arterial vasodilators can be determined in this context and provides important information on whether a patient with pulmonary hypertension will be acceptable for cardiac transplantation. Also, the pulmonary artery wedge pressure is useful for assessing volume status and usually estimates the left ventricular end-diastolic pressure if no obstruction to flow between the left atrium and left ventricle exists. Although determination of hemodynamic variables at rest suffices in most patients, exercise helps to reveal the presence or magnitude of abnormal intracardiac pressures and flow in some patients. Pulmonary hypertension, for example, can be highly dynamic, and exercise measurements may be needed.

Use of hemodynamic monitoring to guide therapy was evaluated in patients with advanced HF in the Evaluation Study of Congestive Heart Failure and Pulmonary Artery Catheterization Effectiveness (ESCAPE) trial.[39] The results showed no clear benefit on morbidity or mortality of pulmonary artery–guided management compared to careful clinical assessment. The failure to affect postdischarge outcomes appears to be related to the hemodynamic improvements affected during hospitalization reverting toward baseline within a relatively short time. Consequently, “tailored therapy” of HF is used less often now than in the past, although it has a role particularly in patients with HF complicated by hypotension, systemic hypoperfusion, or end-organ dysfunction.

Endomyocardial Biopsy

The role of endomyocardial biopsy for evaluating patients with HF is discussed in **Chapter 79**. In general, biopsy of the myocardium is performed if a disorder with a unique prognosis is suspected, or if the patient might benefit from a specific treatment regimen, and the diagnosis cannot be made by conventional methods. The incremental diagnostic, therapeutic, and prognostic benefit offered by the information obtained from a biopsy must be weighed against the risks of the procedure. The sensitivity of endomyocardial biopsy may vary, depending on the cause of HF; for example, sensitivity is higher in more diffuse disease states such as myocarditis or amyloidosis, whereas more patchy disease states such as sarcoidosis may be less easily detected using biopsy.

Detection of Comorbid Conditions

The incidence of HF rises sharply from the sixth decade on, coincident with the ages when other chronic diseases begin to manifest. In addition, many of the conditions leading to the development of HF (e.g.,

diabetes, hypertension, atherosclerosis) affect organs other than the heart. Thus, comorbidities are quite common in HF patients and have a profound effect on the course; in fact, a substantial percentage of hospitalizations in patients with HF are non-HF related and are not precipitated by a cardiac condition in more than half of cases.[40] Comorbidities not only complicate the course of patients with concomitant HF, but also have a substantial impact on ability to manage patients with HF; for example, chronic kidney disease may limit application of agents blocking the renin-angiotensin-aldosterone system. In addition, the presence of comorbidities reduces the prognostic benefits of guideline-directed medical therapy; for example, atrial fibrillation reduces the benefit of many therapies, including beta blockers and CRT. With recent data suggesting that both aggressive management of hypertension and use of sodium-glucose cotransporter-2 inhibitors for diabetes mellitus care may reduce HF events,[41,42] detection and management of comorbidities is a particularly relevant exercise.

Assessment of Quality of Life

Heart failure has a profound effect on quality of life, and poor health-related quality of life is a powerful predictor of adverse prognosis in HF patients. Determinants of poor quality of life in HF include female sex, younger age, higher body mass index, worse symptoms, and the presence of depression and sleep apnea.[43] Improved quality of life has been reported after CRT or in disease management programs with aggressive care. Given its importance, at the initial and subsequent visits, consideration should be given for quality-of-life assessment, whether through standard history or through the use of validated tools for its estimation, such as the Kansas City Cardiomyopathy Questionnaire or Minnesota Living with Heart Failure Questionnaire.

Cardiopulmonary Exercise Testing

Exercise intolerance is a prime symptom of HF (**see Chapter 13**). Despite this fact, quantification of exercise tolerance is imprecise; standard approaches such as the NYHA criteria or the 6-minute walk test are subjective and insensitive measures of functional capacity. Additionally, the 6-minute walk test does not reveal how close the patient may be to her or his maximal capacity for exercise, does not discriminate between the causes of impaired exercise capacity (e.g., cardiac, pulmonary, orthopedic) or poor motivation, and does not account for the effects of conditioning and age; older age may undermine accuracy of the 6-minute walk test. When more precise information is needed, cardiopulmonary exercise testing (CPX) is often used because it allows for identification of causes of exercise intolerance, quantification of exercise capacity, and delivery of important physiologic information not routinely available from standard stress testing.[44] Use of CPX is a standard part of the routine evaluation before heart transplantation; moderate to severely reduced maximal oxygen uptake (V_{O_2}) values (e.g., <14 mL $O_2 \cdot kg^{-1} \cdot min^{-1}$) are often used as a prognostic threshold in this setting, whereas maximal V_{O_2} values less than 10 mL $O_2 \cdot kg^{-1} \cdot min^{-1}$ are considered severe and particularly prognostic when the V_E/V_{CO_2} slope is 45.0 or greater.

Imaging Modalities

Noninvasive cardiac imaging serves a vital role in the assessment of patients with HF and is essential for

determining whether the patient should be classified as HFpEF or HFrEF. Imaging may help confirm the diagnosis of HF by assessing the presence and severity of structural and functional changes in the heart, provide clues about the etiology of cardiac dysfunction (congenital heart disease, valvular abnormalities, pericardial disease, coronary artery disease), risk-stratify patients, and possibly guide treatment strategies. Imaging modalities can also be used to help assess the efficacy of therapeutic interventions, provide ongoing prognostic information, and further guide treatment.

The primary noninvasive cardiac imaging modalities used to evaluate HF patients are echocardiography (**Chapter 14**), magnetic resonance imaging (MRI; **Chapter 17**), computed tomography (CT; **Chapter 18**), and nuclear imaging, including single-photon emission computed tomography (SPECT) and positron emission tomography (PET) techniques (**Chapter 16**). Imaging modalities often provide complementary data, and each has the capacity to provide unique information in individual patients. Although the initial evaluation of a patient with newly diagnosed HF should include a transthoracic echocardiogram, further imaging with MRI, CT, and/or nuclear techniques may be considered depending on the need to further address questions regarding cardiac structure and function, etiology, and issues such as the potential for reversibility of systolic dysfunction with revascularization. The specific indications and advantages for each of these imaging modalities are summarized in **EFig. 21.1** and **ETable 21.2**.

The Task Force for the Diagnosis and Treatment of Acute and Chronic Heart Failure 2012 of the European Society of Cardiology (ECS). Developed in collaboration with the Heart Failure Association (HFA) of the ESC, Eur J Heart Fail 2012;14:803.

Echocardiography and Lung Ultrasound

Transthoracic echocardiography is an important part of the evaluation of HF,[45] can be performed without risk to the patient and at the bedside if necessary, and does not involve radiation exposure. Increasing use of handheld echocardiography has facilitated evaluation at the point of care, such as in the ED with an acute presentation.

Echocardiography is particularly well suited for evaluating the structure and function of both the myocardium and the heart valves and providing information about intracardiac pressure and flow. For patients with HFrEF, left ventricular (LV) volumes and systolic function can be assessed semiquantitatively or can be quantified using the biplane method and the modified Simpson's rule. Information about the morphology and relative sizes of the cardiac chambers may suggest specific diagnoses. For example, concentric LV hypertrophy with severe biatrial enlargement suggests that HF is caused by an infiltrative process such as amyloidosis, particularly in the absence of a prior diagnosis of hypertension. Diastolic function is assessed using Doppler measurements, including analyses of the mitral valve inflow pattern (early [E] and atrial [A] waveforms), tissue velocities at the mitral valve annulus, pulmonary vein flow, and the left atrial volume indexed to body surface area (**see Chapter 14**). Diastolic dysfunction can be further classified as grades I to III based on these measurements, with incremental prognostic importance in HF as worsening grades of diastolic dysfunction are noted. Ratio of early mitral valve inflow to mitral valve annulus velocity determined using tissue Doppler (E/e′) is particularly helpful to determine presence and severity of diastolic dysfunction; a ratio of 15 or greater is abnormal. Pulmonary hypertension in patients without significant systolic dysfunction or pulmonary disease suggests that diastolic dysfunction may be present. Another advantage of echocardiography is the ability to estimate right-sided heart pressures noninvasively. For example, right atrial (RA) pressures are estimated by the inferior vena cava (IVC) diameter and the relative change in diameter on inspiration. Normal IVC diameter and inspiratory collapse of at least 50% are associated with normal RA pressures, whereas increased IVC diameter and smaller inspiratory changes indicate elevated RA pressure.

Lung ultrasound (LUS) has become increasingly used to evaluate patients presenting to the ED. LUS has been found to be useful to diagnose interstitial pulmonary edema and fluid overload through the detection of vertical reverberation artifacts, known as Kerley B lines, created at the acoustic interface between two structures with differing acoustic impedances, such as fluid-filled structures and alveolar air. Also known as “comets” in the appropriate setting, Kerley B lines may be highly sensitive and specific for presence of HF, particularly when incorporated with clinical judgment and other tools, such as chest radiography and natriuretic peptide testing.

Magnetic Resonance Imaging

MRI provides high-quality imaging of the heart and involves no radiation, which is a significant advantage over CT. Diagnostic images can be obtained in almost all patients, and unlike echocardiography, images can be obtained in arbitrary tomographic planes. MRI is excellent for evaluating cardiac morphology, chamber sizes, and cardiac function. Using different pulse sequences with and without gadolinium contrast, MRI can characterize myocardial tissue and assess myocardial viability. Cardiac MRI can distinguish ischemic from nonischemic cardiomyopathies based on the pattern of delayed gadolinium enhancement from T1-weighted images; ischemic cardiomyopathies usually show characteristic subendocardial enhancement at sites of prior infarction, whereas nonischemic dilated cardiomyopathies typically have no enhancement, midwall enhancement, or other patterns, depending on the etiology (**Fig. 21.4**). Additionally, MRI is extremely useful to identify the presence of myocarditis and may be similarly helpful in the diagnosis of specific cardiomyopathies, such as infiltrative processes or LV noncompaction. A major limitation is that the current implantable pacemakers or defibrillators are not safe for the patient to undergo MRI, although this limitation may be overcome with greater use of MRI-compatible devices (**see Chapter 17**).

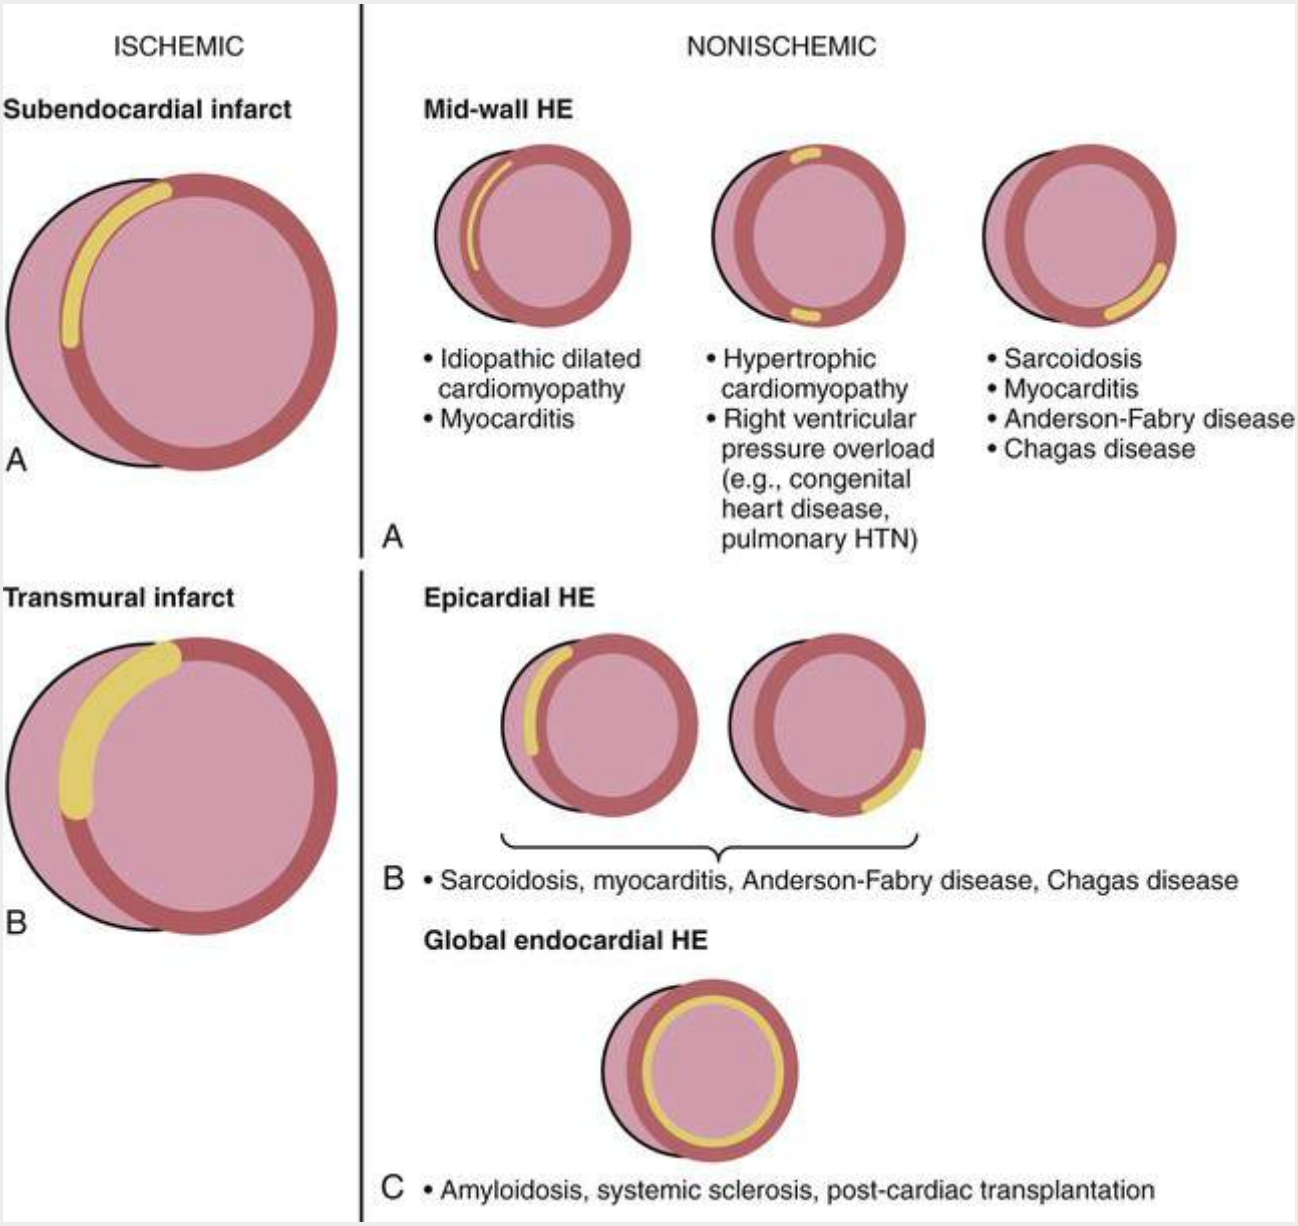

FIGURE 21.4 Patterns of hyperenhancement (*HE*) with MRI in various disease states; *HTN,* hypertension. (Modified from Mahrholdt H, Wagner A, Judd RM, et al. Delayed enhancement cardiovascular magnetic resonance assessment of non-ischaemic cardiomyopathies. Eur Heart J 2005;26:1461.)

Cardiac Computed Tomography

The current role of cardiac CT in HF is mainly to help determine whether or not obstructive CAD is present through the use of CT angiography, an important application particularly for patients with lower likelihood for CAD. Emerging applications of CT angiography may be to assist in assessment of coronary venous anatomy before CRT lead placement. Recent advances in CT technology have led to less radiation exposure, but cardiac CT angiography still involves administering iodinated contrast, a concern in patients at risk for developing nephrotoxicity (**see Chapter 18**).

Nuclear Imaging

A wide array of nuclear imaging techniques have been developed for the assessment of HF. In particular, SPECT and PET technologies are well suited for assessing myocardial ischemia and viability and for evaluating myocardial function. The use of nuclear imaging to determine myocardial viability is discussed in **Chapter 16**. Fluorine-18 fluorodeoxyglucose (^{18}F-FDG) PET scanning may be particularly helpful for diagnosis prognosis, and management of cardiac sarcoidosis[46]; a characteristic heterogeneous uptake pattern in the myocardium may be seen in patients with cardiac sarcoidosis, in contrast to diffuse

uptake seen in dilated cardiomyopathy and normal individuals. After successful treatment with immunosuppressive medication, ^{18}F-FDG uptake may normalize. Technetium-99m pyrophosphate (^{99m}Tc-PYP) scanning shows promise in diagnosing transthyretin (TTR) amyloidosis (**Fig. 21.5**). Although more frequently positive in patients with TTR amyloidosis, ^{99m}Tc-PYP scans can also be positive in patients with AL amyloidosis[47] (**see Chapter 77**). Lastly, cardiac scans using iodine-123 (^{123}I) metaiodobenzylguanidine (MIBG) may provide objective evaluation of cardiac sympathetic function and may predict risk for sudden death from arrhythmia in NYHA Class II or III HFrEF when the heart-to-mediastinum ratio of ^{123}I-MIBG is low[48] (**EFig. 21.2**).[48]

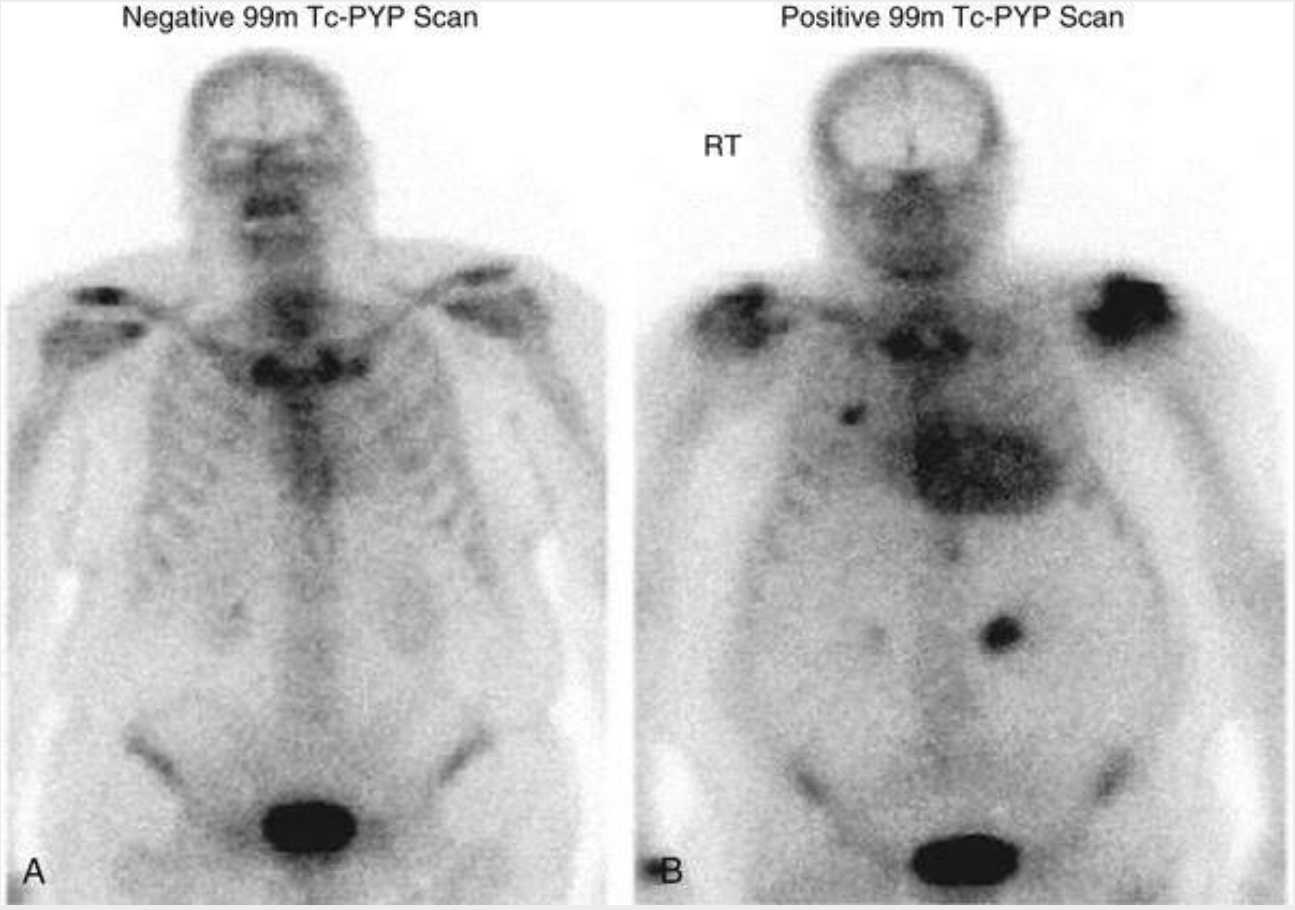

FIGURE 21.5 Technetium 99m pyrophosphate imaging in two patients with heart failure with preserved ejection fraction for diagnosis of transthyretin (TTR) amyloidosis. Compared to the control patient on the left **(A),** the patient on the right has radiotracer (*RT*) uptake **(B),** consistent with a diagnosis of TTR amyloidosis

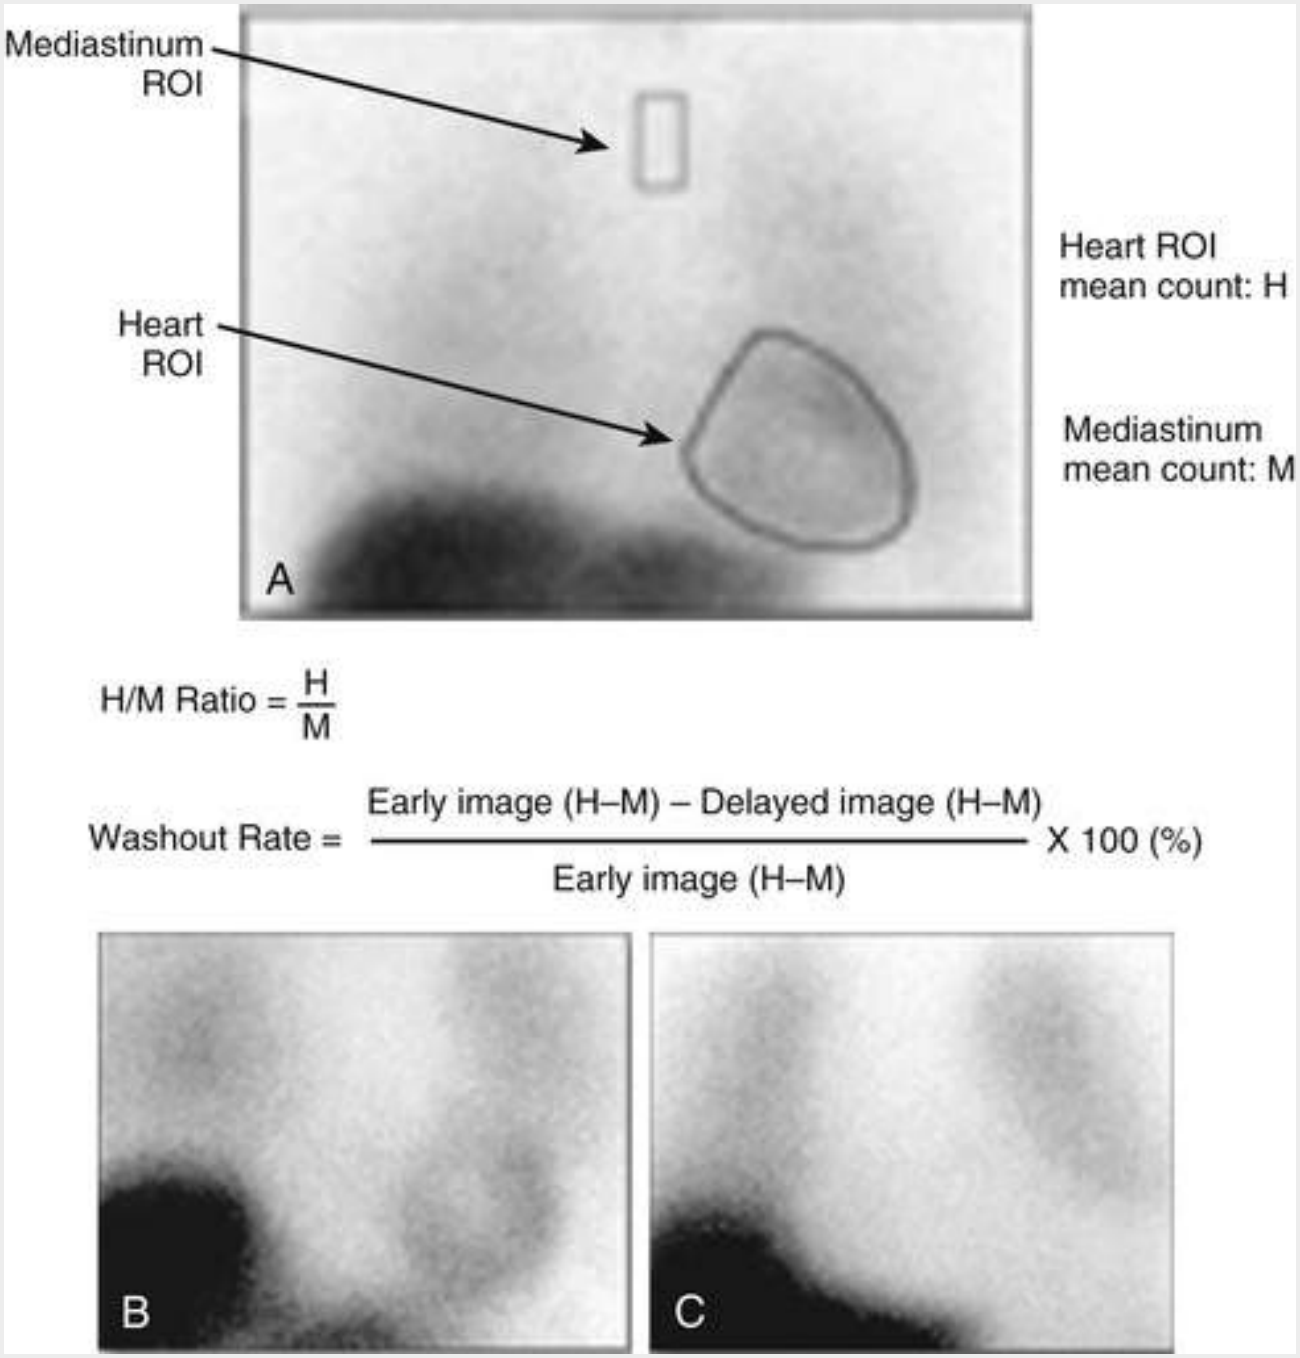

EFIGURE 21.2 Metaiodobenzylguanidine (MIBG) imaging to determine the severity of heart failure. **A,** Calculation the MIBG heart (*H*)/mediastinum (*M*) ratio and washout rate on an anterior view of the thorax. (From Carrio I, Cowie MR, Yamazaki J, et al. Cardiac sympathetic imaging with mIBG in heart failure. JACC Cardiovasc Imaging 2010;3:92.)

Future Perspectives

As treatment options for heart failure continue to evolve, there will be increased emphasis on more rapid, accurate, and cost-effective assessment of patients, with the goal of providing unambiguous information about the presence, severity, and cause of HF. New insights into the biology of cardiac dysfunction are likely to lead to the development of therapeutic approaches that are specific to the underlying etiology. Continued advances in the use of biomarkers and imaging techniques to diagnose, stage, and determine etiology of HF will be needed to meet these future demands. Even as these diagnostic modalities increase in their precision and accuracy, the information obtained through the history and physical examination will

remain at the core of our ability to understand how to employ these tests most judiciously and to treat patients most effectively.

Guidelines

Initial Evaluation of the Patient with Heart Failure

James L. Januzzi Jr and Douglas L. Mann

A joint task force of the American College of Cardiology and the American Heart Association (ACC/AHA) published updated comprehensive guidelines for the evaluation and management of heart failure (HF) in 2013.[1] These were updated in two sequential "focused" guidelines in 2016[2] and 2017[3] that provided several recommendations regarding new medical therapies for HF with reduced ejection fraction (HFrEF), but did not provide new guidelines for devices for monitoring or treating HF. Beginning in 2016 and for all subsequent guidelines thereafter, the Heart Failure Society of America (HFSA) has partnered with the ACC and the AHA to provide coordinated recommendations about HF guidelines. The European Society of Cardiology (ESC) guidelines for the diagnosis and treatment of chronic HF were published 2016,[4] which superseded previous complete guidelines in 2012.[5] Guidelines for the initial evaluation of the patient with HF are reviewed in this chapter; guidelines for the management of the hospitalized patient are reviewed in **Chapter 24**, for patients with a reduced ejection fraction in **Chapter 25**, for heart failure with a preserved ejection fraction in **Chapter 26**, and for the use of devices for managing heart failure in **Chapter 27**.

As discussed in **Chapters 21 and 25**, the ACC/AHA guidelines classify patients according to the following four stages:

Stage A: patients at high risk for developing heart failure but without structural disorders of the heart
Stage B: patients with a structural disorder of the heart but no symptoms of heart failure
Stage C: patients with past or current symptoms of heart failure associated with underlying structural heart disease
Stage D: patients with end-stage disease who require specialized treatment strategies such as mechanical circulatory support, continuous inotropic infusions, cardiac transplantation, or hospice care

The guidelines are organized into recommendations for each stage. As with other ACC/AHA guidelines, these recommendations classify interventions into one of three classes of recommendation (COR), including two levels for the class II (intermediate) group and two levels for the class III (no benefit or harm) group:

Class I (Strong): Procedure/Treatment/Diagnostic Testing **is recommended/indicated** (Benefit > Risk)
Class IIa (Moderate): Procedure/Treatment/Diagnostic Testing **is reasonable/can be useful** (Benefit Risk)
Class IIb (Weak): Procedure/Treatment/Diagnostic Testing **might be reasonable/considered** (Benefit ≥ Risk)

Class III: No Benefit (Moderate): Treatment/Diagnostic Testing **is not recommended/indicated/useful** (Benefit = Risk) *or*
Class III: Harm (Strong): Treatment/Diagnostic Testing **is potentially harmful/causes harm/is associated with excess morbidity/mortality/ should not be performed** (Risk > Benefit)

The ACC/AHA/HFSA guidelines also adopt a convention for rating levels of evidence on which recommendations have been based, as follows:

Level A recommendations are derived from data from multiple populations with data from multiple randomized clinical trials and/or meta-analyses.
Level B recommendations are derived from data from limited populations with data from a single randomized clinical trial or nonrandomized studies
B-R = moderate-quality evidence from one or more randomized clinical trials
B-NR = moderate-quality evidence from one or more nonrandomized clinical trials
Level C recommendations are based on very limited populations or the consensus opinion of experts or case studies or standard of care
C-LD = randomized or nonrandomized observational/registry studies or a meta-analysis
C-EO = consensus of expert opinion

The term *guideline-directed medical therapy* (GDMT) represents optimal medical therapy as defined by the ACC/AHA guideline–recommended therapies (primarily class I).

Initial Patient Evaluation

The ACC/AHA guidelines state that a complete history and physical examination should be the first step in the evaluation of patients with HF (**Table 21G.1**). This evaluation may provide insight into the cause of the patient's HF and the presence or absence of structural cardiovascular abnormalities. Other issues to be addressed include presence or absence of history of diabetes, rheumatic fever, chest radiation, exposure to cardiotoxic drugs, and use or abuse of alcohol, illicit drugs, or alternative therapies. The patient's functional and volume status should also be evaluated to assess prognosis and guide management. New recommendations include a three-generational family history for patients with dilated cardiomyopathy (DCM) and the use of validated multivariable risk models for assessing subsequent mortality risk.

TABLE 21G.1

ACC/AHA Guidelines for Initial and Serial Evaluation of Heart Failure

CLASS	INDICATION: HISTORY, PHYSICAL EXAMINATION, AND RISK SCORING	LEVEL OF EVIDENCE
I	A thorough history and physical examination should be obtained/performed in patients presenting with HF to identify cardiac and noncardiac disorders or behaviors that might cause or accelerate the development or progression of HF.	C
	In patients with idiopathic DCM, a three-generational family history should be obtained to aid in establishing the diagnosis of familial DCM.	C
	Volume status and vital signs should be assessed at each patient encounter. This includes serial assessment of weight, as well as estimates of jugular venous pressure and the presence of peripheral edema or orthopnea.	B
IIa	Validated multivariable risk scores can be useful to estimate subsequent risk of mortality in ambulatory or hospitalized patients with HF.	C
INDICATION: DIAGNOSTIC TESTS AND BIOMARKERS (ALSO SEE BELOW)		
I	Initial laboratory evaluation of patients presenting with HF should include complete blood count, urinalysis, serum electrolytes (including calcium and magnesium), blood urea nitrogen, serum creatinine, glucose, fasting lipid profile, liver function tests, and thyroid-stimulating hormone.	C
	Serial monitoring, when indicated, should include serum electrolytes and renal function.	C
	A 12-lead ECG should be performed initially on all patients presenting with HF.	C
	In ambulatory patients with dyspnea, measurement of BNP or N-terminal pro-B-type natriuretic (NT-proBNP) is useful to support clinical decision making regarding the diagnosis of HF, especially in the setting of clinical uncertainty, and measurement of BNP or NT-proBNP is useful for establishing prognosis or disease severity in chronic HF.	A
IIa	Screening for hemochromatosis or HIV is reasonable in select patients who present with HF.	C
	Diagnostic tests for rheumatologic diseases, amyloidosis, or pheochromocytoma are reasonable in patients presenting with HF in whom there is a clinical suspicion of these diseases.	C
	BNP-guided or NT-proBNP–guided HF therapy can be useful to achieve optimal dosing of GDMT in select, clinically euvolemic patients followed in a well-structured HF disease management program.	B
IIb	The usefulness of serial measurement of BNP or NT-proBNP to reduce hospitalization or mortality in patients with HF is not well established. The measurement of other clinically available tests, such as biomarkers of myocardial injury or "fibrosis," may be considered for additive risk stratification in patients with chronic HF.	B
INDICATION: NONINVASIVE CARDIAC IMAGING		
I	Patients with suspected or new-onset HF, or those presenting with acute decompensated HF, should undergo a chest radiograph to assess heart size and pulmonary congestion and to detect alternative cardiac, pulmonary, and other diseases that may cause or contribute to the patient's symptoms.	C
	A two-dimensional echocardiogram with Doppler should be performed during initial evaluation of patients presenting with HF to assess ventricular function, size, wall thickness, wall motion, and valve function.	C
	Repeat measurement of EF and measurement of the severity of structural remodeling are useful to provide information in patients with HF who have had a significant change in clinical status; who have experienced or recovered from a clinical event; who have received treatment, including GDMT, that might have had a significant effect on cardiac function; or who may be candidates for device therapy.	C
IIa	Noninvasive imaging to detect myocardial ischemia and viability is reasonable in patients presenting with de novo HF who have known CAD and no angina, unless the patient is not eligible for revascularization of any kind.	C
	Viability assessment is reasonable in select situations when planning revascularization in HF patients with CAD.	B
	Radionuclide ventriculography or MRI can be useful to assess LVEF and volume when echocardiography is inadequate.	C
	MRI is reasonable when assessing myocardial infiltrative processes or scar burden.	B
III: no benefit	Routine repeat measurement of LV function assessment in the absence of clinical status change or treatment interventions should not be performed.	B
INDICATION: INVASIVE EVALUATION		
I	Invasive hemodynamic monitoring with a pulmonary artery catheter should be performed to guide therapy in patients who have respiratory distress or clinical evidence of impaired perfusion in whom the adequacy or excess of intracardiac filling pressures cannot be determined from clinical assessment.	C
IIa	Invasive hemodynamic monitoring can be useful for carefully selected patients with acute HF who have persistent symptoms despite empiric adjustment of standard therapies and (a) whose fluid status, perfusion, or systemic or pulmonary vascular resistance is uncertain; (b) whose systolic pressure remains low, or is associated with symptoms, despite initial therapy; (c) whose renal function is worsening with therapy; (d) who require parenteral vasoactive agents; or (e) who may need consideration for mechanical circulatory support or transplantation.	C
	When ischemia may be contributing to HF, coronary arteriography is reasonable for patients eligible for revascularization.	C
	Endomyocardial biopsy can be useful in patients presenting with HF when a specific diagnosis is suspected that would influence therapy.	C
III: no benefit	Routine use of invasive hemodynamic monitoring is not recommended in normotensive patients with acute decompensated HF and congestion with symptomatic response to diuretics and vasodilators.	B
III: harm	Endomyocardial biopsy should not be performed in the routine evaluation of patients with HF.	C

ACC, American College of Cardiology; *AHA,* American Heart Association; *BNP,* B-type natriuretic peptide; *CAD,* coronary artery disease; *DCM,* dilated cardiomyopathy, *EF,* ejection fraction; *GDMT,* guideline-directed medical therapy; *HIV,* human immunodeficiency virus; *LVEF,* left ventricular ejection fraction; *MRI,* magnetic resonance imaging.

The guidelines recommend that the initial evaluation should include a complete blood count, urinalysis, serum electrolytes (including calcium and magnesium), blood urea nitrogen, serum creatinine, glucose, fasting lipid profile, liver function tests, and thyroid-stimulating hormone, and that serial monitoring of electrolytes should be performed when indicated. The guidelines also recommend a chest radiograph and a 12-lead electrocardiogram; two-dimensional echocardiography with Doppler to assess left ventricular function and detect underlying myocardial, valvular, or pericardial disease was considered a more valuable initial test than radionuclide ventriculography or magnetic resonance imaging. Screening tests for hemochromatosis, amyloidosis, the human immunodeficiency virus, sleep-disturbed breathing, connective tissue diseases, amyloidosis, or pheochromocytoma are also reasonable in select patients.

Screening for and assessment of coronary artery disease in HF patients are given less weight in the 2013 ACC/AHA guidelines than in previous guidelines. When ischemia may be contributing to HF, the guidelines indicate that coronary arteriography is reasonable for patients eligible for revascularization (class IIa, level of evidence C). The guidelines also support noninvasive imaging to detect myocardial ischemia and viability in patients presenting with de novo HF who have known CAD and no angina, unless the patient is not eligible for revascularization of any kind, as well as viability testing in select patients when planning revascularization (class IIa, level of evidence B or C). Although the guidelines support the use of endomyocardial in patients presenting with HF when a diagnosis that would influence therapy is suspected (class IIb, level of evidence C), the routine use of endomyocardial biopsy is not recommended (class III: harm). The guidelines do not support serial measurement of left ventricular function in the absence of change in clinical status. The updated ACC/AHA guidelines now give a class I (level of evidence C) recommendation the use of invasive hemodynamic monitoring with a pulmonary artery catheter to guide therapy in patients who have respiratory distress or clinical evidence of impaired perfusion in whom the adequacy or excess of intracardiac filling pressures cannot be determined from clinical assessment (**see Chapter 24** guidelines).

Indications for the Use of Biomarkers

The updated ACC/AHA/HFSA and ESC guidelines reflect recent research on biomarkers, including B-type natriuretic peptide (BNP) and N-terminal proBNP (NT-proBNP)[3,4] (**Fig. 21G.1** and **Table 21G.2**). Clinical assays for natriuretic peptide biomarkers, including BNP and NT-proBNP, have been used reliably to establish the diagnosis and prognosis of HF. In general, both natriuretic peptide biomarker values track in a similar fashion, and either can be used in patient care settings, with the understanding that their respective absolute values and cutoffs are different and cannot be used interchangeably. Importantly, the type of natriuretic peptide assay performed must be considered during interpretation of natriuretic peptide biomarker levels in patients receiving angiotensin receptor neprilysin inhibitors (ARNIs; **see Chapter 25**). Use of ARNIs will lead to elevated levels of BNP but will not falsely affect the circulating levels of NT-proBNP. Indeed, in clinical studies with ARNIs, NT-proBNP levels were reduced, and in one analysis, reduction in NT-proBNP levels was associated with improved clinical outcomes.

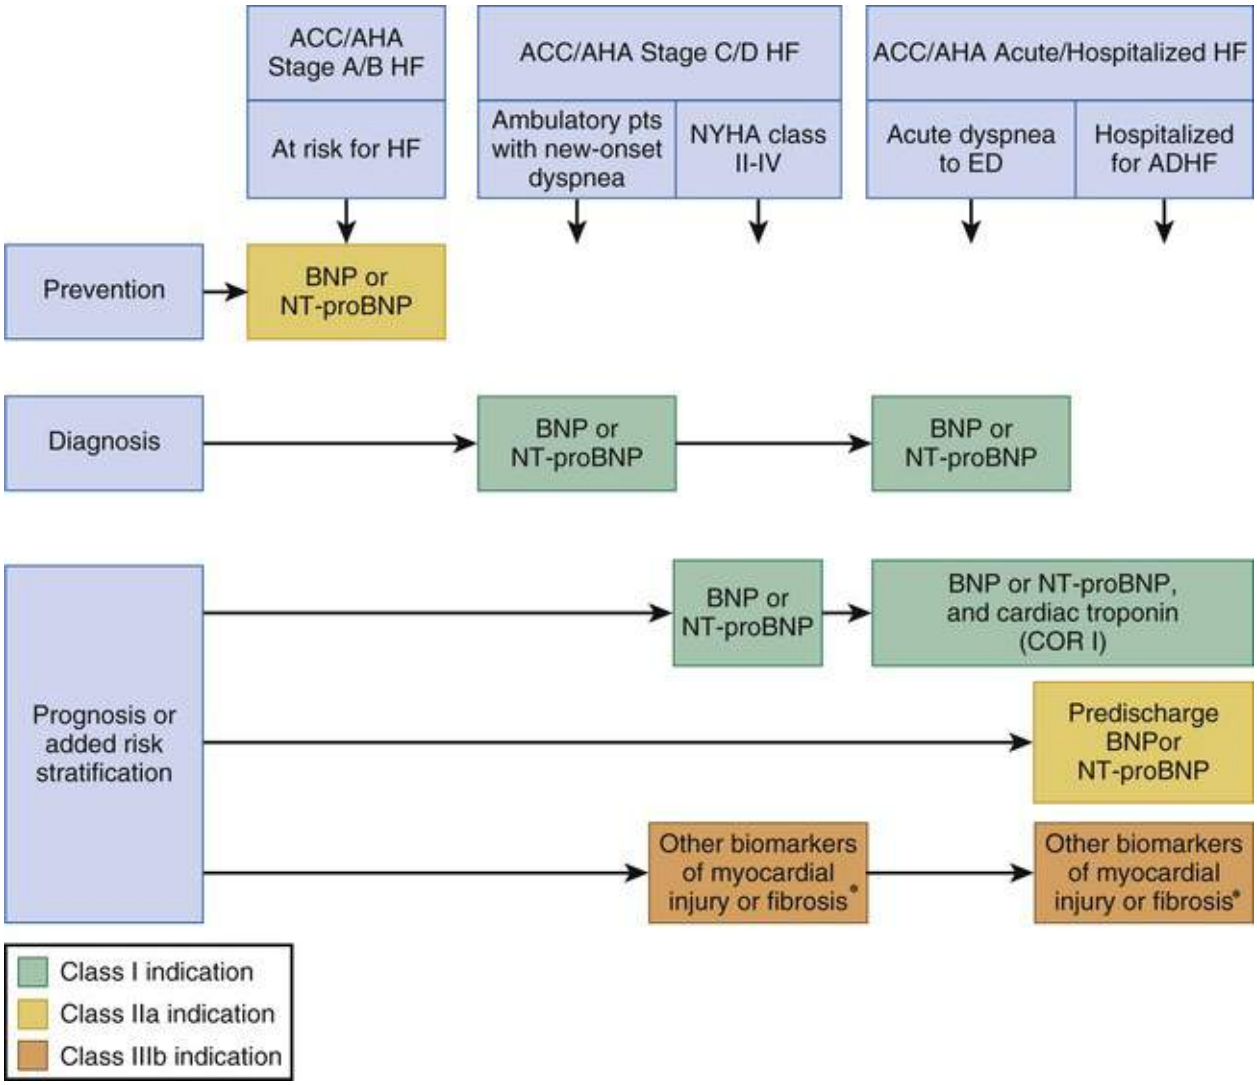

FIGURE 21G.1 Indications for the use of biomarkers in heart failure. *Other biomarkers of injury or fibrosis include soluble ST2 receptor, galectin-3, and high-sensitivity troponin. *ACC,* American College of Cardiology; *AHA,* American Heart Association; *ADHF,* acute decompensated heart failure; *BNP,* B-type natriuretic peptide; *COR,* class of recommendation; *ED,* emergency department; *HF,* heart failure; *NT-proBNP,* N-terminal pro-B-type natriuretic peptide; *NYHA,* New York Heart Association; *pts,* patients.
(Modified from Yancy CW, Jessup M, Bozkurt B, et al. 2017 ACC/AHA/HFSA focused update of the 2013 ACCF/AHA guideline for the management of heart failure: a report of the American College of Cardiology/American Heart Association Task Force on Clinical Practice Guidelines and the Heart Failure Society of America. Circulation. J Am Coll Cardiol 2017;70(6):776.

TABLE 21G.2

ACC/AHA/HFSA Guidelines for Use of Biomarkers in Heart Failure

CLASS	BIOMARKERS FOR PREVENTION OF HF	LEVEL OF EVIDENCE
IIa	For patients at risk of developing HF, natriuretic peptide biomarker–based screening can be useful to prevent the development of left ventricular dysfunction (systolic or diastolic) or new-onset HF.	B-R
BIOMARKERS FOR DIAGNOSIS		
I	In patients presenting with dyspnea (acute or chronic), measurement of natriuretic peptide biomarkers is useful to support a diagnosis or exclusion of HF.	A
BIOMARKERS FOR PROGNOSIS OR ADDED RISK STRATIFICATION		
I	Measurement of BNP or NT-proBNP is useful for establishing prognosis or disease severity in chronic HF.	A
I	Measurement of baseline levels of natriuretic peptide biomarkers and/or cardiac troponin on admission to the hospital is useful to establish a prognosis in acutely decompensated HF.	A
IIa	During a HF hospitalization, a predischarge natriuretic peptide level can be useful to establish a postdischarge prognosis.	B-NR
IIb	In patients with chronic HF, measurement of other clinically available tests, such as biomarkers of myocardial injury or fibrosis, may be considered for additive risk stratification.	B-NR

The 2017 ACC/AHA guidelines give a class I (level of evidence A) recommendation for the use of

BNP or NT-proBNP to evaluate patients with acute and chronic dyspnea, and a class I (level of evidence A) recommendation for the use of BNP or NT-proBNP for establishing prognosis or disease severity in acute or chronic HF. In addition, the guidelines recognized the additive prognostic value of a predischarge measurement of BNP or NT-proBNP for patients with acute HF with a class II (level of evidence A) recommendation. Other biomarkers may be useful for prognosticating HF, including troponin (class I) and "fibrosis" markers such as soluble ST2 (class IIb). Lastly, based on the results of the STOP-HF trial (**see Chapter 25**),[6] the updated guidelines give a class IIa recommendation (level of evidence B-R) for the use of natriuretic peptide–based screening in conjunction with team-based care to optimize GDMT to prevent the development of systolic and diastolic dysfunction or new-onset HF.

Mechanisms of Cardiac Contraction and Relaxation

Donald M. Bers, Barry A. Borlaug

Microanatomy of Contractile Cells and Proteins

Ultrastructure of Contractile Cells

The major function of cardiac muscle cells (*cardiomyocytes* or *myocytes*) is to execute cardiac excitation-contraction-relaxation that depends on the electrical calcium ion (Ca^{2+}) transport and contractile properties.[1,2] Cardiomyocytes constitute approximately 75% of total ventricular volume and weight, but only one third of the total number of cells there.[1-4] Approximately half of each ventricular myocyte is occupied by myofibrils of the myofibers and 30% by mitochondria (**Fig. 22.1 and Table 22.1**). A *myofiber* is a group of cardiomyocytes held together by surrounding collagen connective tissue, the latter being a major component of the extracellular matrix. Further strands of collagen connect myofibers to each other.

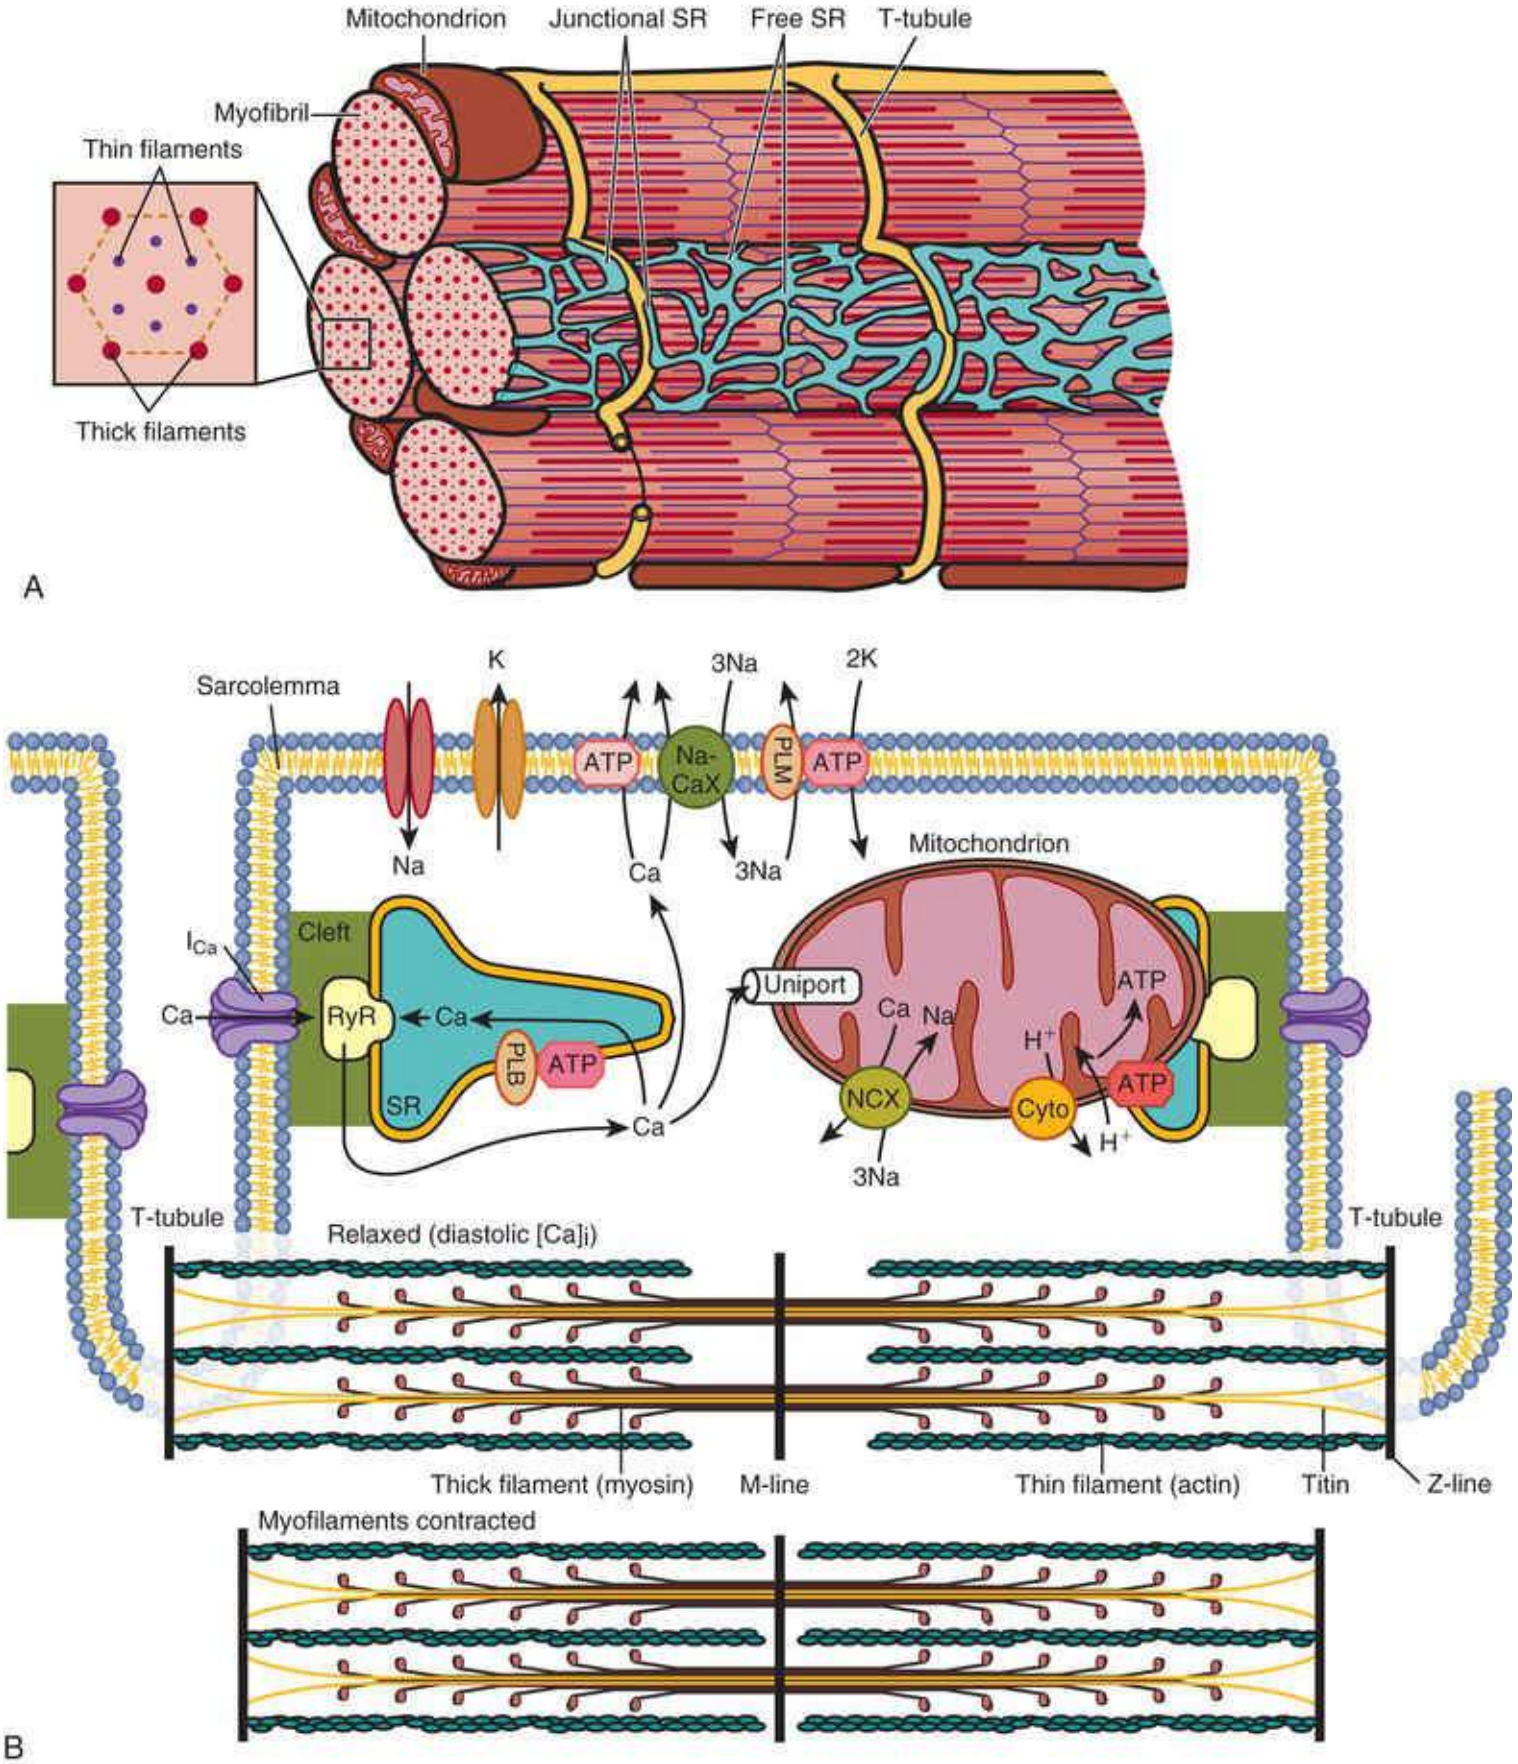

FIGURE 22.1 Ultrastructural components of excitation-contraction coupling in ventricular myocytes, viewed anatomically (**A,** with *inset* showing an end-on view of thick and thin filament organization) and schematically **(B).** The action potential is conducted along the surface sarcolemma and sarcolemma that extends into the T tubules. Ca^{2+} current (I_{Ca}) at sites of junctional SR clefts trigger local Ca^{2+} release, and the Ca^{2+} diffuses throughout the cytosol to activate myofilament contraction. The $[Ca^{2+}]_i$ quickly declines at each beat because of Ca^{2+} uptake via the SR Ca^{2+}-ATPase (ATP/PLB), extrusion via sarcolemmal Na^+/Ca^{2+} exchange (NCX) and Ca^{2+}-ATPase (and mitochondrial Ca^{2+} uniport), allowing relaxation (diastole) to proceed. The myofibrils are bundles of contractile proteins that are organized into a regular

sarcomeric array, bounded longitudinally by Z-lines that are immediately adjacent to T tubules that run in parallel. In diastole (*bottom*) the thin filaments (containing mainly actin) create a cage around the thick filaments (containing mainly myosin) that have cross-bridges (myosin heads) that extend toward the thin filament. Myosin molecule tails all face the center of the sarcomere, creating a zone around the M-line devoid of myosin heads. During systole, the myosin cross-bridges pull the thin filament "cage" toward the M-line, thus shortening the sarcomere length (additional details are in subsequent figures). (**A,** Redrawn, based on a classic sketch by Fawcett and McNutt [J Cell Biol 1969;42:1-45].)

TABLE 22.1

Characteristics of Cardiac Cells, Organelles, and Contractile Proteins

MICROANATOMY OF HEART CELLS			
	Ventricular Myocyte	**Atrial Myocyte**	**Purkinje Cells**
Shape	Long and narrow	Elliptical	Long and broad
Length (μm)	75-170	20-100	150-200
Diameter (μm)	15-30	5-6	35-40
Volume (μm^3)	15,000-100,000	400-1500	135,000-250,000
T tubules	Plentiful	Rare or none	Absent
Intercalated disc	Prominent end-to-end transmission	Side-to-side as well as end-to-end transmission	Very prominent abundant gap junctions Fast; end-to-end transmission
General appearance	Mitochondria and sarcomeres very abundant Rectangular branching bundles with little interstitial collagen	Bundles of atrial tissue separated by wide areas of collagen	Fewer sarcomeres, paler

COMPOSITION AND FUNCTION OF VENTRICULAR CELL		
Organelle	**Percentage of Cell Volume**	**Function**
Myofibril	≈50-60	Interaction of thick and thin filaments during contraction cycle
Mitochondria	16 in neonate 33 in adult rat 23 in adult man	Provide ATP chiefly for contraction
T-system	≈1	Transmission of electrical signal from sarcolemma to cell interior
SR	10 in neonate 2-3 in adult	Takes up and releases Ca^{2+} during contraction cycle
SR terminal cisternae	0.33 in adult	Site of calcium storage and release
Rest of network of SR	Rest of volume	Site of calcium uptake en route to cisternae
Sarcolemma	Very low	Control of ionic gradients, channels for ions (action potential), maintenance of cell integrity, receptors for drugs and hormones
Nucleus	≈3	Transcription
Lysosomes	Very low	Intracellular digestion and proteolysis
Sarcoplasm (= cytoplasm) (includes myofibril but not mitochondria or SR)	~60	Cytosolic volume within which $[Ca^{2+}]_i$ rises and falls

ATP, Adenosine triphosphate; *SR,* sarcoplasmic reticulum.

Ventricular myocytes are roughly brick shaped, typically 150 × 20 × 12 μm (**Table 22.1**), and are connected at the long ends by specialized junctions that mechanically and electrically couple the myocytes with each other (**Fig. 22.2**). Atrial myocytes are smaller and more spindle shaped (<10 μm in diameter and <100 μm in length). When examined under a light microscope, atrial and ventricular myocytes have cross striations and are often branched. Each myocyte is bounded by a complex cell membrane, the *sarcolemma* (*sarco*, "flesh"; *lemma*, "thin husk"), and is filled with rodlike bundles of *myofibrils* containing the contractile elements. The sarcolemma invaginates to form an extensive transverse tubular network (*T tubules*) that extends the extracellular space into the interior of the cell (**see Figs. 22.1 and 22.2**). Ventricular myocytes are typically binucleate, and these nuclei contain most of the cell's genetic information. Some myocytes have one or three to four nuclei. Rows of mitochondria are located between the myofibrils and also immediately beneath the sarcolemma. Mitochondria function mainly to generate the energy, in the form of adenosine triphosphate (ATP), that is needed to maintain cardiac contractile function and the associated ion gradients. The *sarcoplasmic reticulum* (SR) is a specialized form of

endoplasmic reticulum that is critical for calcium (Ca^{2+}) cycling, which is the on-off switch for contraction. When the wave of electrical excitation reaches the T tubules, voltage-gated Ca^{2+} channels open to provide relatively small entry of Ca^{2+}, which triggers additional release of Ca^{2+} from the SR via closely apposed Ca^{2+} release channels. This is the Ca^{2+} that initiates myocardial contraction. Ca^{2+} sequestration by the SR and extrusion from the myocyte causes relaxation (diastole).

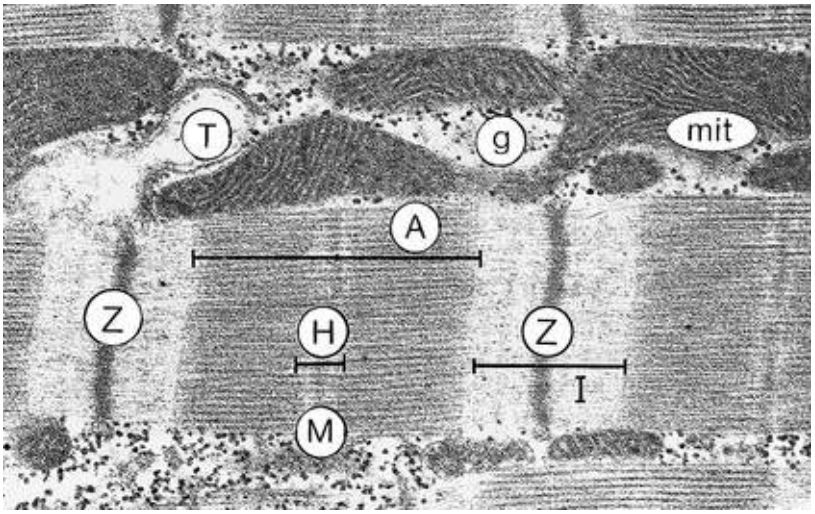

FIGURE 22.2 The sarcomere is the distance between the two Z-lines. Note the presence of numerous mitochondria (*mit*) sandwiched between the myofibrils and the presence of T tubules (*T*), which penetrate into the muscle at the level of the Z-lines. This two-dimensional picture should not disguise the fact that the Z-line is really a "Z-disc," as is the M-line (*M*), also shown in **Fig. 22.1**. *A,* Band of actin-myosin overlap; *g,* glycogen granules; *H,* central clear zone containing only myosin filament bodies and the M-line; *I,* band of actin filaments, titin, and Z-line (rat papillary muscle, 32,000×). (Courtesy Dr. J. Moravec, Dijon, France.)

Anatomically, the SR is a lipid membrane–bounded, fine interconnected network spreading throughout the myocytes. The *Ca^{2+} release channels* (or *ryanodine receptors* [RyRs]) are concentrated at the part of the SR that is in very close apposition to the T tubular Ca^{2+} channel. These are called *terminal cisternae* ("boxes" or "baskets," Latin) or the *junctional sarcoplasmic reticulum* (jSR). The second part of the SR, the *longitudinal*, *free*, or *network sarcoplasmic reticulum*, consists of ramifying tubules that surround the myofilaments (**see Fig. 22.1**) that take Ca^{2+} back up into the SR and thus drive relaxation. Such Ca^{2+} uptake is achieved by the ATP-consuming Ca^{2+} pump known as *SERCA* (sarcoendoplasmic reticulum Ca^{2+}–adenosine triphosphatase, or SR Ca-ATPase). The Ca^{2+} taken up into the SR is then stored at high concentration, in part bound to Ca^{2+}-buffering proteins, including *calsequestrin*, before being released again in response to the next wave of depolarization. *Cytoplasm* or *sarcoplasm* refers to the intracellular fluid and proteins therein, but excludes the contents of organelles such as the mitochondria, nucleus, and SR. The cytoplasm is crowded with myofilaments, but this is the fluid within which the concentration of Ca^{2+} rises and falls to cause cardiac contraction and relaxation.

Subcellular Microarchitecture

The molecular signal systems that convey messages from surface receptors to intracellular organelles may be directed to specific sites by molecules that "anchor" components of the signaling cascades to specific loci, such as around beta-adrenergic receptors and Ca^{2+} channels at the T tubule–SR junction and *caveolae* (small, flask-shaped sarcolemmal invaginations). *Scaffolding proteins* such as caveolin or the RyR itself bring interacting molecules closely together at these locations. These complexes can also release components that translocate and signal elsewhere in the cell, such as the nucleus, where they can

signal for myocyte growth. Another type of subcellular shuttling is involved in transporting the ATP produced in mitochondria to sites where it is used (e.g., myofilaments), which is facilitated by the location of creatine kinase, an enzyme that converts creatine phosphate to ATP.

Mitochondrial Morphology and Function

The typical ventricular myocyte has approximately 8000 mitochondria, each of which is ovate with a long axis measuring 1 to 2 μm and short axis of 300 to 500 nm. Mitochondria have two membranes: outer and inner mitochondrial membranes (OMM and IMM; **Fig. 22.3**). The IMM is "crumpled" into folds called *cristae,* which provide a large surface area within a small volume. The IMM also contains the cytochrome complexes that make up the respiratory chain, including F_0-F_1 ATP synthase. The space within the IMM, the mitochondrial matrix, contains enzymes of the tricarboxylic acid (TCA) cycle and other key metabolic components. These components provide reducing equivalent protons that are pumped out of the matrix by the cytochromes, and it is this proton pumping that creates the very negative voltage with respect to cytosol (Ψ_m = −180 mV). The proton pumping out of the matrix also creates a trans-IMM [H^+] gradient, which together with the very negative Ψ_m creates a strong electrochemical gradient for protons to enter the matrix. The energy from this "downhill" proton flux is used by the F_0-F_1 ATP synthase to make ATP. However, in the absence of the normal proton and Ψ_m, this elegant F_0-F_1 ATP synthase runs backward, consuming ATP. The ATP produced in the matrix is transported across the IMM by an adenine nucleotide transporter that exchanges mitochondrial ATP for cytosolic adenosine diphosphate (ADP). This system is exquisitely regulated to maintain cytosolic [ATP] and [ADP] [concentration] constant during dramatic changes in cardiac workload.[5] The multiple control mechanisms involved in this process are not fully understood, but one is relevant to excitation-contraction coupling. Increased cardiac work in a physiologic setting is usually driven by higher-amplitude and/or more frequent Ca^{2+} transients. This elevation in average intracellular [Ca^{2+}] ($[Ca^{2+}]_i$) also increases mitochondrial matrix [Ca] ($[Ca^{2+}]_m$), which activates key dehydrogenases in the TCA cycle and also pyruvate dehydrogenase to restore levels of reduced nicotinamide adenine dinucleotide (NADH), which drives cytochrome activity and helps restore [ATP] toward normal.

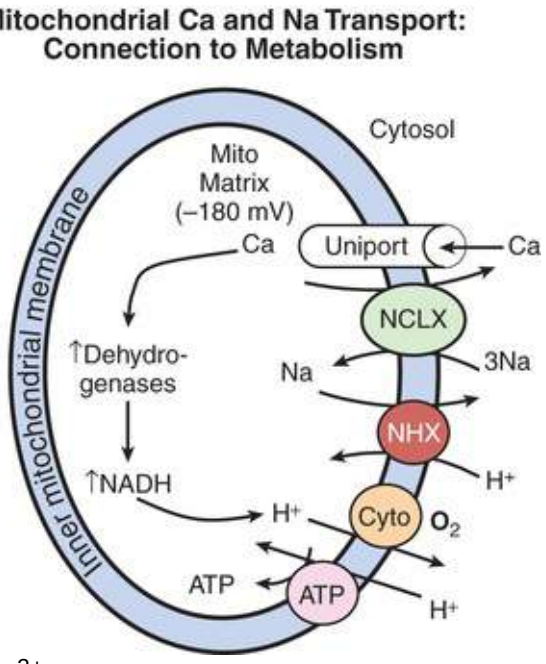

FIGURE 22.3 Mitochondrial Ca^{2+} regulation. The intramitochondrial matrix is very negative with respect to the cytosol (−180 mV). Ca^{2+} enters mitochondria via the Ca^{2+} uniporter in the inner mitochondrial membrane and is extruded by Na^+/Ca^{2+} exchange (*NCLX*). Na^+ is extruded via Na^+/H^+ exchange (*NHX*). Protons (H^+) are pumped out of mitochondria by the cytochrome (*Cyto*) systems, thereby allowing H^+ to enter via F_0-F_1 ATP synthase (*ATP*). When mitochondrial $[Ca^{2+}]$ is increased, it activates mitochondrial dehydrogenases, which increase NADH levels and provide additional reducing equivalent protons to the electron transport chain. (Modified from Bers DM. Excitation-Contraction Coupling and Cardiac Contractile Force. Dordrecht, Netherlands: Kluwer Academic; 2001.)

This raises the issue of how mitochondria regulate $[Ca^{2+}]_m$, because there is also a huge electrochemical gradient favoring entry of Ca^{2+} into mitochondria.[2] Indeed, $[Ca^{2+}]_m$ is typically similar to $[Ca^{2+}]_i$ and is kept at that level by a mitochondrial Na/Ca exchanger (NCLX), which uses the also steep Na^+ electrochemical gradient to pump Ca^{2+} out of the mitochondria.[2] However, this would load the mitochondria with Na^+, so Na^+ must also be extruded from the mitochondria. This is accomplished by the mitochondrial Na/H exchanger in the IMM, but a consequence is that this influx of H^+ costs energy. That is, these protons could have entered the mitochondria via the F_0-F_1 ATP synthase making ATP, but instead they were used to extrude Na^+ and Ca^{2+}. Thus in a sense the mitochondrion can make ATP or extrude Ca^{2+}. This becomes important when myocytes (or other cells) experience Ca^{2+} overload. In the short term, mitochondria can take up large amounts of Ca^{2+} to protect the cell from short-term Ca^{2+} overload, but chronic high $[Ca^{2+}]_i$ has dire consequences. First, this Ca^{2+} uptake can diminish Ψ_m and occurs at the expense of ATP production (as noted), thus hampering energetic recovery from such stress. Second, elevated $[Ca^{2+}]_i$ and $[Ca^{2+}]_m$ can facilitate opening of the mitochondrial permeability transition pore, which immediately wipes out Ψ_m and allows the matrix contents to be released to the cytosol. This can be the death knell for individual mitochondria, as well as the cells that rely on their function.

Thus, mitochondria can rapidly become agents of cell death as just described, as well as by producing excessive reactive oxygen species (ROS), which can promote necrotic cell death through the mitochondrial permeability transition pore and release of proapoptotic proteins[6] (**see Chapter 23**). Mitochondria can also induce mitochondrial autophagy, or *mitophagy*, which selectively and adaptively clears damaged mitochondria. Increased oxidative stress and apoptotic proteases can inactivate mitophagy and thereby cause cell death.[7]

Contractile Proteins

The two chief contractile proteins are the motor protein *myosin* on the thick filament and *actin* on the thin filament (**see Figs. 22.1 and 22.2**). Ca^{2+} initiates the contraction cycle by binding to the thin filament regulatory protein *troponin C* to relieve the inhibition otherwise exerted by this troponin complex (**Fig. 22.4**). The thin actin filaments are connected to the *Z-lines* (Z for German *Zuckung*, "contraction") at either end of the *sarcomere*, which is the functional contractile unit that is repeated through the filaments. The sarcomere is limited on either side by a Z-line, which with the thin filaments creates a "cage" around the thick myosin filament that extends from the center of the sarcomere outward toward, but not reaching, the Z-line. During contraction, the myosin heads grab onto actin and pull the actin filaments toward the center of the sarcomere. The thin and thick filaments can thus slide over each other to shorten the sarcomere and cell length, without the individual actin or myosin molecules actually changing length (**Fig. 22.1B**). The interaction of the myosin heads with actin filaments that is switched on when Ca^{2+} arrives is called *cross-bridge cycling*. As the actin filaments move inward toward the center of the sarcomere, they draw the Z-lines closer together so that the sarcomere length shortens. The energy for contraction is provided by breakdown of ATP (myosin is an ATPase).

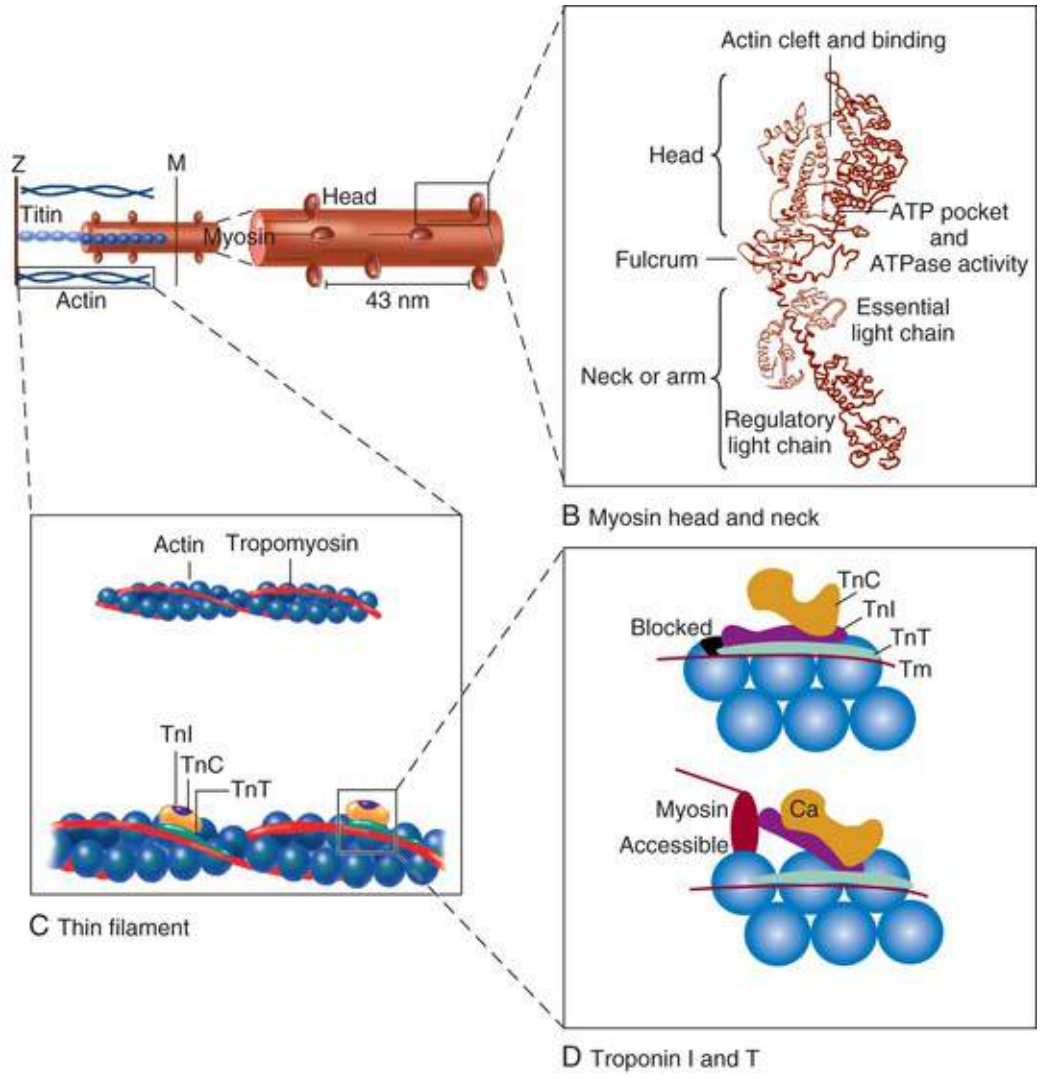

FIGURE 22.4 Key contractile protein interactions. The thin actin filament **(A)** interacts with the myosin head **(B)** when Ca^{2+} ions arrive at troponin C (*TnC*) **(C).** This causes troponin-tropomyosin shifts to expose the actin site to which a myosin head can attach. **A,** The thin actin filament contains TnC and its Ca^{2+} binding sites. When TnC is not activated by Ca^{2+}, troponin I (*TnI*) stabilizes troponin T (*TnT*) and tropomyosin (*Tm*) along the actin filament to block myosin cross-bridge binding **(D). B,** The molecular structure of the myosin head, based on Rayment and colleagues,[8] is composed of heavy and light chains. The heavy head chain in turn has two major domains: one of 70 kDa (i.e., 70,000 molecular weight) that interacts with actin at the actin cleft and has an ATP binding pocket. The "neck" domain of 20 kDa, also called the "lever," is an elongated alpha helix that extends and bends and has two light chains surrounding it as a collar. The essential light chain is part of the structure. The other regulatory light chain may respond to phosphorylation to influence the extent of the actin-myosin interaction. **C,** TnC with sites in the regulatory domain for activation by calcium and for interaction with TnI. **D,** Binding of calcium to TnC causes TnI to shift binding from TnT to TnC, allowing the TnT-Tm complex to shift deeper into the actin groove and expose the myosin binding domain on actin. (Modified from Opie LH. Heart Physiology, from Cell to Circulation. Philadelphia: Lippincott Williams & Wilkins; 2004. Figure copyright L. H. Opie, © 2004. **D,** Modified from Solaro RJ, Van Eyk J. Altered interactions among thin filament proteins modulate cardiac function. J Mol Cell Cardiol 1999;28:217.)

Titin and Length Sensing

Titin is a giant molecule, the largest protein yet described. It is extraordinarily long, elastic, and slender (**Fig. 22.5**). Titin extends from the Z-line into the thick filament, approaching the M-line, and connects the thick filament to the Z-line (**see Fig. 22.1**). Titin has two distinct segments: an inextensible anchoring segment and an extensible elastic segment that stretches as sarcomere length increases. Thus the titin molecule can stretch between 0.6 and 1.2 μm in length and has multiple functions. First, it tethers myosin and thick filaments to the Z-line, thereby stabilizing sarcomeric structure. Second, as it stretches and

relaxes, its elasticity contributes to the stress-strain relationship of cardiac and skeletal muscle. At short sarcomere lengths, the elastic domain is coiled up on itself to generate restoring force (**Fig. 22.5**), similar to a spring, helping to relengthen the sarcomere and aid early diastolic filling. These changes in titin help explain the *series elastic element* that was inferred from mechanics studies as elasticity in series with the myosin filaments. Third, the increased diastolic stretch of titin as the length of the sarcomere in cardiac muscle is increased causes the enfolded part of the titin molecule to straighten. This stretched molecular spring then limits overstretching of sarcomeres and end-diastolic volume and returns some potential energy during systole as the sarcomeres shorten during cardiac ejection.[4] Fourth, titin may transduce mechanical stretch into growth signals. Sustained diastolic stretch, as in volume overload, can cause titin-dependent signaling to muscle LIM protein (MLP) attached to the Z-line end of titin.[8] MLP is proposed to be a stretch sensor that transmits the signals that result in the myocyte growth pattern characteristic of volume overload, and it may be defective in a subset of human dilated cardiomyopathy.[9]

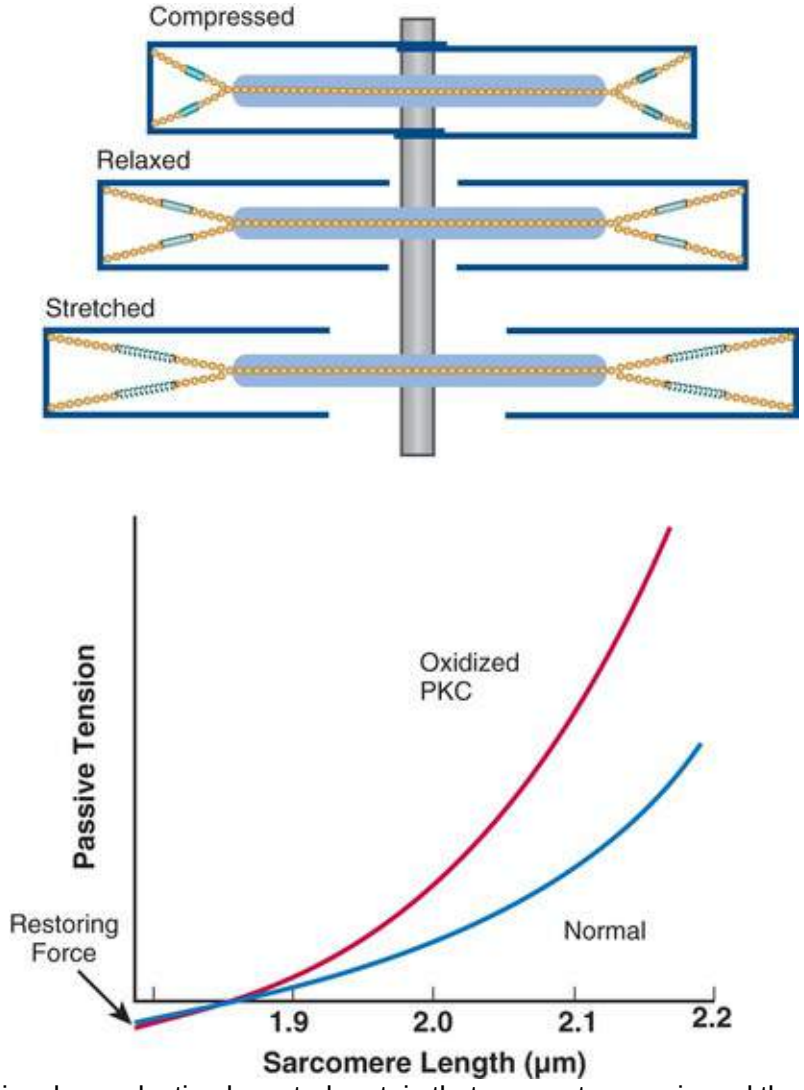

FIGURE 22.5 Titin is a huge elastic elongated protein that connects myosin and the M-line to the Z-line. It is a bidirectional spring that develops passive force in stretched sarcomeres and resting force in shortened sarcomeres. **Upper panel,** As the sarcomere is stretched to its maximum physiologic diastolic length of 2.2 μm, titin stretches and increases passive force generated (contributing to end-diastolic pressure). At short lengths (*top*), which may reflect end-systole, substantial restoring force is generated **(lower panel).** (Modified with permission of the American Heart Association, from Lewinter MM, Granzier HL. Titin is a major human disease gene. Circulation 2013;127:938-44.)

Molecular Basis of Muscular Contraction

Although the molecular level details underlying the cross-bridge cycle are complex, cross bridges appear to exist in either a strong or a weak binding state. During diastole, myosin heads normally have ATP bound (**Fig. 22.6B**) and hydrolyzed to ADP plus inorganic phosphate (P_i), although ADP-P_i is not yet released and the energy of ATP is not yet fully consumed (**Fig. 22.6C**). Thus the cross bridges are poised and ready to bind to actin. This interaction is permitted when Ca^{2+} arrives and binds to troponin C, shifting the position of the troponin-tropomyosin complex on the actin filament (**see Fig. 22.4C, D**). This enables the poised myosin heads to form strong binding cross bridges with actin molecules (**Fig. 22.6D**) and use the energy stored in myosin-ADP-P_i to rotate the myosin head while bound to actin in the *power stroke* (and release P_i) while still in the strong binding state (**Fig. 22.6D, E**). Once a particular cross bridge proceeds through the power stroke (using the energy previously stored in the ATP molecule), it will remain in the strong binding or *rigor* state (**Fig. 22.6A**) until ATP binds again to myosin, causing a shift back to the weak binding state and allowing cross-bridge detachment and ATP hydrolysis (**Fig. 22.6C**). As long as $[Ca^{2+}]_i$ and [ATP] remain high, the cycle can continue with myosin-ADP-P_i binding to a new actin molecule. The weak binding state predominates when $[Ca^{2+}]_i$ falls and Ca^{2+}dissociates from troponin C, allowing relaxation during diastole. If intracellular [ATP] declines too far (e.g., during ischemia), ATP cannot bind and disrupt the rigor linkage, leaving cross bridges locked in the strong binding state (as in rigor mortis).

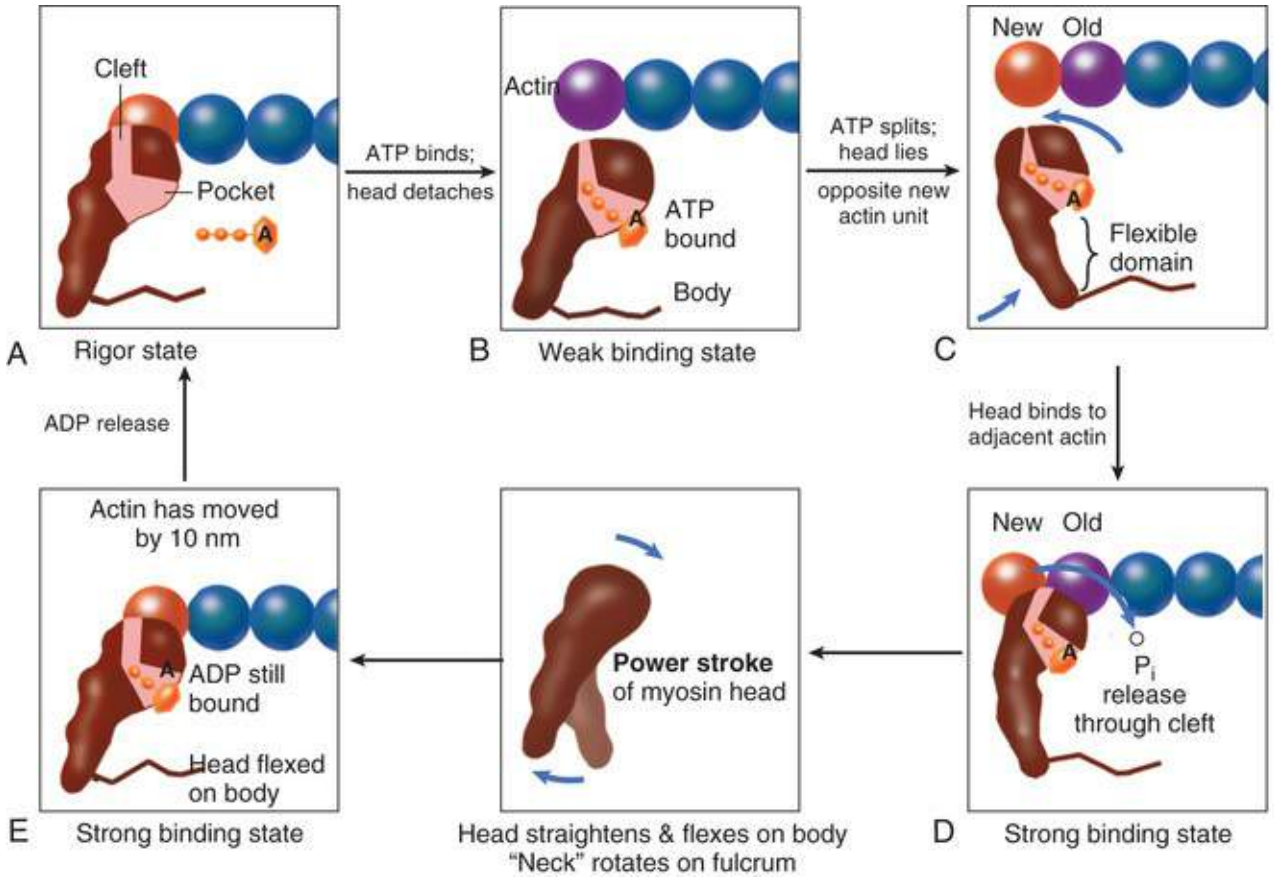

FIGURE 22.6 Cross-bridge cycling molecular model. The cross-bridge (only one myosin head depicted) is pear shaped, and the catalytic motor domain interacts with the actin molecule and is attached to an extended alpha helical "neck region," which acts as a lever arm. The nucleotide pocket that binds ATP is in the catalytic domain. The actin binding cleft bisects the catalytic motor domain. Starting with the rigor state **(A),** binding of ATP to the pocket **(B)** is followed by ATP hydrolysis **(C)**, which alters the actin binding domain, favoring release from actin. The binding to actin is enhanced when phosphate is released, and the myosin head strongly attaches to actin to induce the power stroke **(D, E).** During the power stroke the head rotates around the head-neck fulcrum. As the head flexes, the actin filament can be displaced by ~10 nm **(E),** causing shortening (although during isometric contraction the neck region stretches and bears force). In this process, ADP is also released, so the binding pocket becomes vacant, resulting in the rigor state again **(A)** until ATP binds to release the cross bridge.

Actin and Troponin Complex

The Ca^{2+} on-switch of cross-bridge cycling is mediated by a series of interactions within the troponin, tropomyosin, and actin complex (**see Fig. 22.4C, D**). Thin filaments are composed of two helical intertwining actin filaments, with a long tropomyosin molecule that spans seven actin monomers located in the groove between the two actin filaments. Also, at every seventh actin molecule (38.5 nm along this structure) there is a three-protein regulatory *troponin complex:* troponin C (Ca^{2+} binding), I (inhibitory), and T (tropomyosin binding).

When $[Ca^{2+}]_i$ is low, the position of tropomyosin blocks the myosin heads from interacting effectively with actin. As a result, most cross bridges are in the "blocked position," with a few visiting the weak binding state. Ca^{2+} binding with troponin C causes troponin C to bind more tightly to troponin I (**see Fig. 22.4D**), which allows tropomyosin to roll deeper into the thin filament groove,[1] thereby opening access to allow myosin binding to actin. This allows the cross-bridge cycle to proceed (**see Fig. 22.6**). As they form, strong cross bridges can nudge tropomyosin deeper into the actin groove, allowing cross-bridge attachment at one site to enhance actin-myosin at its "nearest-neighbor" sites. This cooperatively spreads activation farther along the myofilaments.[1,4]

Myosin Structure and Function

Each myosin head is the terminal part of the myosin heavy chain molecule. The other ends of two myosin molecules (tails) intertwine as a coil that forms the bulk of the thick filament. Also, a short "neck" leads to the myosin head that protrudes out from the filament (**see Fig. 22.4**). According to the Rayment model, the base of the head and/or neck region changes configuration during the power stroke previously described.[8] Each head has an *ATP-binding pocket* and a narrow cleft that extends from the base of this pocket to the actin-binding face[10] (**see Fig. 22.6**). During the power stroke when there is no mechanical load on the muscle, the myosin head flexes and can move the actin filament by approximately 10 nm.[1] When the pocket releases ADP and binds ATP, the cross bridge releases back to an orientation more perpendicular to the direction of the thin and thick filaments. During isometric (or isovolumic) contraction, the cross bridges rotate but cannot fully move the actin filament, and the stretched strong binding cross bridges bear force. During shortening (ejection), the actin filament moves during the power stroke, accompanied by decreases in sarcomere length and ventricular volume.

Note that myosin heads stick out from the thick filament in six directions in an organized array to allow interactions with each of six actin filaments that surround each thick filament (**see Fig. 22.1**). The myosin molecules are also oriented in reversed longitudinal directions on either side of the M-line (which itself contains only myosin tails), such that each side is trying to pull the Z-lines toward the center. That is, when cross bridges are in the strong binding or rigor linkages, they form "chevrons" (or arrows) pointing toward the Z-line on that side of the M-line.

Each cycle of the cross bridge consumes one molecule of ATP, and this *myosin ATPase activity* is the major site of ATP consumption in the beating heart. Thus, when the heart is more strongly activated, the level of ATP consumption is similarly increased. The two myosin heads that stick out from an intertwined pair of myosin molecules seem to work through a hand-over-hand action such that the myosin dimer never fully releases the thin filament during the activation period.[11] There are also two main myosin isoforms in cardiac myocytes, alpha and beta, which have similar molecular weight but exhibit substantially different cross-bridge cycle and ATPase rates. The beta-myosin heavy chain (β-MHC) isoform exhibits a slower ATPase rate and is the predominant form in adult humans. In small mammals (rats and mice), the faster α-MHC form normally predominates but shifts to the β-MHC pattern during chronic stress and heart failure.[4]

Each myosin molecule neck also has two light chains (**see Fig. 22.4A**). The *essential myosin light chain* (MLC-1) is more proximal to the myosin head and may limit the contractile process by interaction with actin. The *regulatory myosin light chain* (MLC-2) is a potential site for phosphorylation (e.g., in response to beta-adrenergic stimulation) and may promote cross-bridge cycling.[12] In vascular smooth muscle, which lacks the troponin-tropomyosin complex, contraction is activated by the Ca^{2+}-dependent *myosin light chain kinase* (MLCK) rather than by Ca^{2+} binding to troponin C (as in striated muscle). Myosin-binding protein C appears to traverse the myosin molecules in the A-band, thereby potentially tethering the myosin molecules and stabilizing the myosin head with respect to the thick and thin filaments. Defects in myosin, myosin-binding protein C, and several other myofilament proteins are genetically linked to familial hypertrophic cardiomyopathy.[13]

Graded Effects of $[Ca^{2+}]_i$ on Cross-Bridge Cycle

The myofilaments are activated in a graded rather than all-or-none manner as a function of $[Ca^{2+}]_i$ (**Fig. 22.7**). The dynamics and regulation of Ca^{2+} transients in cardiac myocytes are discussed in the following section, but a major physiologic mechanism for regulating cardiac contractility (e.g., during sympathetic

activity) is to increase peak $[Ca^{2+}]_i$ and more fully activate the myofilaments. The higher the $[Ca^{2+}]_i$, the more fully saturated are the Ca^{2+} binding sites on troponin C, and consequently, more sites are available for cross bridges to form. When more cross bridges are working in parallel, the myocyte (and heart) can develop greater force. There is high cooperativity in this process, in large part because of the "nearest-neighbor" effect mentioned earlier. That is, Ca^{2+} bound to a single troponin C molecule encourages local cross-bridge formation, and both Ca^{2+} binding and cross-bridge formation directly enhance the likelihood of cross-bridge formation in the seven actin molecules controlled by one tropomyosin molecule. Furthermore, the openness of that domain directly enhances that of the neighboring domain with respect to both Ca^{2+} binding and cross-bridge formation. This cooperativity means that a small change in $[Ca^{2+}]_i$ can have a great effect on the strength of contraction.

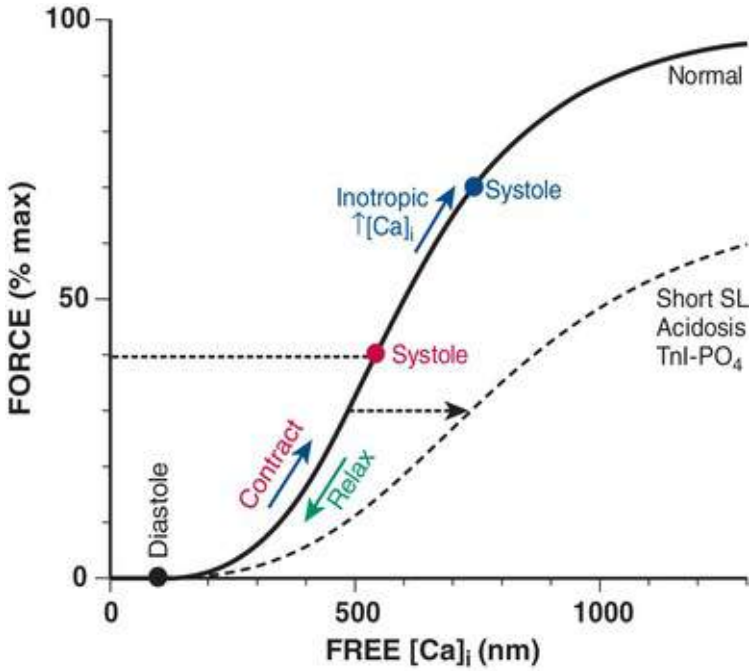

FIGURE 22.7 Myofilament Ca^{2+} sensitivity. Active force development in cardiac muscle depends on the cytosolic free $[Ca]_i$. As $[Ca]_i$ rises during systole, force develops as dictated by the sigmoidal myofilament Ca^{2+} sensitivity curve (*solid curve*; Force = 100/(1+ [600 nm]/$[Ca]_i)^4$). As $[Ca]_i$ declines relaxation ensues and force declines. If peak $[Ca]_i$ increases (as in inotropy) the peak force can reach a higher value. At shorter sarcomere length (SL), acidosis, and troponin I (TnI) phosphorylation, the myofilament Ca^{2+} sensitivity is reduced, and the former two also decrease maximal force (*dashed curve*).

Length-Dependent Activation and the Frank-Starling Effect

Besides $[Ca^{2+}]_i$, the other major factor influencing the strength of contraction is *sarcomere length* at the end of diastole (preload), just before the onset of systole. Both Otto Frank and Ernest Starling observed that the more the diastolic filling of the heart, the greater the strength of the heartbeat. The increased heart volume translates into increased sarcomere length, which acts by a length-sensing mechanism. A part of this *Frank-Starling effect* has historically been ascribed to increasingly optimal overlap between the actin and myosin filaments. Clearly, however, there is also a substantial increase in myofilament Ca^{2+} sensitivity with an increase in sarcomere length (**Fig. 22.7**).[1] A plausible mechanism for this regulatory change may reside in the decreasing interfilament spacing as heart muscle is stretched. That is, the myocyte is at constant volume (over the cardiac cycle), so as the cell shortens, it must thicken, and

conversely, when it is stretched, the cell becomes thinner and filament spacing becomes narrower. This attractive lattice-dependent explanation for the Frank-Starling relationship has been challenged by careful x-ray diffraction studies,[4] which found that reducing sarcomere lattice spacing by osmotic compression failed to influence myofilament Ca^{2+} sensitivity. Although several mechanisms could contribute to myofilament Ca^{2+} sensitization at longer sarcomere length, the issue is unresolved.

When changes in diastolic length (or preload) are the cause of altered contractile strength, it is said to be a Frank-Starling (or Starling) effect. Conditions in which contraction is strengthened independent of sarcomere length (e.g., typically by increased Ca^{2+} transient amplitude) are referred to as positive *inotropic states* or enhanced *contractility*. The distinction between these heterometric (Starling) and homeometric (inotropic) mechanisms of altered cardiac strength is functionally and therapeutically important.

Cross-Bridge Cycling Differs From Cardiac Contraction-Relaxation Cycle

The cardiac cycle of Wiggers (see later) must be distinguished from the cross-bridge cycle. The cardiac cycle reflects the overall changes in pressure in the left ventricle, whereas the cross-bridge cycle is the repetitive interaction between myosin heads and actin. During isovolumic contraction (before aortic valve opening), the sarcomeres do not shorten appreciably, but cross bridges are developing force, although not all simultaneously. That is, at any given moment, some myosin heads will be flexing or flexed (resulting in force generation), some will be extending or extended, and some will be attached weakly to actin and some detached from actin. Numerous such cross-bridge cycles, each lasting microseconds, are integrated to produce the resulting force (and pressure). When ventricular pressure (sum of cross-bridge forces) reaches aortic pressure (afterload), ejection begins and is associated with the cross bridges actively moving the thin actin filaments toward the central of the sarcomere (M-line), thereby shortening the sarcomere. Note that as ejection proceeds (and sarcomeres shorten), myofilament Ca^{2+} sensitivity declines (**see Fig. 22.7**). Thus, both $[Ca^{2+}]_i$ decline and shortening cause a progressive decline in the contractile state as systole gives way to diastole. Both the Ca^{2+} transient properties and the myofilament Ca^{2+} sensitivity and cross-bridge cycling rate are altered under physiologic conditions, such as sympathetic stimulation and local acidosis or ischemia, as discussed later.

Force Transmission

Volume and pressure overload may have different effects on myocardial growth because of different patterns of force transmission.[4] Whereas increased diastolic force is transmitted longitudinally by titin to reach MLP, the postulated sensor (see earlier), increased systolic force may be transmitted laterally (i.e., at right angles) by the Z-disc and cytoplasmic actin to reach the cytoskeletal proteins and cell-to-matrix junctions, such as the focal adhesion complex. This mechanical force is translated into signals that activate the growth pathways, such as those leading to mitogen-activated protein kinase (MAPK) and altered gene regulation and cell size and shape, as addressed in other chapters.

Contractile Protein Defects and Cardiomyopathy.
Genetic-based hypertrophic and dilated cardiomyopathies not only produce hearts that look and behave very differently but also have diverse molecular causes. These cardiomyopathies in general are linked to mutant genes that cause abnormalities in the force-generating system, such as β-MHC, MLCs, myosin-binding protein C, troponin subunits, and tropomyosin (**see Chapter 77**). One hypothesis is that

mutations that increase myofilament calcium sensitivity, contractility, and energy demand result in concentric hypertrophy,[14] whereas mutations that reduce myofilament calcium sensitivity or force generation or that result in non–force-generating cytoskeletal proteins (e.g., dystrophin, nuclear lamin, cytoplasmic actin, titin) lead to a dilated cardiomyopathy. Although useful, such broad distinction between the two types of cardiomyopathy is oversimplified, with several examples of overlapping mechanisms.

Calcium Ion Fluxes in Cardiac Contraction-Relaxation Cycle

Calcium Movements and Excitation-Contraction Coupling

Ca^{2+} is a central regulator of cardiac contraction and relaxation. Details of the associated Ca^{2+} fluxes that link contraction to the wave of excitation (*excitation-contraction coupling*) are now reasonably well clarified and accepted.[1,2] Relatively small amounts of Ca^{2+} (*trigger* Ca^{2+}) enter and leave the cardiomyocyte during each cardiac cycle, with larger amounts being released and taken back up by the SR (**Fig. 22.8**). Each action potential depolarization traveling down the T tubules opens the voltage-gated L-type Ca^{2+} channels that are physically near the junctional SR, which is mainly in the T tubule, and activates SR Ca^{2+} release channels (RyRs). In this *Ca^{2+}-induced Ca^{2+} release* mechanism, a smaller amount of Ca^{2+} entering via the calcium current (I_{Ca}) triggers the release of a larger amount of Ca^{2+} into the cytosol.[1,4] In the human ventricle and large mammals, SR Ca^{2+} release is three to four times higher than Ca^{2+} influx by I_{Ca}. In rat and mouse myocytes, however, SR Ca^{2+} cycling is more than 10 times greater than sarcolemmal Ca^{2+} flux.[1] The combined Ca^{2+} release and influx elevates $[Ca^{2+}]_i$ and promotes binding of Ca^{2+} to troponin C and thus contractile activation.

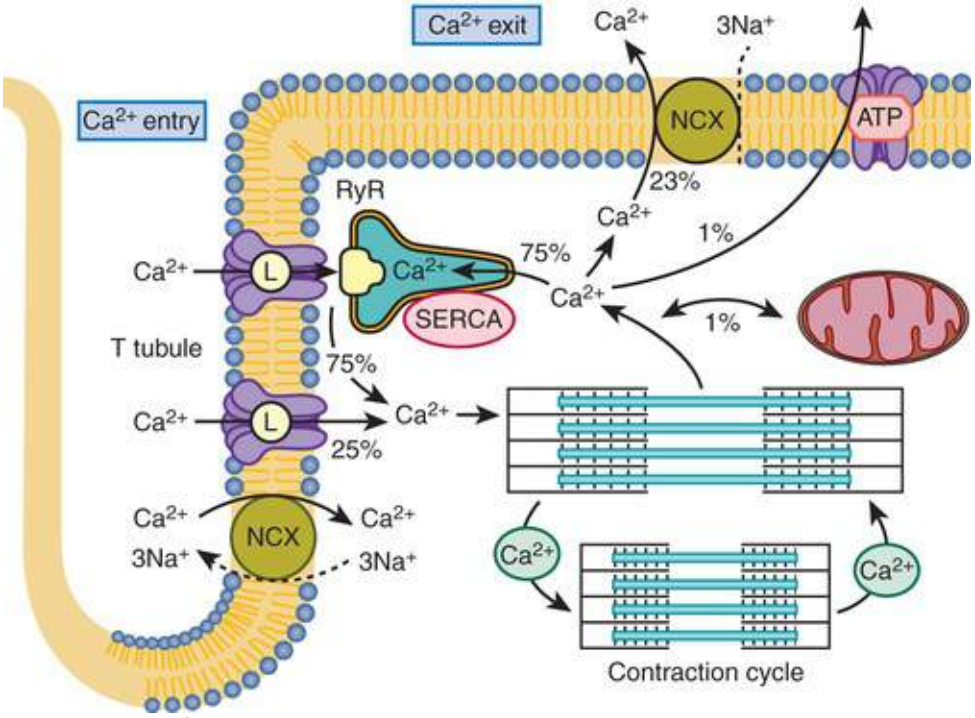

FIGURE 22.8 Myocyte Ca^{2+} fluxes during excitation-contraction (E-C) coupling. Crucial features are (1) Ca^{2+} entry via the voltage-activated L-type Ca^{2+} channels, which triggers release of more Ca^{2+} from the SR; (2) a tiny amount of Ca^{2+} may enter via Na^+/Ca^{2+} exchange early in the action potential; and (3) removal of Ca^{2+} ions from the cytosol is mainly via the SR Ca-ATPase (SERCA; 75%) and Na^+/Ca^{2+} exchange (24%), with tiny amounts transported by mitochondrial Ca^{2+} uniport and the sarcolemmal Ca-ATPase (1%). The sodium pump (Na^+/K^+-ATPase) extrudes the Na^+ ions that entered during Na^+ current and Na^+/Ca^{2+} exchange action. Note that extracellular and intra-SR [Ca^{2+}] (1-2 mm) is much higher than diastolic $[Ca^{2+}]_i$ (0.10 µm). Mitochondria can act as a buffer against excessive changes in cytosolic Ca^{2+}.

Calcium Release and Uptake by Sarcoplasmic Reticulum

Sarcoplasmic Reticulum Network and Ca^{2+} Movements

Electron and fluorescence microscopy studies show that the SR is a continuous network surrounding the myofilaments with connections across Z-lines and transversely between myofibrils. Moreover, the lumens of the entire SR network and nuclear envelope are connected in adult cardiac myocytes. This allows relatively rapid diffusion of Ca^{2+} within the SR to balance free [Ca^{2+}] within the SR ($[Ca^{2+}]_{SR}$).[15,16] The total SR Ca^{2+} content is the sum of $[Ca^{2+}]_{SR}$ plus Ca^{2+} bound to intra-SR Ca^{2+} buffers (especially calsequestrin). SR Ca^{2+} content is critical to normal cardiac function and electrophysiology, and its abnormalities contribute to systolic and diastolic dysfunction and arrhythmias. $[Ca^{2+}]_{SR}$ dictates the SR Ca^{2+} content and driving force for Ca^{2+} release and also regulates RyR release channel gating.[16]

Junctional Sarcoplasmic Reticulum and Ryanodine Receptor

The RyR channels that mediate SR release Ca^{2+} are mainly located in the jSR membrane at the junctions with the T tubule.[1] Each junction has 50 to 250 RyR channels on the jSR that are directly under a cluster of 20 to 40 sarcolemmal L-type Ca^{2+} channels across a 15-nm junctional gap (that is crowded with protein). RyR2 (the cardiac isoform) functions both as a Ca^{2+} channel and as a scaffolding protein that localizes numerous key regulatory proteins to the jSR.[1,4] On the large cytosolic side, these include proteins that can stabilize RyR gating (e.g., *calmodulin* [CaM], FK-506 binding protein [FKBP-12.6]);

kinases that can regulate RyR gating by phosphorylation (e.g., protein kinase A [PKA], *Ca^{2+}/CaM-dependent protein kinase II* [CaMKII]); and the protein phosphatases PP1 and PP2A, which dephosphorylate the RyR. Inside the SR, the RyR also couples to several proteins (e.g., junctin, triadin, and via these, calsequestrin) that similarly regulate RyR gating and, in the case of calsequestrin, provides a local reservoir of buffered Ca^{2+} close to the release channel. The actual RyR channel is made up of a symmetric tetramer of RyR molecules, each of which may have the aforementioned regulatory proteins associated with it. Thus the RyR receptor complex is very large (>7000 kDa; **Fig. 22.8**).[17] When the T tubule is depolarized, one or more L-type Ca^{2+} channels open, and local cleft [Ca^{2+}] increases sufficiently to activate at least one local jSR RyR (multiple channels here ensure high-fidelity signaling). The Ca^{2+} released from these first openings recruit additional RyRs in the junction through Ca^{2+}-induced Ca^{2+} release to amplify release of Ca^{2+} into the junctional space. The Ca^{2+} diffuses out of this space throughout the sarcomere to activate contraction. Each of the approximately 20,000 jSR regions in the typical ventricular myocyte seems to function independently in response to local activation by I_{Ca}. Thus the global Ca^{2+} transient in the myocyte at each beat is the spatiotemporal summation of SR Ca^{2+} release events from thousands of jSR regions, synchronized by the upstroke of the action potential and activation of I_{Ca}.

Turning Off Ca^{2+} Release: Breaking Positive Feedback

Ca^{2+}-induced Ca^{2+} release is a positive feedback process, but it is now known that SR Ca^{2+} release turns off when $[Ca]_{SR}$ drops by approximately 50% (i.e., from a diastolic value of 1 mM to a nadir of 400 µM).[14] Elegant studies have documented how I_{Ca} is inactivated by high local [Ca^{2+}], and this robust calcium-dependent inactivation is mediated by binding of Ca^{2+} to the CaM that is already associated with that channel. When Ca^{2+} binds to CaM, it alters channel conformation such that I_{Ca} inactivation is favored. I_{Ca} is also subject to voltage-dependent inactivation during the action potential plateau, and thus inactivation limits further entry of Ca^{2+} into the cell.

As for Ca^{2+}-dependent RyR activation, several mechanisms may contribute to breaking its inherent positive feedback. Although not necessarily most compelling, one mechanism is analogous to Ca^{2+}/CaM-dependent inactivation of I_{Ca}. That is, binding of Ca^{2+} to CaM that is prebound to RyR2 favors closure of RyR channels and inhibits reopening[18] (**Fig. 22.9**). A second mechanism, undoubtedly important, is that RyR2 gating is also sensitive to luminal $[Ca^{2+}]_{SR}$ such that high $[Ca^{2+}]_{SR}$ favors opening and low $[Ca^{2+}]_{SR}$ favors closure.[19] Indeed, release of Ca^{2+} from the SR during normal Ca^{2+} transients is robustly turned off when $[Ca^{2+}]_{SR}$ falls to approximately half its normal value (400 µM, which is still 500 times higher than bulk $[Ca^{2+}]_i$), almost regardless of the rate of SR Ca^{2+} release.[14,15] A third and related mechanism is that as Ca^{2+} release proceeds and $[Ca^{2+}]_{SR}$ declines, Ca^{2+} flux through the RyR falls and junctional [Ca^{2+}] also falls, all of which tend to disrupt the positive feedback. That is, the RyR is less sensitive to activating Ca^{2+} (because $[Ca^{2+}]_{SR}$ is low) and lower [Ca^{2+}] on the cytosolic side also activates more weakly.[20]

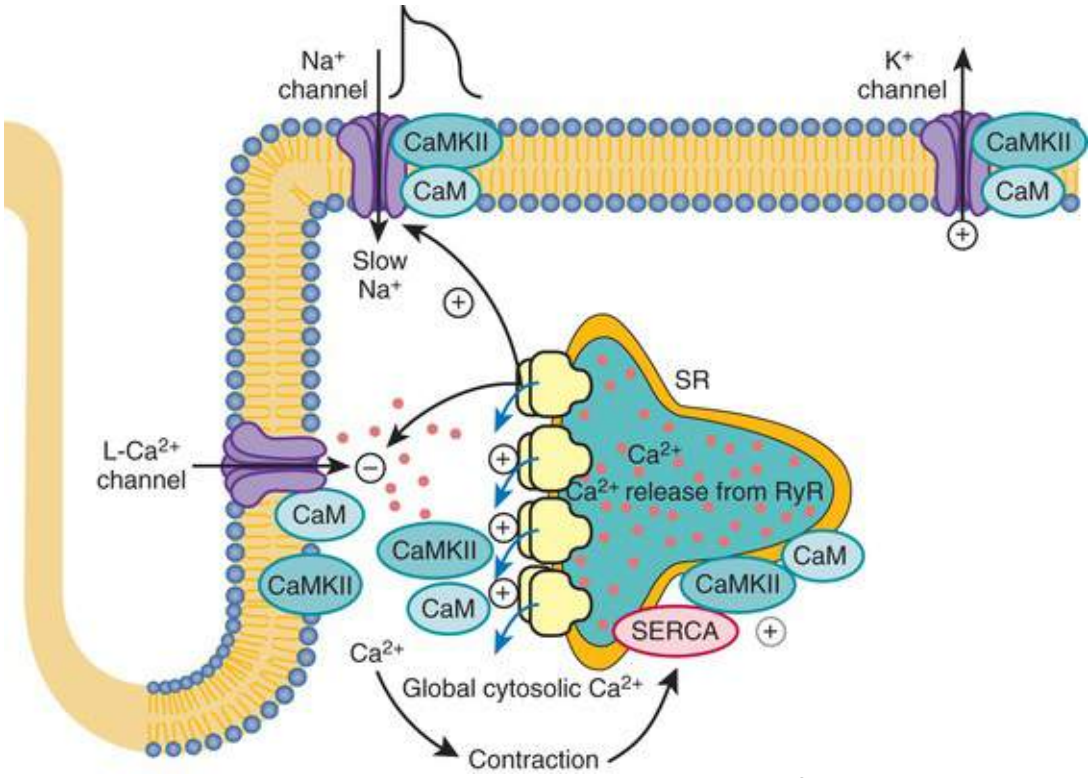

FIGURE 22.9 Role of CaM and CaMKII in regulating intracellular [Ca^{2+}]. The rising cytosolic Ca^{2+} concentration in systole activates the Ca^{2+} regulatory system whereby Ca^{2+}-CaM causes inactivation of L-type Ca^{2+} current and RyR release. This negative feedback system limits cellular Ca^{2+} gain. The effects of CaMKII can also modulate these systems.[21] For example, (1) CaMKII limits the extent of Ca^{2+}-dependent inactivation and enhances Ca^{2+} current amplitude, (2) it increases the fraction of SR Ca^{2+} released from the RyR in response to the Ca^{2+} current trigger (which can be arrhythmogenic), (3) it phosphorylates PLB to enhance SR Ca^{2+} uptake by SERCA, and (4) it can modulate Na^+ and K^+ channel gating in ways that are also proarrhythmic.[21,22]

Calmodulin: Versatile Mediator of Ca^{2+} Signaling.

CaM has four Ca^{2+}-binding sites, resembles troponin C, and participates in many different cellular pathways, from ion channels to transcriptional regulation.[18] In many cases (e.g., L-type Ca^{2+}, Na^+, and some K^+ channels; RyR and inositol 1,4,5-triphosphate receptors), CaM is already prebound or "dedicated" such that elevation of local $[Ca^{2+}]_i$ can rapidly induce Ca^{2+}-CaM effects on their targets[21,22] (**Fig. 22.9**). Indeed, more than 90% of the CaM in myocytes is already bound to cellular targets before Ca^{2+} binds to and activates it. Nevertheless, many myocyte CaM targets (e.g., CaMKII, calcineurin, nitric oxide synthase [NOS]) compete for this limited pool of "promiscuous" CaM. Thus, CaM signaling in myocytes is complex and is further complicated by the effects of CaMKII, which influences some of the same targets and processes as CaM itself does.[18,22]

Calcium Sparks and Waves.

In addition to SR Ca^{2+} release triggered by I_{Ca} during normal excitation-contraction coupling, there is a finite probability that a given RyR will open stochastically. Because of local Ca^{2+}-induced Ca^{2+} release in the junctional cleft, this can lead to spontaneous local SR Ca^{2+} release events known as Ca^{2+} *sparks*.[20,23] Under normal resting conditions, these Ca^{2+} sparks have a low probability (approximately 10^{-4}), which means that at any moment there might be one or two Ca^{2+} sparks per myocyte. Because local $[Ca^{2+}]_i$ declines rapidly as Ca^{2+} diffuses away from the initiating cleft, the resulting local $[Ca^{2+}]_i$ at the

next cleft (1 to 2 μm away) is normally too low to trigger that neighboring site. Thus, Ca^{2+} sparks are very local events (within 2 μm in the cell). However, the probability of Ca^{2+} sparks is greatly enhanced when $[Ca^{2+}]_i$ or $[Ca^{2+}]_{SR}$ is elevated or under conditions in which the RyR is otherwise sensitized (e.g., by oxidation or CaMKII). These conditions can greatly enhance the likelihood that SR Ca^{2+} release from one junction will be sufficient to trigger neighboring junctions 1 to 2 μm away and result in propagating Ca^{2+} waves throughout the whole myocyte. These Ca^{2+} waves can be arrhythmogenic. The Ca^{2+} wave can activate substantial inward current through Na^+/Ca^{2+} exchange (NCX; see later), which can depolarize the membrane potential and contribute to both early and delayed afterdepolarizations (EADs and DADs) during the action potential plateau or during diastole, respectively. EADs result in prolongation of the action potential duration, and DADs can initiate premature ventricular complexes (PVCs).

Calcium Uptake into Sarcoplasmic Reticulum by SERCA

Ca^{2+} is transported into the SR by SERCA, which constitutes almost 90% of the SR protein. Its molecular weight is 115 kDa, with 10 transmembrane domains and large cytosolic and small SR-luminal domains. Three isoforms exist, but in cardiac myocytes the dominant form is SERCA2a. For each molecule of ATP hydrolyzed by this enzyme, two calcium ions are taken up into the SR (**Fig. 22.10**; **see also Fig. 22.9**). SR Ca^{2+} uptake is the primary driver of cardiac myocyte relaxation, and reuptake starts as soon as $[Ca^{2+}]_i$ begins to rise. Because Ca^{2+} removal is slower than Ca^{2+} influx and release, a characteristic rise and fall in $[Ca^{2+}]_i$ called the Ca^{2+} *transient*, takes place. As $[Ca^{2+}]_i$ falls, Ca^{2+} dissociates from troponin C, which progressively switches off the myofilaments. A reduction in SERCA expression or function (as seen in heart failure or energetic limitations) can thus directly result in slower rates of cardiac relaxation. In addition, the strength of SR Ca^{2+} uptake directly influences the diastolic SR Ca^{2+} content and $[Ca^{2+}]_{SR}$, which dictates both the sensitivity of the RyR and the flux rate of SR Ca^{2+} release. Thus, SR Ca^{2+} uptake and release are an integrated system.

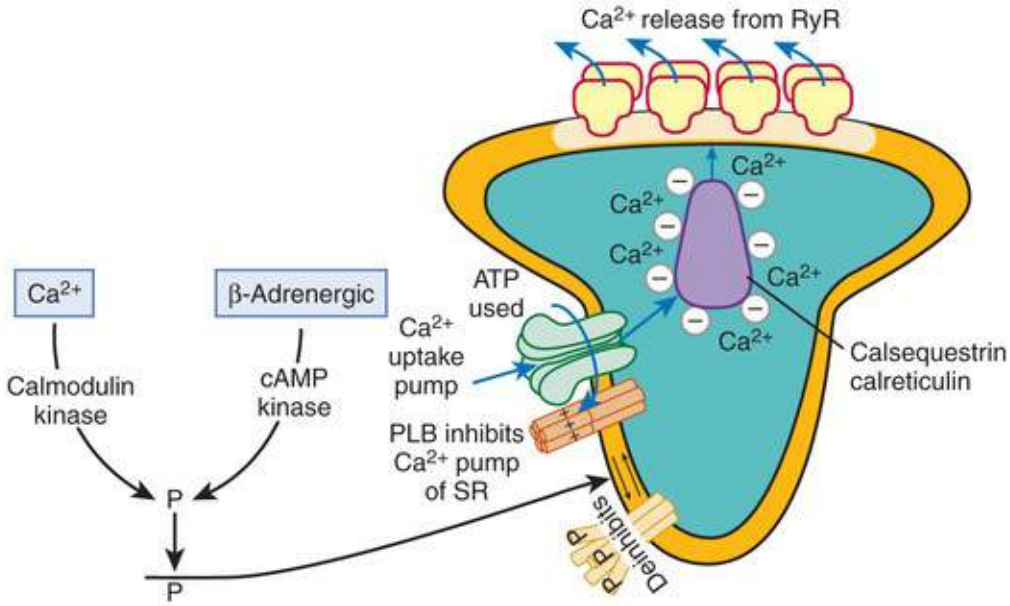

FIGURE 22.10 Ca^{2+} uptake into the SR by SERCA2a. An increased rate of uptake of Ca^{2+} into the SR enhances the rate of relaxation (*lusitropic effect*). PLB, when phosphorylated (*P*), removes the inhibition exerted on the Ca^{2+} pump by its dephosphorylated form. Thereby, Ca^{2+} uptake is increased either in response to enhanced cytosolic [Ca^{2+}] or in response to beta-adrenergic agonists or CaMKII activation (which can be secondary to the beta-adrenergic system).[1,22,31]

Phospholamban (PLB) was so named by its discoverers Tada and Katz[24] to mean "phosphate receiver." PLB is a single-transmembrane pass protein that binds directly to SERCA2a. Under basal conditions, this reduces the affinity of SERCA for cytosolic Ca^{2+}, which results in weaker SR Ca^{2+} uptake at any given $[Ca^{2+}]_i$. However, when PLB is phosphorylated by either PKA or CaMKII (at Ser16 or Thr17, respectively), the inhibitory effect is relieved, thereby resulting in increased rates of SR Ca^{2+} uptake, cardiac relaxation (*lusitropic effect*), and increased SR Ca^{2+} content, which drives stronger contraction (*inotropic effect*; **Fig. 22.10**).

The Ca^{2+} taken up into the SR is stored within the SR before further release. The highly charged, low-affinity Ca^{2+} buffer (K_d approximately 600 µM) *calsequestrin* is found primarily at the jSR and enhances the local availability of Ca^{2+} for release by the nearby RyR. *Calreticulin* is another Ca^{2+}-storing protein that is similar in structure to calsequestrin and probably similar in function. There is also evidence that calsequestrin and two other proteins located in the SR membrane (junctin and triadin) may regulate the properties of the RyR and may be part of the mechanism by which higher $[Ca]_{SR}$ enhances RyR opening.[19] Reuptake by SERCA occurs everywhere in the SR membrane in the network that surrounds the myofilaments. Diffusion of Ca^{2+} within the SR is relatively fast, which allows restoration of $[Ca^{2+}]_{SR}$ at the jSR to occur quickly because Ca^{2+} is taken back up everywhere.[25] Indeed, during normal Ca^{2+} release, intra-SR Ca^{2+} diffusion is rapid enough to limit Ca^{2+} gradients between SR release sites in the jSR and the Ca^{2+} uptake sites. This diffusion also ensures that $[Ca^{2+}]_{SR}$ is relatively uniform throughout the myocyte, which facilitates the uniformity of SR Ca^{2+} release and myofilament activation throughout the cell.

Sarcolemmal Control of Ca^{2+} and Na^{+}

Calcium and Sodium Channels

Excitation-contraction coupling is initiated by voltage-induced opening of the sarcolemmal L-type Ca^{2+} channels. The channels are pore-forming macromolecular proteins that span the sarcolemmal lipid bilayer

to allow a highly selective pathway for transfer of ions into the heart cell when the channel changes from a closed to an open state. Ion channels have two major properties: gating and permeation. Ca^{2+} and Na^{+} channels have two functional "gates," activation and inactivation. At the normal resting membrane potential, the activation gate is closed and the inactivation gate is open, so the channels are available to open on depolarization in their characteristic *voltage-gated* manner. On activation, the inactivation gate starts to close, and the kinetics of inactivation depends on voltage, time, and local $[Ca^{2+}]_i$. Recovery from inactivation (which makes the channels available for activation again) is also time, voltage, and Ca^{2+} dependent. Thus, after the action potential ends, time is required for the Ca^{2+} and Na^{+} channels to recover from inactivation.

Permeation (or conductance) refers to the actual flow of ions or current through the open channel. Ca^{2+} and Na^{+} channels are highly selective for Ca^{2+} and Na^{+}, respectively, relative to other physiologic ions. However, nonphysiologic ions can also permeate; barium (Ba^{2+}) and strontium (Sr^{2+}) readily permeate Ca^{2+} channels, and lithium (Li^{+}) permeates Na^{+} channels, and these ions are sometimes used experimentally to study I_{Ca} and I_{Na}. The concentration of the permeant ion influences the conductance, and in simple Ohm's law terms ($I_{Ca} = g_{Ca}[E_m - E_{Ca}]$), current is the product of conductance (g_{Ca}; which depends on gating and permeation) times the electrochemical driving force ($E_m - E_{Ca}$), which is the difference between the membrane potential (E_m) and the potential that exactly counterbalances the transmembrane $[Ca^{2+}]$ gradient (E_{Ca}, typically +120 mV but changes as $[Ca]_i$ changes). Thus, depolarization activates both Ca^{2+} and Na^{+} channels but also decreases the driving force for the currents.

Molecular Structure of Ca^{2+} and Na^{+} Channels

Both Ca^{2+} and Na^{+} channels contain a major alpha subunit with four transmembrane domains (I to IV), each of which has six transmembrane helices (S1 to S6) and a pore loop between S5 and S6. Each channel also has associated auxiliary subunits (α2δ, β, and γ for Ca^{2+} channels) that may influence trafficking and gating.[1] Activation is now understood in molecular terms as outward movement of the charged S4 transmembrane segment (called the *voltage sensor*) in each of the four domains of Na^{+} and Ca^{2+} channels. This S4 voltage dependence differs among channels, and Na^{+} channels are activated at more negative E_m than are Ca^{2+} channels. *Inactivation* is more complex and involves multiple channel domains, and channels accumulate in this state during prolonged depolarization. The open state is typically the last of a sequence of multiple molecular closed conformations. However, there is typically a binary switch between closed and open such that the single-channel conductance is either near zero or at a constant open conductance. This stochastic nature means that it is often better to speak of the *probability of channel opening* for a single channel, while the whole-cell current integrates flux through all the stochastic channels.

T- Versus L-Type Ca^{2+} Channels

The cardiovascular system has two major types of sarcolemmal Ca^{2+} channels, T-type and L-type channels. T (transient)–type channels open at a more negative voltage, have short bursts of opening, and do not interact with conventional Ca^{2+} antagonist drugs.[1] In adult ventricular myocytes, there does not seem to be appreciable T-type I_{Ca} (except under pathophysiologic conditions). Even when expressed in ventricular myocytes, T-type channels do not seem to target the regions where RyRs are, and consequently they do not participate in excitation-contraction coupling per se. However, measurable T-type I_{Ca} is present in neonatal ventricular myocytes, Purkinje fibers, and some atrial cells (including pacemaker

cells). In these locations the negative activation voltages may allow T-type I_{Ca} to contribute to pacemaker function. Thus, in ventricular myocytes, L-type currents predominate.

L-Type Ca^{2+} Channel Localization and Regulation

L (long-lasting)–type Ca^{2+} channels are concentrated in the T tubules at jSR sites, where they are positioned for Ca^{2+}-induced Ca^{2+} release from the RyR. A fraction of L-type Ca^{2+} channels are also localized in caveolae, where they may participate in local Ca^{2+} signaling, which is somewhat distinct from triggering of SR Ca^{2+} release. L-type Ca^{2+} channels are inhibited by Ca^{2+} channel blockers such as verapamil, diltiazem, and the dihydropyridines. I_{Ca} is rapidly activated during the rising phase of the action potential, but the combination of Ca^{2+} influx via I_{Ca} itself and local SR Ca^{2+} release causes rapid Ca^{2+}-dependent inactivation of I_{Ca}. Voltage-dependent inactivation also contributes to I_{Ca} decline during the action potential, but I_{Ca} continues at low levels throughout the action potential.[26] Inward I_{Ca} is an important contributor to the plateau phase of the cardiac action potential, and excess I_{Ca} or failure of inactivation can prolong the duration of the action potential.

During beta-adrenergic stimulation, cyclic adenosine monophosphate (cAMP) and PKA activity increases and results in phosphorylation of the Ca^{2+} channel and alteration of its gating properties. Notably, most of the molecular components of this beta-adrenergic receptor–cAMP-PKA and phosphatase pathway are localized directly at the L-type Ca^{2+} channel, which facilitates rapid sympathetic activation of changes in I_{Ca}. PKA-dependent phosphorylation of the channel shifts activation (and inactivation) to more negative voltages and increases the open time of the channel. This combination can greatly increase I_{Ca}, which increases both the fraction of SR Ca^{2+} release and the Ca^{2+} load of the cell and SR (to enhance further the Ca^{2+} transient amplitude and inotropic state).

Sodium Channels

Voltage-gated cardiac Na^+ current is carried mainly by the Nav1.5 *cardiac* isoform, but a minor component is attributed to several other, *neuronal* isoforms. The Nav1.5 channels seem to be especially concentrated at the ends of the myocyte near intercalated discs, but the overall density of I_{Na} is relatively uniform between the T tubule and surface membrane.[27] Depolarization activates I_{Na}, and peak I_{Na} is very large and drives the upstroke of the cardiac action potential. Voltage-dependent inactivation of I_{Na} is very rapid, and under normal conditions, Na^+ channels inactivate within a few milliseconds of depolarization. However, a small number of Na^+ channels remain open (or reopen), thereby creating a small but persistent influx of Na^+ throughout the plateau of the action potential. This so-called late sodium current (I_{NaL}) is characterized by ultraslow, voltage-independent inactivation and reactivation.[28] Although the amplitude of I_{NaL} is small (<1% of peak I_{Na}), because peak I_{Na} is so large, this I_{NaL} still constitutes a significant inward current during the plateau phase of the action potential. Under pathophysiologic conditions, the amount of I_{NaL} can increase significantly, which can result in acquired long-QT (LQT) syndrome and also cause Na^+ and Ca^{2+} loading of myocytes, which carries additional arrhythmogenic potential. Thus, I_{NaL} has emerged as a potentially important therapeutic target.[21,29]

Ca^{2+}/Calmodulin-Dependent Protein Kinase II Alters Gating of I_{Na}, I_{Ca}, and Other Channels.

CaMKII is known to be upregulated and chronically activated in numerous pathophysiologic conditions

(e.g., ischemia-reperfusion, heart failure, ROS). Also, CaMKII-dependent Na^+ channel phosphorylation causes increased I_{NaL}, which may produce an acquired form of LQT3 syndrome in patients with genetically normal Na^+ channels[21,29] (**see Fig. 22.9**). At the same time, CaMKII also shifts Na^+ channel availability to more negative voltages, enhances intermediate inactivation, and slows recovery from inactivation, all loss-of-function effects that could cause an acquired Brugada syndrome–like condition. Indeed, this can foster both phenotypes, depending on the heart rate: LQT syndrome at a lower heart rate and Brugada syndrome at a higher heart rate.[21] CaMKII also modulates Ca^{2+} and potassium (K^+) channel currents, which can further promote arrhythmogenesis through EADs and enhanced transmural dispersion of repolarization.[21]

Ion Exchangers and Pumps

To maintain steady-state Ca^{2+} and Na^+ balance, the amount of Ca^{2+} and Na^+ entering during each action potential must be exactly balanced by efflux before the next beat. This is the definition of steady state. For Ca^{2+}, Na^+/Ca^{2+} exchange (NCX) is responsible for extruding most of the Ca^{2+} that entered by I_{Ca} and NCX, whereas a minor fraction is extruded by the plasma membrane Ca^{2+}-ATPase (PMCA). NCX uses the inward $[Na^+]$ electrochemical gradient from 3 Na^+ ions to pump each Ca^{2+} ion into the extracellular space against a large electrochemical gradient (and PMCA uses 1 ATP to pump each Ca^{2+} ion). The main mechanism for extruding Na^+ from the cell is Na^+,K^+-ATPase, which pumps 3 Na^+ ions out for each ATP consumed. Note that NCX also indirectly uses the energy from Na^+,K^+-ATPase to perform its function.

Sodium-Calcium Exchanger

During relaxation, SR Ca^{2+}-ATPase and NCX compete for the removal of cytosolic Ca^{2+}, with the SR pump normally being dominant.[1,4] NCX is reversible, so the direction of Ca^{2+} flux depends on the membrane potential and $[Na^+]$ and $[Ca^{2+}]$ on both sides of the sarcolemma. The E_m at which the inward electrochemical potential is the same for 3 Na^+ ions as for 1 Ca^{2+} ion to enter is the reversal or equilibrium potential (E_{NCX}, similar to that for ion channels). When E_m is higher than this voltage, entry of Ca^{2+} is favored, whereas for E_m below E_{NCX}, the Ca^{2+} efflux mode is thermodynamically favored. During diastole (E_m = −80 mV), NCX normally extrudes Ca^{2+}, but because $[Ca^{2+}]_i$ is low during diastole, the Ca^{2+} flux rate is low (low substrate concentration). As the action potential rises to a peak, E_m normally exceeds E_{NCX} and Ca^{2+} influx is favored, but this occurs only briefly because the high local $[Ca^{2+}]_i$ near the membrane drives NCX back into the Ca^{2+} extrusion mode. When the action potential repolarizes, the negative E_m further enhances the Ca^{2+} extrusion flux, and at this time, $[Ca^{2+}]_i$ is above the diastolic level, so NCX can transport Ca^{2+} effectively. Note that if SR Ca^{2+} release is small and/or I_{Ca} is small or $[Na^+]_i$ is abnormally high (as occurs in heart failure), NCX can continue to bring Ca^{2+} into the cell during much of the action potential duration and in that sense can partially compensate for the lack of I_{Ca} or SR Ca^{2+} release.[1] NCX is also allosterically activated by increasing $[Ca^{2+}]_i$.[30] Although such regulation is time dependent, it may provide a mechanism to enhance the cell's ability to extrude Ca^{2+} when $[Ca^{2+}]_i$ is chronically high, as well as to keep NCX from driving $[Ca^{2+}]_i$ and indirectly $[Ca^{2+}]_{SR}$ to inappropriately low levels when cytosolic Ca^{2+} is in short supply.

Under normal conditions in human or rabbit ventricular myocytes, the steady-state condition occurs when the relative Ca^{2+} removal from the cytosol by SERCA and NCX is 70% to 75% and 20% to 25%, respectively, with PMCA contributing 1% or less (**see Fig. 22.8**). In heart failure, in which SERCA is

downregulated and NCX may be upregulated, the SERCA and NCX contributions are closer to the same. In the mouse and rat ventricle, the difference is larger (92% SERCA, 7% NCX). This steady state involves all the various Ca^{2+} transport systems dynamically, but the relative rates of Ca^{2+} flux by SERCA and NCX at physiologic $[Ca^{2+}]_i$ provide a good estimate. These removal fluxes must also pertain to the integrated Ca^{2+} fluxes into the cytosol. That is, the combination of Ca^{2+} entry by I_{Ca} and NCX in human and mouse ventricle would be 25% and 8%, respectively. In other words, amplification of the Ca^{2+} transient by SR Ca^{2+} release is only approximately fourfold for human or rabbit ventricle (and less in heart failure) but approximately 12-fold for mouse or rat ventricle.

Heart Rate and Na^+/Ca^{2+} Exchange.

NCX participates in the force-frequency relationship (treppe or Bowditch phenomenon).[1] An increasing heart rate (independent of sympathetic activation) increases the amount of Na^+ and Ca^{2+} entry per unit time and also diminishes the time available for extrusion of Na^+ and Ca^{2+}. This will tend to increase the amount of Ca^{2+} in the SR simply because of more frequent I_{Ca} pulses and less time for removal of Ca^{2+} from the cell. However, the same happens for Na^+, and the elevation in $[Na^+]_i$ also limits the ability of NCX to extrude Ca^{2+}, which further increases the amount of Ca^{2+} in the myocyte and SR when the cell achieves a new steady state. This NCX effect (once referred to as the “sodium pump lag” hypothesis) thus amplifies the intrinsic inotropic effect of an increase in heart rate.

Sodium Pump (Na^+,K^+–Adenosine Triphosphatase)

During the normal heartbeat, Na^+ enters the myocyte mainly by Na^+ channels and NCX, with NCX being quantitatively most important.[31] Na^+/H^+ exchange also mediates significant Na^+ influx, particularly when cells are acidotic. In the steady state, this Na^+ influx is matched by an equal Na^+ efflux, mediated mainly by sarcolemmal Na^+,K^+-ATPase, or the Na^+ pump. The Na^+ pump is activated by internal Na^+ or external K^+ and transports 3 Na^+ ions out and 2 K^+ ions in per ATP molecule used. During this process, one positive charge leaves the cell, and thus Na^+,K^+-ATPase is electrogenic and carries an outward current.[31] Na^+,K^+-ATPase in the heart is modulated by the endogenous accessory protein *phospholemman* (PLM), which works in a manner analogous to the PLB-SERCA2a mechanism. That is, at baseline, PLM reduces the intracellular Na^+ affinity of Na^+,K^+-ATPase, but when it is phosphorylated (by either PKA or protein kinase C [PKC]), that inhibitory effect is relieved.[31] Thus, during sympathetic activation, Na^+,K^+-ATPase activity is increased at any given $[Na^+]_i$ to keep up better with the higher rates of Na^+ influx that occur under this condition.

Digitalis glycosides inhibit Na^+,K^+-ATPase and have been used for more than 200 years as a cardiac inotropic drug for the treatment of heart failure, although their use has diminished in recent years (**see also Chapter 25**). Partial inhibition of Na^+,K^+-ATPase causes an increase in $[Na^+]_i$ in myocytes, which limits the ability of NCX to extrude Ca^{2+}, resulting in enhanced myocyte and SR Ca^{2+} loading and release. A limitation with this approach is the narrow therapeutic range, and too much inhibition can lead to myocyte Ca^{2+} overload and trigger arrhythmias. However, this emphasizes the close interrelationship between Na^+ and Ca^{2+} regulation mediated by the powerful NCX present in cardiac myocytes.

Adrenergic Signaling Systems

Physiologic Fight-or-Flight Response

During the classic adrenergic fight-or-flight response, cardiac myocyte beta-adrenergic receptors are activated, which leads to increased cAMP production and PKA activation and consequent phosphorylation and altered function of numerous myocyte targets. This results in an increased heart rate (*positive chronotropy*), increased contractility (*positive inotropy*), faster cardiac relaxation (*positive lusitropy*), and enhanced conduction velocity through the conduction system (*positive dromotropy*). These events enhance cardiac output by enhancing the heart rate, stroke volume, and diastolic filling. Thus the adrenergic response is a key physiologic mechanism for increasing cardiac output in response to increased metabolic and hemodynamic demands.

During the adrenergic response, norepinephrine is released by sympathetic neurons at small swellings on small end-branches, or *varicosities*, into the local myocyte environment (**Fig. 22.11**), analogous to synaptic transmission. Norepinephrine is synthesized in the varicosities from dopa and dopamine and the amino acid tyrosine. The norepinephrine thus synthesized is stored within the terminals in *storage granules* (or *vesicles*) to be released on stimulation by an adrenergic nervous impulse. Thus, when central stimulation increases during excitement or exercise, an increased number of sympathetic nerve impulses liberate an increased amount of norepinephrine from the terminals into the synaptic cleft. Most of the norepinephrine released is taken up again by the nerve terminal varicosities to reenter the storage vesicles or to be metabolized. The norepinephrine in these *synaptic clefts* interacts with both alpha- and beta-adrenergic receptors on myocytes and also alpha-adrenergic receptors in arterioles (**Table 22.2**). The beta-adrenergic effects on the sinoatrial (SA) node and conduction system contribute to the chronotropic and dromotropic effects mentioned earlier, whereas those on myocytes are responsible mainly for the inotropic and lusitropic effects. These effects can also be modulated by coactivation of myocyte alpha-adrenergic receptors. Increased alpha-adrenergic activity causes arteriolar constriction and increased vascular impedance, although local metabolic control of arteriolar resistance is strong in the heart and dominates coronary resistance in arterioles. Parasympathetic (vagal) innervation is strongest in the conduction system, where local release of acetylcholine (ACh) activates muscarinic receptors and tends to slow the heart rate and conduction velocity (**Fig. 22.11**). In these conditions the heart rate and blood pressure fall. The influence of these main effector pathways is also modulated by numerous other signaling factors, such as local adenosine and nitric oxide (NO) and the powerful neuromodulator angiotensin II, which can also potentiate release of norepinephrine and vasoconstriction. Both alpha- and beta-adrenergic receptors are part of the family of seven–transmembrane domain G protein–coupled receptors (GPCRs).

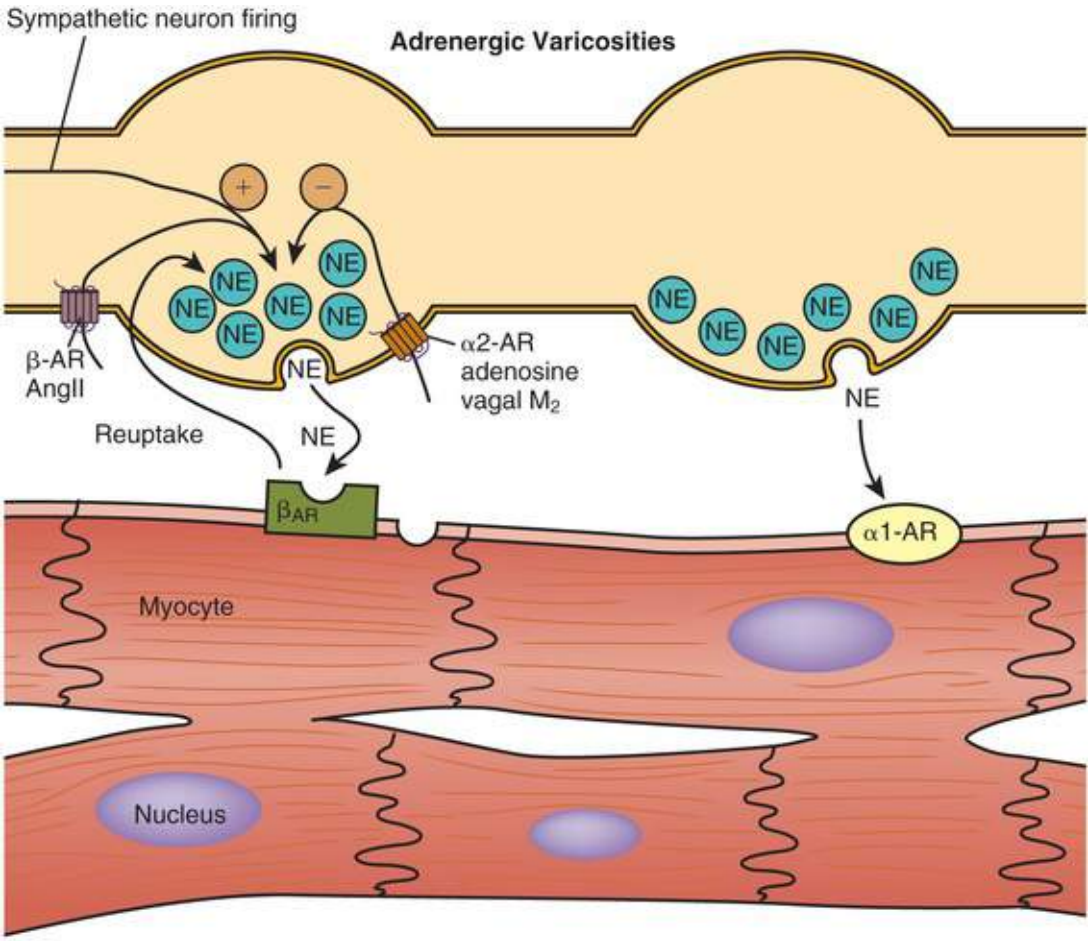

FIGURE 22.11 Norepinephrine (NE) release from sympathetic neurons**.** NE is released from storage granules in adrenergic varicosities into narrow, synapse-like spaces near its receptors in the sarcolemma of the cardiac and smooth muscle myocytes of the heart and arterial walls. In cardiomyocytes, beta-adrenergic receptor (AR) activation increases heart rate (chronotropy), contractile force (inotropy) and relaxation (lusitropy), and conduction (dromotropy). However, NE also activates cardiac myocyte $alpha_1$-adrenergic receptors, which can further modulate contractility and myocyte signaling cascades. In arterioles, NE predominantly causes vasoconstriction via postsynaptic $alpha_1$ receptors. NE also stimulates presynaptic $alpha_2$ receptors to invoke feedback inhibition that can limit its own release. Circulating epinephrine stimulates vascular vasodilatory $beta_2$ receptors but also presynaptic receptors on the nerve terminal, which promotes NE release. Angiotensin II (AngII) is also powerfully vasoconstrictive and acts both by stimulation of NE release (presynaptic receptors, as indicated schematically) and directly on arteriolar AngII receptors. M_2 is muscarinic receptor, subtype two.

TABLE 22.2

Comparative Cardiovascular Effects of Alpha- and Beta-Adrenergic Receptor Stimulation

	ALPHA$_1$ MEDIATED	BETA MEDIATED
Electrophysiologic effects	±	++
		Conduction
		Pacemaker
		Heart rate
		− AP duration
Myocardial mechanics	±	++
		Contractility, lusitropy
		Stroke volume
		Cardiac output
Myocardial metabolism	±	++
	Glycolysis	O_2 uptake ↑
		ATP
Signal systems	GPCR, can activate PKC and MAPK	GPCR, activates cAMP and PKA
Coronary arterioles	++	+ Direct dilation
	Constriction	+++ Indirect dilation (metabolic)
Peripheral arterioles	+++	+
	Constriction	Dilation
	SVR ↑	SVR ↓
	SBP ↑	SBP ↓

AP, Action potential; *GPCR,* G protein–coupled receptor; *MAPK,* mitogen-activated protein kinase; *PK,* protein kinase; *SBP,* systolic blood pressure; *SVR,* systemic vascular resistance.

Beta-Adrenergic Receptor Subtypes

Cardiac beta-adrenergic receptors are chiefly the beta$_1$ subtype, whereas most noncardiac receptors are beta$_2$. Beta$_2$ receptors constitute approximately 20% of the total beta receptor population in the left ventricle. Whereas beta$_1$ receptors are linked to the stimulatory G protein G_s, a component of the G protein–adenylyl cyclase system, beta$_2$ receptors are linked to both G_s and the inhibitory protein G_i (**Fig. 22.12**), so their signaling pathway bifurcates at the first postreceptor step.[4] In humans the positive inotropic response to beta$_2$ stimulation by salbutamol (albuterol) occurs, at least in part, through beta$_2$ receptors on the terminal neurons of cardiac sympathetic nerves, thereby releasing norepinephrine, which in turn exerts dominant beta$_1$ effects.[4] Indirect evidence suggests that the G_i pathway is relatively augmented in heart failure, whereas the strength of the G_s path is lessened because of uncoupling of G_s from the beta receptor (**see Chapter 23**). There also appear to be a small number of beta$_3$-adrenergic receptors in cardiac myocytes that seem to produce more G_i-mediated negative inotropic signaling, mediated in part by NO, but this pathway is not as well understood. The beta-adrenergic receptor site is highly stereospecific, the best fit among catecholamines being achieved with the synthetic agent isoproterenol rather than with the naturally occurring catecholamines norepinephrine and epinephrine. In the case of beta$_1$ receptors, the order of agonist activity is isoproterenol > epinephrine = norepinephrine, whereas in the case of beta$_2$ receptors, the order is isoproterenol > epinephrine > norepinephrine. Human beta$_1$ and beta$_2$ receptors have both been cloned and studied extensively.[4] The transmembrane domains are the site of agonist and antagonist binding, whereas the cytoplasmic domains interact with G proteins.

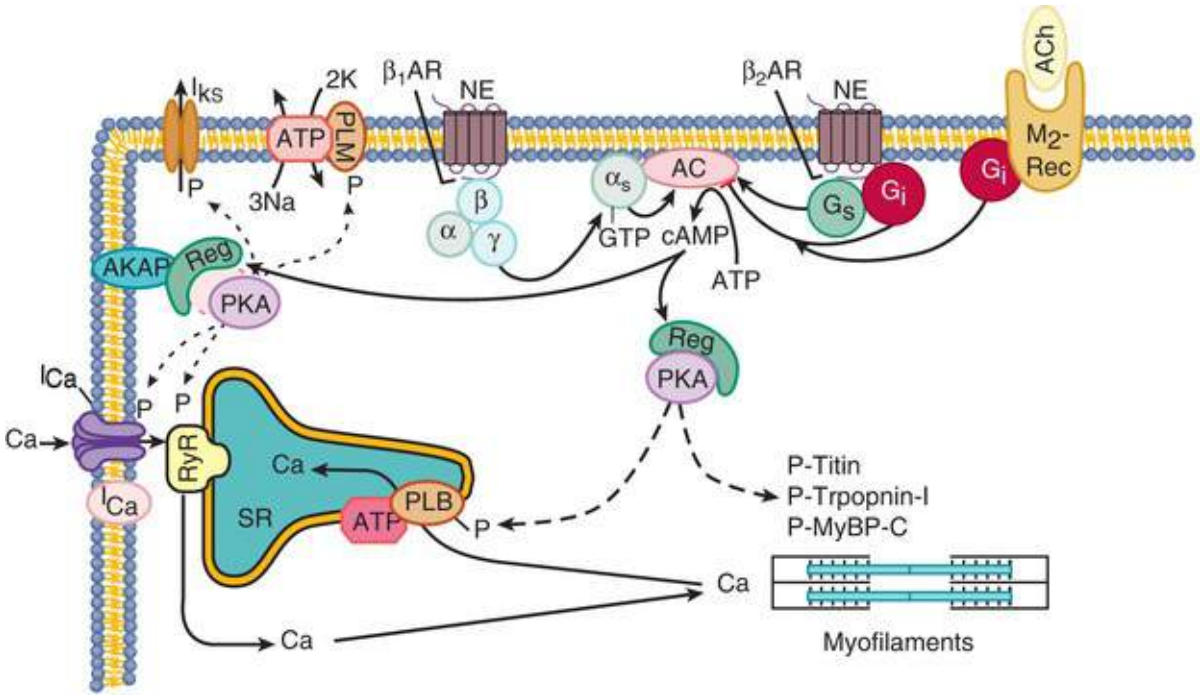

FIGURE 22.12 Beta-adrenergic and muscarinic activation in cardiac myocytes interact. Activation of beta$_1$-adrenergic receptors (β_1*AR*) activate adenylyl cyclase (*AC*) via G_s (via the activated alpha subunit (α_s) dissociation from the beta and gamma subunits (β and γ). AC produces cAMP, which activates protein kinase A (*PKA*), which phosphorylates (*P*) several key functional targets (*broken arrows*). β_2-AR activate both G_s and G_i, which activate or inhibit AC, respectively. Activation of muscarinic M_2 receptors (*M_2-Rec*) by acetylcholine (*ACh*) from parasympathetic neurons inhibits AC via G_i. *Reg,* Regulatory subunit of PKA; *PLM,* phospholemman; *PLB,* phospholamban. (Modified from Bers DM. Excitation-Contraction Coupling and Cardiac Contractile Force. Dordrecht, Netherlands: Kluwer Academic; 2001.)

Alpha-Adrenergic Receptor Subtypes

The two alpha-adrenergic receptor isoforms are alpha$_1$ and alpha$_2$. Those on the sarcolemma of vascular smooth muscle are vasoconstrictor alpha$_1$ receptors, whereas those situated on the terminal varicosities are alpha$_2$-adrenergic receptors that feed back (**see Fig. 22.11**) to inhibit release of norepinephrine. Pharmacologically, an alpha$_2$-adrenergic receptor mediates a response in which the effects resemble those of the pharmacologic agent phenylephrine. Among catecholamines, the relative potencies of alpha$_1$-agonists are norepinephrine > epinephrine > isoproterenol. Physiologically, norepinephrine liberated from nerve terminals is the chief stimulus to vascular alpha$_1$-adrenergic activity. Both alpha$_1$ and alpha$_2$ receptors are also found in cardiac myocytes, where their activation can fine-tune Ca^{2+} transients, ionic currents, and myofilament properties acutely, but they are also known to be important modulators of cardiac remodeling (in both adaptive and maladaptive contexts).[32]

G Proteins

G proteins are a superfamily of proteins that bind guanine triphosphate (GTP) and other guanine nucleotides. G proteins are crucial in carrying the signal onward from the agonist and its receptor to the activity of the membrane-bound enzyme system that produces the second messenger cAMP (**Fig. 22.13**; **see also Fig. 22.12**).[4] Thus the combination of the beta receptor, G protein complex, and adenylyl cyclase is the crux of beta-adrenergic signaling.

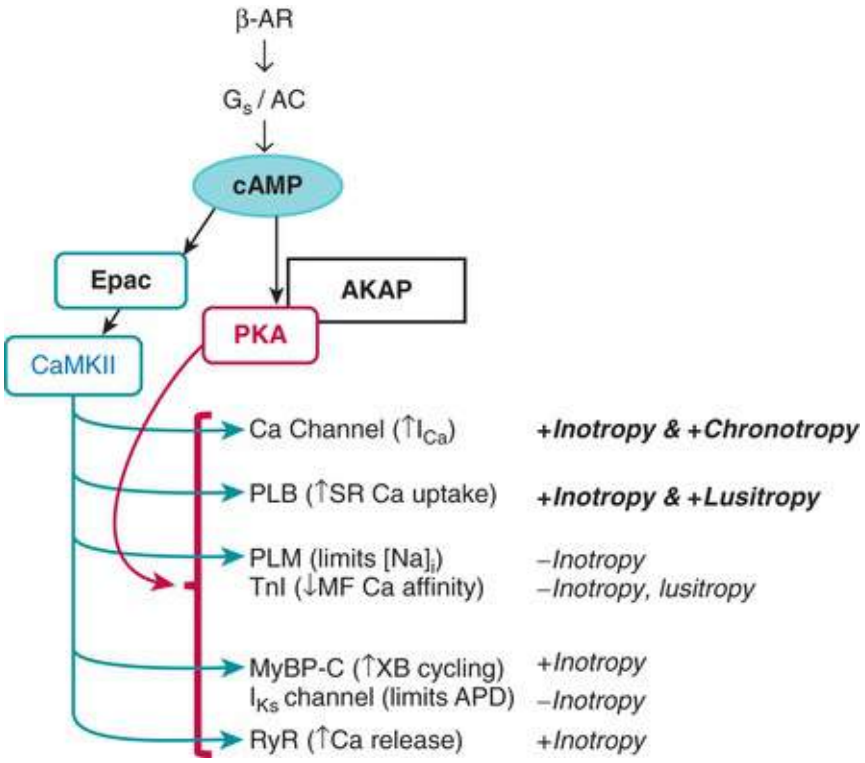

FIGURE 22.13 Key roles of PKA (and CaMKII) in beta-adrenergic responses. Major intracellular effects of beta-agonist catecholamines are via the formation of cAMP, which increases the activity of PKA and also Epac (exchange protein activated by cAMP). PKA is localized by A-kinase anchoring proteins (AKAPs) that target PKA function to local nanodomains. Epac also activates CaMKII which can phosphorylate and modulate function of some of the same targets as PKA (often by phosphorylation at different amino acids).

The Stimulatory G Protein G_s.

The G protein itself is a heterotrimer composed of G_α, G_β, and G_γ, which on receptor stimulation splits into the alpha subunit that is bound to GTP and the beta-gamma subunit. Either of these subunits may regulate different effectors such as adenylyl cyclase, phospholipase C, and ion channels. The activity of adenylyl cyclase is controlled by two different G protein complexes, namely, G_s, which stimulates, and G_i, which inhibits. The alpha subunit of G_s (α_s) combines with GTP and then separates from the other two subunits to enhance the activity of adenylyl cyclase. The beta and gamma subunits (beta-gamma) appear to be linked structurally and functionally.

The Inhibitory G Protein G_i.

In contrast, a second trimeric GTP-binding protein, G_i, is responsible for inhibition of adenylyl cyclase.[4] During stimulation of muscarinic and some $beta_2$-adrenergic receptors, GTP binds to the inhibitory alpha subunit α_i. The latter then dissociates from the other two components of the G protein complex, which are, as in the case of G_s, the combined beta-gamma subunits. The beta-gamma subunits act as follows. By stimulating the enzyme guanosine triphosphatase (GTPase), they break down the active α_s subunit (α_s-GTP) such that less activation of adenylyl cyclase occurs in response to alpha stimulation. Furthermore, the beta-gamma subunit activates the K_{ACh} channel, which can slow SA node firing and thereby contribute to the bradycardic effect of cholinergic stimulation. The α_i subunit may also activate another potassium channel (K_{ATP}) that stabilizes the diastolic potential. The major physiologic stimulus for G_i is thought to be vagal muscarinic receptor stimulation (although $beta_2$-adrenergic receptors may contribute as well). In

addition, adenosine, by interaction with A_1 receptors, couples to G_i to inhibit contraction and heart rate. The adenosine A_2 receptor paradoxically increases cAMP. The latter effect, only of ancillary significance in the myocardium, is of major importance in vascular smooth muscle, where it induces vasorelaxation. Pathologically, G_i is increased in experimental postinfarct heart failure[4] and in donor hearts before cardiac transplantation.[4]

A Third G Protein, G_q.

This protein links a group of GPCRs, including the alpha-adrenergic receptor and those for angiotensin II and endothelin-1, to another membrane-associated enzyme, phospholipase C, and then to PKC and PKD (and IP_3-induced Ca^{2+} mobilization). G_q has at least four isoforms, two of which have been found in the heart. This G protein, unlike G_i, is not susceptible to inhibition by pertussis toxin. Overexpression of G_q in mice induces a dilated cardiomyopathy,[4] which is of interest because angiotensin II and endothelin, which act through G_q, are overactive in human heart failure. Conversely, when the activity of G_q is genetically inhibited, the hypertrophic response to pressure overload is attenuated, wall stress increases, but cardiac function is relatively well maintained.

Cyclic Adenosine Monophosphate and Protein Kinase A

Adenylyl Cyclase

Adenylyl cyclase (also called adenylate or adenyl cyclase) catalyzes formation of the second messenger cAMP. Several isoforms exist, but AC5 and AC6 are most prominent in cardiac myocytes, and these isoforms are partially inhibited by high $[Ca^{2+}]_i$. Adenylyl cyclase, when stimulated by G_s, produces cAMP, which acts through multiple intracellular signals (including importantly PKA) to mediate the chronotropic, inotropic, lusitropic, and dromotropic effects of cardiac beta-adrenergic agonists. In contrast, cholinergic (and vagal) stimulation can inhibit adenylyl cyclase through G_i, to slow heart rate, but also limit cAMP formation downstream of G_s activation.

Adenylyl cyclase is the only enzyme that produces cAMP, using low concentrations of Mg^{2+}-ATP as substrate. It is a transmembrane enzyme, with most mass on the cytoplasmic side where G proteins interact. Cyclic guanosine monophosphate (cGMP) is a related second messenger that often antagonizes cAMP effects. cAMP has very rapid turnover as a result of a constant dynamic balance between its formation by adenylyl cyclase and conversion to AMP by phosphodiesterases (PDEs). Several major PDE isoforms have different substrate specificity (cAMP versus cGMP) and are differentially regulated by cyclic nucleotides and Ca^{2+}/calmodulin.[33] In general, directional changes in the tissue content of cAMP can be related to directional changes in cardiac contractile activity, but local subcellular domains may have differential cAMP and PKA regulation that depends in part on PDE isoform localization. For example, while beta-adrenergic stimulation increases both cAMP and PKA target phosphorylation, differences may occur at ion channel and myofilament target sites.[34] *Forskolin* is a potent direct adenylyl cyclase activator, and isobutyl methylxanthine (*IBMX*) is a PDE inhibitor that inhibits all PDE isoforms. These are widely used agents experimentally, but isoform-specific PDE inhibitors are being explored as more targeted therapeutic strategies. A number of hormones or peptides can couple to myocardial adenylyl cyclase independent of the beta-adrenergic receptor. These include glucagon, thyroid hormone, prostacyclin, and calcitonin gene–related peptide.

There is also a GTP *e*xchange *p*rotein directly *a*ctivated by *c*AMP (*Epac*) that is activated in parallel to cAMP-dependent PKA activation. This allows additional parallel signaling downstream of beta-

adrenergic activation. For example, beta-adrenergic activation of SR Ca^{2+} release is mediated by cAMP-Epac–dependent signaling to CaMKII and consequent RyR2 phosphorylation,[35] and not by PKA activation.

Protein Kinase A

PKA occurs in two isoforms, but PKA-II predominates in cardiac cells. It is now clear that many key cAMP effects are mediated by activation of PKA and phosphorylation of key proteins.[36] Each PKA complex is composed of two regulatory (R) and two catalytic (C) subunits, the latter of which transfers the terminal phosphate of ATP to serine and threonine residues of the protein substrates. When cAMP interacts with the inactive protein kinase, it binds to the R subunits, causing partial release and activation of the C subunits. A former dogma was that the C subunits were completely released from the R subunits, but more recent evidence suggests that a loose tethering remains when PKA is active. The R subunits are in turn bound to specific *A-kinase anchoring proteins* (AKAPs) that target PKA-dependent phosphorylation at specific subcellular targets.[37] This helps to explain the local compartmentalization of cAMP and PKA signaling. Indeed, there is good evidence that beta-adrenergic receptors, G proteins, adenylyl cyclase, PKA, AKAP, PDE, and phosphatases can all complex on targets such as the L-type Ca^{2+} channel and RyR2 to facilitate local PKA-dependent signaling[15,38,39] (**Fig. 22.13**).

$Beta_1$-Adrenergic and PKA Signaling in Ventricular Myocytes

The sequence of events for PKA activation is as follows (**see Fig. 22.12**): catecholamine stimulation → beta receptor → molecular changes → binding of GTP to the α_s subunit of G protein → GTP-α_s subunit stimulating adenylyl cyclase → formation of cAMP from ATP → activation of cAMP-dependent PKA, locally bound by an AKAP → phosphorylation of the target proteins. The L-type Ca^{2+} channel is rapidly phosphorylated by this cascade, which results in both a large increase in the amount of peak I_{Ca} and a shift in the activation voltage to more negative potentials. This increases the amount of Ca^{2+} that enters the cell at each beat and also enhances excitability (including in pacemaker cells). In addition, the higher I_{Ca} triggers more SR Ca^{2+} release, but the higher peak I_{Ca} and SR Ca^{2+} release also enhance Ca-dependent inactivation of I_{Ca}, which limits the total amount of Ca^{2+} entry during the action potential. This contributes to an increased Ca^{2+} transient amplitude, the inotropic effect, and also the chronotropic and dromotropic effects of PKA in heart (**Figs. 22.12 to 22.14**).

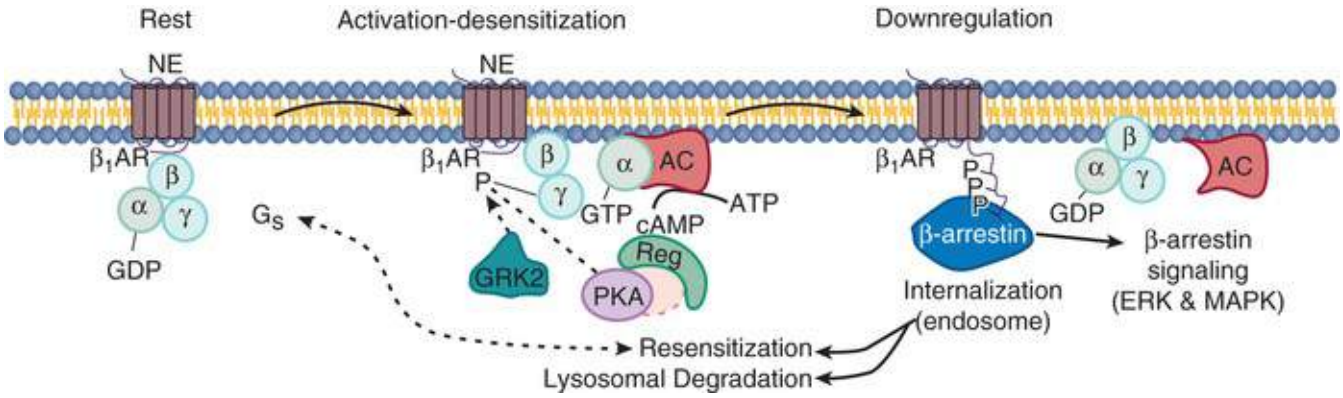

FIGURE 22.14 Beta$_1$-adrenergic receptor (β_1AR) activation, desensitization, downregulation, and recycling. Prolonged β_1AR activation causes recruitment of a G-protein receptor kinase (GRK2) that phosphorylates the receptor and favors recruitment of beta-arrestin (β-arrestin). β-arrestin promotes its own signaling cascades (e.g. via extracellular receptor and MAP kinase (ERK and MAPK) as well as internalization of the β_1AR into endosomes. From there β_1AR can either be degraded or recycled to the cell surface. (Modified from Bers DM. Excitation-Contraction Coupling and Cardiac Contractile Force. Dordrecht, Netherlands: Kluwer Academic; 2001.)

Another major contributor to the inotropic effect of PKA in the heart is phosphorylation of phospholamban. PLB is associated with SERCA2 and at baseline inhibits the Ca^{2+} pump by reducing its affinity for Ca^{2+}. On phosphorylation of PLB by PKA (or CaMKII), the inhibitory effect is relieved and the Ca^{2+} pumping function greatly enhanced. This allows more Ca^{2+} to accumulate inside the SR during the cardiac cycle, which enhances the amount that can then be released (thereby contributing to inotropy). The faster rate of SR Ca^{2+} uptake is also the major factor in accelerating relaxation, the lusitropic effect of PKA. This occurs because twitch $[Ca^{2+}]_i$ decline is faster, which allows faster Ca^{2+} dissociation from the myofilaments.

Phosphorylation of troponin I by PKA also contributes to the enhanced lusitropic effect of beta-adrenergic agonists (**see Fig. 22.13**). PKA-dependent troponin I phosphorylation reduces myofilament sensitivity for calcium, which is intrinsically negatively inotropic, but has the benefit of faster dissociation of Ca^{2+} from myofilaments, which hastens relaxation and diastolic filling. In addition, myosin-binding protein C is also a target for PKA, and its phosphorylation appears to be responsible for accelerating the cross-bridge turnover rate. This effect also serves largely to offset the negative inotropic effect of troponin I phosphorylation and may also hasten the rate of sarcomere shortening at a given $[Ca^{2+}]$ and mechanical load, which could enhance stroke volume.[40]

PKA also phosphorylates the RyR, although the impact of this effect is controversial.[41] One group has suggested that this displaces the immunophilin FKBP-12.6 from its binding to RyR2, thereby activating RyR openings, and that this is an important part of the beta-adrenergic inotropy and cardiac dysfunction in heart failure.[42] However, this idea has been strongly challenged by extensive mechanistic experimental data and theoretical arguments from numerous groups worldwide.[41] Even though the effects of PKA on the cardiac RyR may enhance the rate of RyR activation during excitation-contraction coupling, it does not seem to increase the amount released (for a given I_{Ca} trigger and SR Ca^{2+} load),[43] nor does it directly enhance the likelihood of spontaneous SR Ca^{2+} release events.[44] Moreover, even when the RyR is sensitized, it causes enhanced SR Ca^{2+} release only for several beats, which then drives greater efflux of Ca^{2+} from the cell (by NCX) and reduces the SR Ca^{2+} content such that it cannot explain the enhanced Ca^{2+} transients during beta-adrenergic activation.[45]

PKA also phosphorylates PLM, a small PLB-like protein that regulates Na^+,K^+-ATPase (see earlier).[31] This is actually a sensible integral part of the fight-or-flight response because the increase in heart rate

incurs more frequent I_{Na} pulses and Ca^{2+} influx (by I_{Ca}) that causes more Na^+ influx by NCX, resulting in a major increase in $[Na^+]_i$. This Na^+,K^+-ATPase activation limits the rise in $[Na^+]_i$ during sympathetic activation and thus allows NCX to remain functional in removing Ca^{2+} from the myocyte. The increase in Na^+,K^+-ATPase function thus is somewhat negatively inotropic (by limiting $[Na^+]_i$). This is opposite the effect mediated by inhibition of Na^+,K^+-ATPase by digitalis cardiac glycosides. Notably, digitalis toxicity is associated with cellular Ca^{2+} overload and arrhythmogenesis. Consequently, Na^+,K^+-ATPase stimulation may limit these arrhythmogenic consequences associated with higher Ca^{2+} loading.

Beta-Adrenergic Receptor Desensitization.
There is a potent and rapid feedback mechanism whereby beta-adrenergic receptor stimulation can be muted so that the signal can be turned off (**Fig. 22.14**). Physiologically, this mechanism of beta-adrenergic receptor *desensitization* occurs within minutes**.** Sustained beta-agonist stimulation recruits a G protein–coupled receptor kinase (GRK2; also called beta-adrenergic receptor kinase 1 [βARK1]). GRK2 phosphorylates a site on the carboxyl-terminal of the beta-adrenergic receptor, which by itself does not switch off signaling. However, GRK2 activity increases beta receptor affinity for *arrestins*, which uncouple receptor signaling. Beta-arrestin is a scaffolding and signaling protein that links to one of the cytoplasmic loops of the beta-adrenergic receptor and lessens activation of adenylyl cyclase, thereby inhibiting receptor function. Furthermore, beta-arrestin can switch agonist coupling from G_s to G_i and also lead to internalization of the beta-adrenergic receptor.[4] *Resensitization* of the receptor occurs if the phosphate groups are removed by a phosphatase, and the receptor then more readily linked to G_s (or by recycling the internalized receptor to the surface). Beta-arrestin signaling can also evoke an alternative protective path by activating the epidermal growth factor receptor (EGFR), which leads to the protective extracellular signal–related kinase (ERK)/MAPK pathway[46] (**Fig. 22.14**). Although the GRK2-arrestin effects are best described for the $beta_2$ receptor, they also occur with the $beta_1$ receptor. Prolonged beta receptor stimulation, as in hyperadrenergic conditions, is linked to adverse end results in that it both impairs contractile function and enhances adverse signaling. As discussed in **Chapter 23**, this mechanism also plays a role in long-term desensitization of the beta-adrenergic receptor as in heart failure, and transgenic mice overexpressing GRK2 are protected from heart failure.[47]

Ca^{2+}/Calmodulin-Dependent Protein Kinase II

CaMKII is a serine/threonine-specific protein kinase that is regulated by the Ca^{2+}/CaM complex. CaMKII is involved in many signaling cascades in the heart, and several of the key proteins that are phosphorylated by PKA are also phosphorylated by CaMKII (**see Fig. 22.13**), typically at different amino acids. Moreover, there is good evidence that CaMKII is activated during beta-adrenergic stimulation.[22] Thus, CaMKII signaling is often coactivated with PKA and can synergize at downstream targets.[22] CaMKII activates L-type Ca^{2+} channels (I_{Ca} facilitation), which results in increased peak I_{Ca} and also slows down inactivation, thereby boosting total Ca^{2+} influx by I_{Ca}. CaMKII also phosphorylates PLB at Thr17 (versus at Ser16 by PKA) and, by the same mechanism as for PKA, can enhance SR Ca^{2+} uptake. However, the CaMKII effects on I_{Ca} and SERCA/PLB are typically smaller in magnitude than the effects of PKA activation, so PKA is probably dominant physiologically at these targets. CaMKII can also phosphorylate RyR2 at Ser2814, close to a recognized PKA target site (2808). In contrast to PKA, it is

more universally agreed that CaMKII strongly activates the RyR and that this effect may be important in causing a diastolic SR Ca^{2+} leak, which can both reduce the SR Ca^{2+} content (contributing to both systolic and diastolic dysfunction) and contribute to triggered arrhythmias.[21,22,41] CaMKII can also phosphorylate cardiac Na^+ and K^+ channels and lead to arrhythmogenic consequences.[21,22] CaMKII-dependent activation of the late Na^+ current may also lead to elevated intracellular [Na^+] and [Ca^{2+}], which can create Ca^{2+} overload and trigger arrhythmias. Myofilament proteins are also targets for CaMKII (e.g., myosin-binding protein C),[48] but the relative functional importance of this effect is not yet fully resolved. The chronic activation of CaMKII in pathologic states such as heart failure makes these pathways important to keep in mind.

Cholinergic and Nitric Oxide Signaling

Cholinergic Signaling

Parasympathetic stimulation reduces the heart rate and is negatively inotropic. As in adrenergic signaling, there is an extracellular messenger (ACh), a GPCR (the *cholinergic* muscarinic receptor), and a sarcolemmal signaling system (G protein system, specifically G_i). The *myocardial* muscarinic receptor (M_2) is a GPCR (**see Fig. 22.12**). Receptor stimulation produces a negative chronotropic response that is inhibited by atropine. NO, also formed by $beta_3$-adrenergic signaling,[49] facilitates cholinergic signaling at two levels, the nerve terminal and the activity of the enzyme system that produces the second messenger cGMP. *Neuregulins* are growth factors that maintain the activity of the muscarinic receptor, thereby indirectly helping to balance the normal parasympathetic modulation of excess beta-adrenergic stimulation.[50,51]

Muscarinic G_i activation also inhibits adenylyl cyclase, which functionally integrates the input from activating G_s (e.g., from $beta_1$-adrenergic and other receptors) and the inhibitory effects of G_i (from M_2 muscarinic and other receptors; **Fig. 22.12**). As a result, vagal stimulation also limits [cAMP] resulting from ambient sympathetic tone. The net effect is slowing of the heart rate. Vagal activity has less strong effects on atrial or ventricular myocyte electrophysiology, Ca^{2+} transients, or contractility than on conduction system cells, in part because of the lower density of vagal innervation at myocytes, but also because of the intrinsic properties of the cells (e.g., lacking major pacemaker function). Nevertheless, vagal activation can shorten the action potential duration in the atria and, to a lesser degree, in the ventricles (primarily by $I_{K(Ach)}$ activation). Similarly, vagal stimulation can cause antiadrenergic effects in myocytes by effects on adenylyl cyclase that limit cAMP levels (see earlier) and the consequent downstream effects associated with a physiologic level of sympathetic tone (**see Figs. 22.12 and 22.13**).

Vagal innervation in the heart is highest in the SA and atrioventricular (AV) nodes, with lower density in atrial myocardium and the lowest density in ventricular myocardium. Activation of M_2 receptors results in activation of the coupled G_i and consequent limitation of cAMP signaling. ACh also directly activates $I_{K(ACh)}$, by a K^+ channel thought to result from heterotetramers of inward rectifier K^+ channel protomers Kir3.1 and Kir3.4. This increased K^+ conductance causes more negative diastolic potential in pacemaker cells and also impairs the rate of diastolic depolarization (in the same way that I_{K1} stabilizes the diastolic potential of atrial and ventricular myocytes). These factors slow the rate of SA node pacemaker firing and thus the heart rate.

Cyclic Guanosine Monophosphate Signaling in the Heart

The second messenger cGMP typically has negative inotropic effects in the heart, in contrast to its cyclic nucleotide cousin cAMP. Cyclic GMP is produced from GTP in cardiac myocytes mainly by soluble and particulate guanylyl cyclases, which are activated downstream of NO and natriuretic peptide receptor activation, respectively (**Fig. 22.15**), and possibly by cholinergic effects. Local subcellular regions in which NO and cGMP signaling take place are also likely to exist.[38] Of note, cell-permeable analogues of cGMP have antiadrenergic effects. When local [cGMP] is elevated, it can stimulate protein kinase G (PKG), which results in inhibitory cardiac effects such as a decreased heart rate and negative inotropic response. These effects are largely achieved by modulation of Ca^{2+} entry through L-type Ca^{2+} channels and through alteration of internal Ca^{2+} cycling.[51,52] PKG has also been suggested to be a critical suppressor of pathophysiologic hypertrophy.[53]

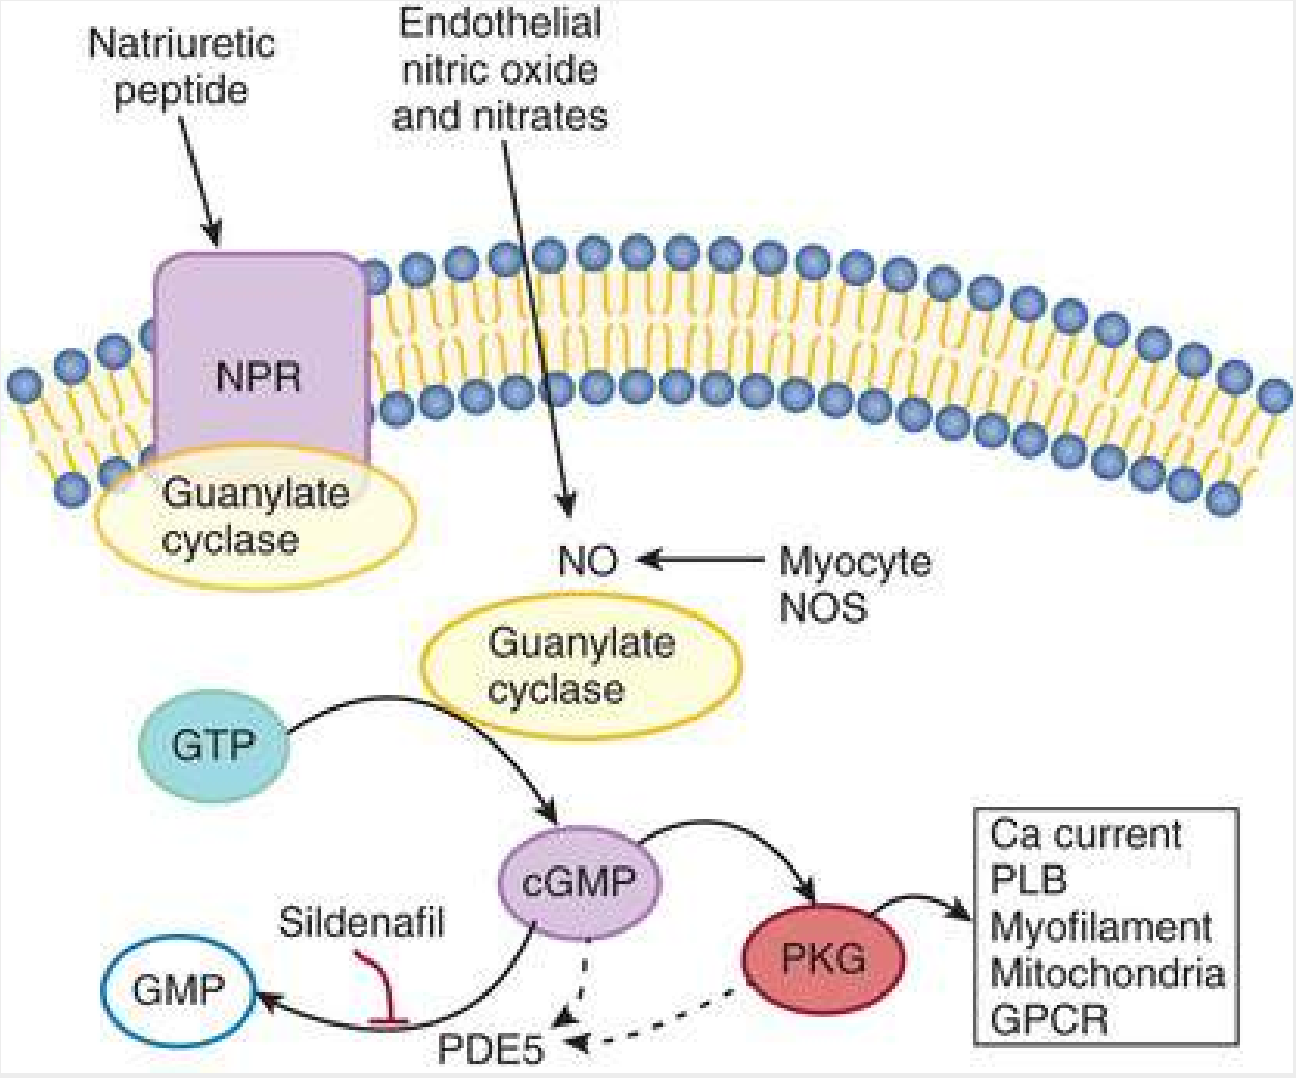

FIGURE 22.15 Nitric oxide (NO) and the natriuretic peptide receptor (NPR) activate guanylate cyclase (via particulate and soluble cyclases, respectively), resulting in production of cGMP and activation of protein kinase G (PKG). PKG can phosphorylate numerous myocyte targets that tend to counteract cAMP and PKA effects at some targets (with some exceptions). Phosphodiesterase 5 (PDE5) breaks down cGMP, and PDE5 inhibitors (e.g., sildenafil) can thus increase cGMP levels. Notably, high cGMP and PKG levels promote vasodilation and negative inotropic effects, and antianginal nitrates promote vasodilation by this mechanism.

cGMP is broken down by PDE, and seven PDE isoforms are expressed in the heart, some of which

break down both cAMP and cGMP (PDE1 to PDE3) whereas PDE4 is cAMP specific and PDE5 is cGMP specific.[52] PDE5 has achieved prominence as a result of its inhibition by sildenafil and related compounds that all enhance penile vasodilation. Emerging data show wider therapeutic potential. Thus sildenafil, by accumulation of cGMP, combats the harmful excessive adrenergic stimulation of contractile function. Furthermore, through cGMP, sildenafil can inhibit excess left ventricular growth in response to aortic constriction.[54] Conversely, in human cardiac hypertrophy and heart failure, PDE5 is more highly expressed, which may exacerbate adverse remodeling. The key target of cGMP, PKG, as with its counterpart PKA, colocalizes with its targets to control substrate phosphorylation.[55] The anchoring protein for PKG may be the same AKAP as for PKA, thus allowing tight subcellular colocalization and regulation of the counterpoised activities of cAMP and cGMP and of their respective upstream signaling cascades.[52]

Nitric Oxide

The focus of the Nobel Prize Award for 1998, NO is a unique messenger in that it is formed in so many tissues, is a gas, and is a physiologic free radical. NO is generated in the heart by one of three isoenzymes.[51] All three isoforms are present in the heart, including NOS1 (nNOS, or neuronal NOS), NOS2 (iNOS, or inducible NOS), and NOS3 (eNOS, or endothelial NOS).[56,57] NO signaling is reviewed in **Chapter 23**.

Contractile Performance of Intact Hearts

There are five main determinants of ventricular mechanical performance: preload (or Frank-Starling mechanism), afterload, contractility, lusitropy (diastolic function), and heart rate. This section describes the cardiac cycle and then the determinants of left ventricular (LV) function.

The Cardiac Cycle

The cardiac cycle, fully assembled by Lewis[58] but first conceived by Wiggers,[59] yields important information on the temporal sequence of events (**Fig. 22.16**). The three basic events with respect to the left ventricle are LV contraction, LV relaxation, and LV filling (**Table 22.3**). Similar mechanical events occur in the right ventricle.

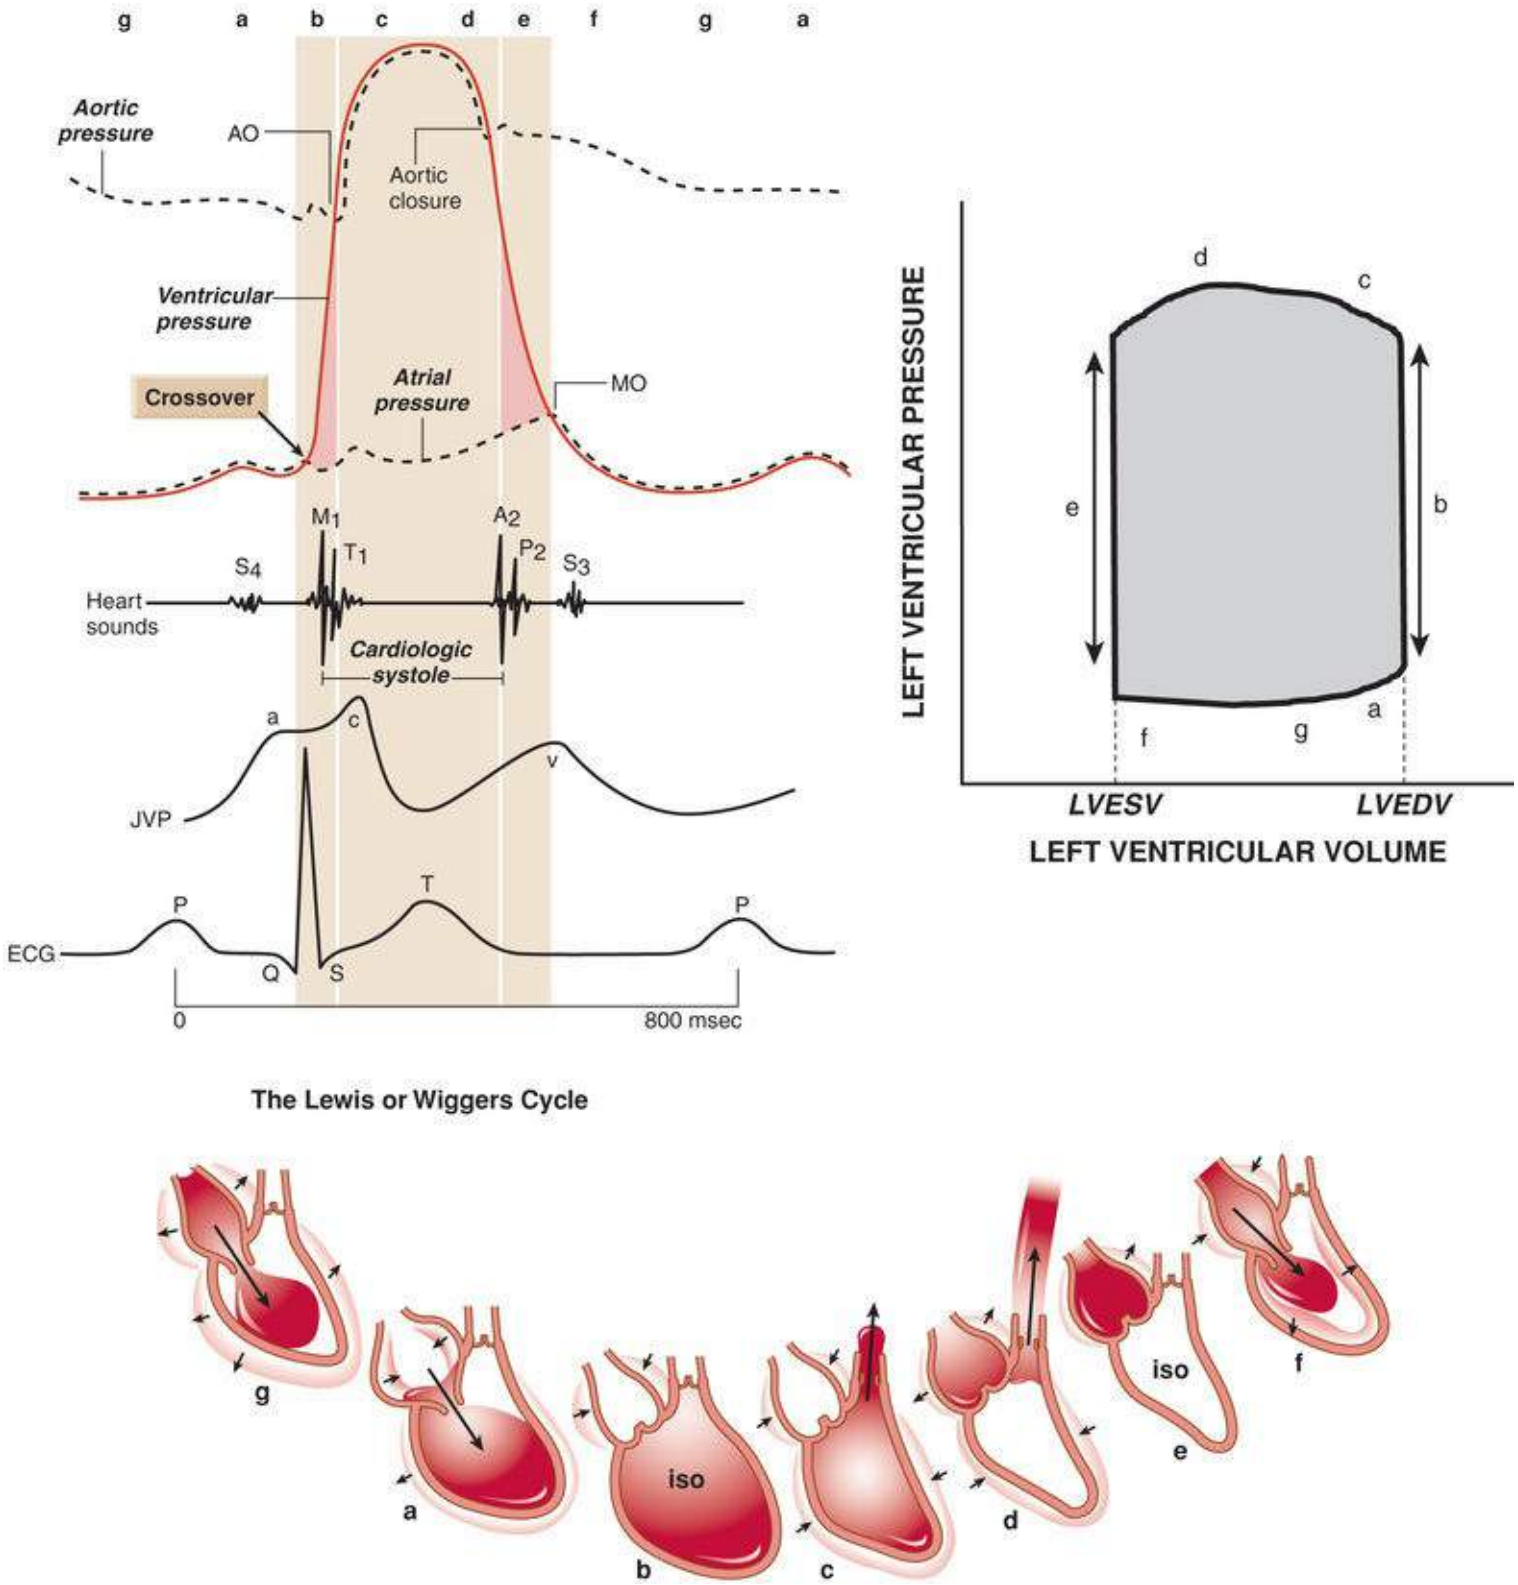

FIGURE 22.16 Mechanical events in the cardiac cycle depicted as pressure versus time **(upper left)** and left ventricular pressure versus volume **(upper right).** The visual phases of the ventricular cycle are shown in the **bottom panel.** For an explanation of phases a to g in upper right and bottom panels, **see Table 22.3**. *ECG,* Electrocardiogram; *JVP,* jugular venous pressure; M_1, mitral component of the first sound at the time of mitral valve closure; T_1, tricuspid valve closure, second component of the first heart sound; *AO,* aortic valve opening, normally inaudible; A_2, aortic valve closure, aortic component of the second sound; *MO,* mitral valve opening, may be audible in mitral stenosis as the opening snap; P_2, pulmonary component of the second sound, pulmonary valve closure; S_3, third heart sound; S_4, fourth heart sound; a, wave produced by right atrial contraction; c, carotid wave artifact during the rapid LV ejection phase; v, venous return wave, which causes pressure to rise with the tricuspid valve closed, *LVESV,* left ventricular end-systolic volume; *LVEDV,* left ventricular end-diastolic volume. (Modified from Opie LH: Heart Physiology, from Cell to Circulation. Philadelphia, Lippincott, Williams & Wilkins, 2004. Figure copyright L.H. Opie, © 2004. **Bottom panel,** Modified from Shepherd JT, Vanhoutte PM. The Human Cardiovascular System. New York: Raven Press;

1979, p 68.)

TABLE 22.3
The Cardiac Cycle

Left Ventricular Contraction
Isovolumic contraction (b)
Maximal ejection (c)
Left Ventricular Relaxation
Start of relaxation and reduced ejection (d)
Isovolumic relaxation (e)
LV filling: rapid phase (f)
Slow LV filling (diastasis) (g)
Atrial systole or kick (a)

The letters a to g refer to the phases of the cardiac cycle shown in Wiggers' diagram (**see Fig. 22.16**). These letters are arbitrarily allocated so that atrial systole (a) coincides with the A wave and (c) with the C wave of jugular venous pressure.

Left Ventricular Contraction

LV pressure increases as Ca^{2+} arrives at the contractile proteins after cellular depolarization triggers actin-myosin interaction.[4] This occurs shortly after the upstroke of the ventricular action potential, indicated by the QRS complex of the electrocardiogram (ECG; **Fig. 22.16**). When LV pressure exceeds that in the left atrium (normally 8 to 15 mm Hg), the mitral valve closes, causing the mitral component of the first sound, M_1. Right ventricular (RV) pressure changes are usually slightly delayed because of electrical conduction, such that tricuspid valve closure (T_1), follows M_1. The phase of LV contraction after mitral closure and before aortic opening when the LV volume is fixed is referred to as *isovolumic contraction*. As more myofibers become activated, LV pressure proceeds to increase until it exceeds aortic pressure, causing the aortic valve to open (usually a clinically silent event). Opening of the aortic valve is followed by the phase of *rapid ejection*. The rate of ejection is determined by the pressure gradient across the aortic valve, as well as the elastic properties of the aorta and the arterial tree, which undergo systolic expansion. LV pressure rises to a peak and then starts to fall.

Left Ventricular Relaxation

As myocyte $[Ca^{2+}]_i$ starts to decline because of SR Ca^{2+} uptake, Ca^{2+} dissociates from troponin C, thereby preventing further cross-bridge formation.[4] As this state of relaxation progresses, the rate of LV ejection of blood into the aorta falls (*phase of reduced ejection*). During this phase, blood flow from the left ventricle to the aorta rapidly diminishes but is maintained by aortic recoil—the Windkessel effect.[4] When the pressure in the aorta significantly exceeds the falling LV pressure, the aortic valve closes, which creates the first component of the second sound, A_2 (the second component, P_2, results from closure of the pulmonic valve as pulmonary artery pressure exceeds RV pressure). Thereafter, the ventricle continues to relax. Because the mitral valve is still closed during this phase after aortic closure, LV volume cannot change (*isovolumic relaxation*). The rate of pressure decay during isovolumic relaxation is related to the magnitude of systolic shortening in the preceding contraction, similar to a spring compressed below its unstressed slack length.[60] When LV pressure falls to below that in the left atrium, the mitral valve opens (normally silent), and the filling phase of the cardiac cycle restarts (**Fig. 22.16**).

Left Ventricular Filling Phases

Following mitral valve opening, the phase of rapid or early filling occurs and accounts for most of the ventricular filling.[4] Under normal circumstances, this is caused by a negative pressure gradient from atrium to the LV apex, creating a suction effect, especially during exercise, when LV filling rates must be augmented to increase cardiac output.[60] Such rapid filling may cause the physiologic third heart sound (S_3), when there is a hyperkinetic circulation or a pathologic S_3 when left atrial and LV diastolic pressures are elevated in congestive heart failure.[4] As pressures in the atrium and ventricle equalize, LV filling virtually stops (diastasis, separation). Renewed filling requires that atrial pressure exceed LV pressure. This is achieved by atrial systole (or the "left atrial kick"), which is especially important at a high heart rate, as during exercise, or when the left ventricle fails to relax normally, as in LV hypertrophy.[4]

Definitions of Systole and Diastole.
In Greek, *systole* means "contraction" and *diastole* means "to send apart." The start of systole can be regarded as the beginning of isovolumic contraction, when LV pressure exceeds the atrial pressure, or as mitral valve closure (M_1). *Physiologic systole* lasts from the start of isovolumic contraction to the peak of the ejection phase (**see Fig. 22.16 and Table 22.3**). *Physiologic diastole* commences as Ca^{2+} is taken back into the SR, so that myocyte relaxation dominates over contraction, and as the LV pressure starts to fall, as shown on the pressure-volume curve. In contrast, *cardiologic systole* is longer than physiologic systole and is demarcated by the interval between the first heart sound (M_1) to the closure of the aortic valve (A_2). The remainder of the cardiac cycle automatically becomes *cardiologic diastole*. For the cardiologist, *protodiastole* is the early phase of rapid filling, the time when S_3 can be heard. This sound probably reflects ventricular wall vibrations during rapid filling and becomes audible with an increase in LV diastolic pressure, wall stiffness, or rate of filling.

Contractility Versus Loading Conditions

Contractility

Contractility, or the *inotropic state*, is the inherent capacity of the myocardium to contract independently of changes in preload or afterload.[60] These are key terms in cardiologic language. At the molecular level, an increased inotropic state is usually explained by either enhanced Ca^{2+} transients or enhanced myofilament Ca^{2+} sensitivity and typically means a greater rate of contraction to reach a greater peak force. Frequently, increased contractile function is associated with enhanced rates of relaxation, or a lusitropic effect (e.g., as during beta-adrenergic activation). Contractile function is an important regulator of myocardial oxygen (O_2) uptake. Factors that increase contractility include exercise, adrenergic stimulation, digitalis, and other inotropic agents.

Preload

It is important to stress that any change in the contractility should be independent of the loading conditions. The preload describes the degree of myocardial stretch or distention before contraction has started and is best represented at the chamber level by the LV end-diastolic volume (EDV). Because volume is difficult to measure accurately and precisely in practice, preload is often estimated by LV end-diastolic pressure (EDP), but it is important to remember that the relationship between EDP and EDV varies between patients, especially when diastolic dysfunction or ventricular interdependence are

present.

Afterload

Afterload refers to the forces opposing LV ejection.[4,60] Afterload is often oversimplified as being equal to aortic blood pressure, but is more accurately described as aortic *impedance* or *elastance*, which incorporates steady and oscillatory components of cardiac load. LV afterload can also be expressed by the wall stress that exists during systole. When preload increases, the stroke volume rises according to Starling's law, if all other factors are held constant. Conversely, when afterload increases, stroke volume drops.

Starling's Law of the Heart

Venous Filling Pressure and Heart Volume

In 1918, Starling related the venous pressure in the right atrium to the heart volume in a dog heart-lung preparation.[4] He proposed that, within physiologic limits, the larger the volume of the heart, the greater the energy of its contraction and the amount of chemical change at each contraction. Starling did not, however, measure sarcomere length. He could only relate *LV volume* to cardiac output. In practice the LV volume is not often measured, rather making use of a variety of surrogate measures, such as LVEDP or the pulmonary capillary wedge pressure (PCWP). The relation between LVEDV and LVEDP is curvilinear, with the slope reflecting LV compliance (bottom portion of pressure-volume loop, **Fig. 22.16**). The venous filling pressure can be measured in humans, although indirectly by Swan-Ganz catheterization, as can the stroke volume.

Frank and Isovolumic Contraction

If a larger heart volume increases the initial length of the muscle fiber, to increase stroke volume and thus cardiac output, diastolic stretch of the left ventricle (and increased sarcomere length) increases the force of contraction.[4] In 1895, Frank had already reported that the greater the initial LV volume, the more rapid the rate of rise, the greater the peak pressure reached, and the faster the rate of relaxation. He described both a positive *inotropic effect* (*ino*, “fiber”; *tropus*, “move”) and an increased lusitropic effect. These complementary findings of Frank and Starling are often combined into the *Frank-Starling law*. Thus an increase in the strength of contraction can generally be categorized as either a *Frank-Starling effect* (increased sarcomere length) or an inotropic effect (altered Ca^{2+} transient or myofilament Ca^{2+} sensitivity), although both effects can occur simultaneously, as with physical exercise. Being able to parse effects mechanistically in this way can be helpful in selecting therapeutic interventions.

Preload and Afterload Are Interlinked

Although the previous distinctions between preload and afterload are useful, one can influence the other. By the Frank-Starling law, an increased LV volume leads to increased contractile function, which in turn will increase the systolic aortic pressure and thus the afterload in the subsequent contraction cycle. During LV ejection, sarcomere length progressively declines, decreasing both myofilament Ca^{2+} sensitivity and maximal force, which along with progressive $[Ca^{2+}]_i$ decline, reduces contractile force. Afterload also dynamically changes during ejection and declines as ejection wanes.

Preload and Diastolic Pressures May Become Uncoupled in Diseased Hearts.
LV pressure and volume are nonlinearly related because of myocardial compliance variations. In patients with reduced diastolic LV compliance, a higher EDP is required to achieve a similar EDV (preload). While the left and right ventricles influence each another in series (right ventricle pumps blood to left ventricle), factors in the right heart and pericardium also may influence LV pressure when there is enhanced ventricular interdependence, for example, with RV dilation from acute infarction or pulmonary embolism, or pericardial restraint caused by fibrotic constrictive pericarditis. In these situations, EDP may be high even when EDV is normal or low, because the right heart and pericardium are applying "external pressure" that uncouples pressure from preload volume.

The true "distending" pressure that determines LV preload volume is referred to as the *left ventricular transmural pressure* and can be calculated by EDP minus the external pericardial pressure. Pericardial pressure is approximated by right atrial pressure; thus transmural pressure can be estimated by the difference between EDP (or PCWP) and right atrial pressure.

Force-Length Relationships and Ca^{2+} Transients

Acute changes in sarcomere length do not alter the Ca^{2+} transient appreciably. Thus the favored explanation for the steep length-tension relationship of cardiac muscles is enhanced myofilament Ca^{2+} sensitivity as the initial sarcomere length increases[4] (**Fig. 22.17**).

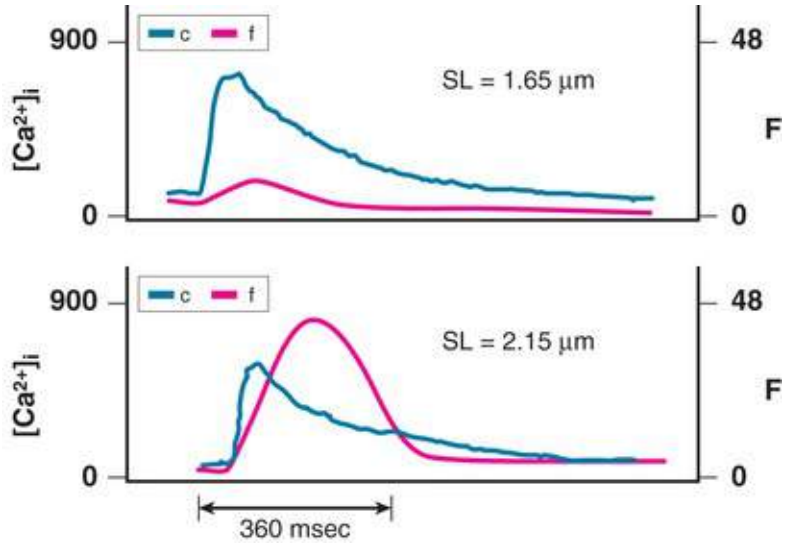

FIGURE 22.17 Length-dependent enhancement of myofilament Ca sensitivity. In the **top panel,** sarcomere length (*SL*) is 1.65 µm, which produces modest developed force (*f*). In the **bottom panel,** at near-maximal sarcomere length (2.15 µm), the Ca^{2+} transient (*c*) is almost unchanged, but causes much greater force development. (Modified from Backx PH, ter Keurs HEDJ. Fluorescent properties of rat cardiac trabeculae microinjected with fura-2 salt. Am J Physiol 1993;264:H1098.)

Anrep Effect: Abrupt Increase in Afterload

When the aortic pressure is elevated abruptly, it limits ejection and tends to increase EDV, which acutely increases force and pressure at the next beat by the Frank-Starling effect. However, in a slower adaptation that takes seconds to minutes, the inotropic state of the heart increases (and Ca^{2+} transients are larger). Both phases of this can be readily recapitulated in isolated muscle strips from the heart. This slow force

response or adaptation is referred to as the *Anrep effect*. Extensive study has implicated stretch-induced activation of several important autocrine/paracrine myocyte signaling pathways in this slowly developing inotropic effect.[59,61]

Wall Stress

Wall stress develops when tension is applied to a cross-sectional area, and the units are force per unit area (**Fig. 22.18**). According to Laplace's law, wall stress = (pressure × radius)/(2 × wall thickness). This equation, although an oversimplification, emphasizes two points. First, the larger the LV size and radius, the higher is the wall stress.[4] Second, at any given radius (LV size), the greater the pressure developed by the left ventricle, the greater is the wall stress. An increase in wall stress achieved by either of these two mechanisms (LV size or intraventricular pressure) will increase myocardial O_2 uptake, because a greater rate of ATP use is required for the myofibrils to develop more tension.

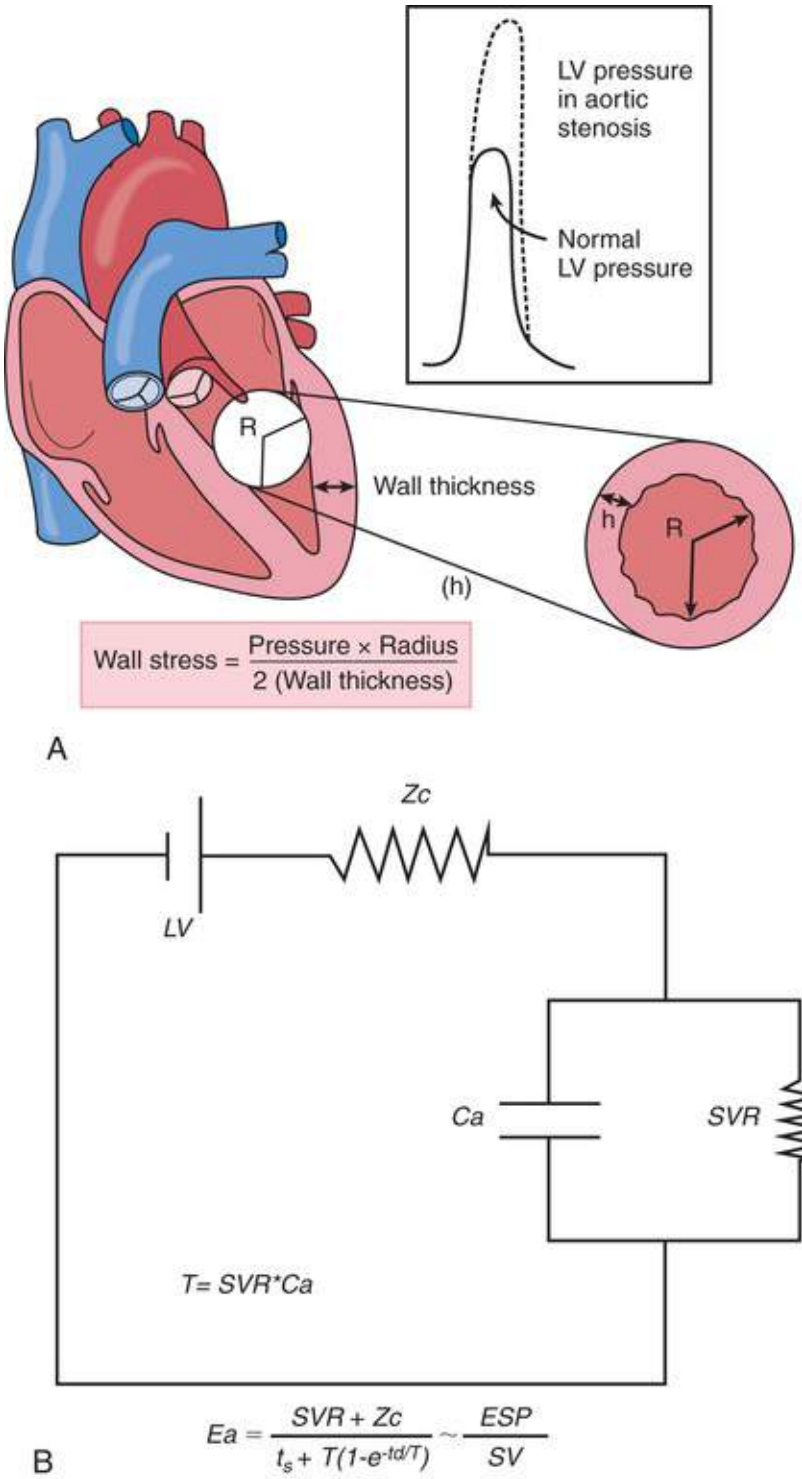

FIGURE 22.18 **A,** Wall stress increases as afterload increases**.** The formula shown is derived from Laplace's law. The increased LV pressure in aortic stenosis is compensated for by LV wall hypertrophy, which decreases the denominator on the right side of the equation. **B,** Electrical circuit analog of the arterial system as it relates to LV afterload, based on the three-element Windkessel model. The LV generates current (flow, cardiac output) that is ejected through an upstream impedance in the proximal aorta (characteristic impedance, *Zc*) upstream of total arterial compliance (*Ca*) and systemic vascular resistance (*SVR*) that arranged in parallel. Effective arterial elastance (*Ea*) is a lumped measure of net arterial "stiffness" that is related to each of these components and can be estimated by the ratio of end-systolic LV pressure (*ESP*) to stroke volume (*SV*). Ea (and thus arterial afterload) increases as Zc or SVR increases or as Ca decreases. *R,* Radius. (From Opie LH. Heart Physiology, from Cell to Circulation. Philadelphia: Lippincott Williams & Wilkins; 2004. Figure copyright L.H. Opie, © 2004.)

In cardiac hypertrophy, Laplace's law explains the effects of changes in wall thickness on wall stress (**Fig. 22.18**). The increased wall thickness from hypertrophy balances the increased pressure, and wall stress remains unchanged during the phase of compensatory hypertrophy.[4] The concept that this change is compensatory and beneficial has been challenged by a mouse model in which the process of hypertrophy

was genetically inhibited so that wall stress increased in response to a pressure load, yet these mice had better cardiac mechanical function than did the wild-type mice in which compensatory hypertrophy developed.[4] Another clinically useful concept is that in congestive heart failure, the heart dilates so that the increased radius elevates wall stress. Furthermore, because ejection of blood is inadequate, the radius stays too large throughout the contractile cycle, and both end-diastolic and end-systolic wall stress is higher. This decreases LV efficiency, increases myocardial O_2 demand, and augments release of natriuretic peptide levels. The overall reduction in heart size decreases wall stress and improves LV function.[4]

Wall Stress, Preload, and Afterload.

This definition brings in both the volume and the fiber length that define the radius.[4] *Preload* can be defined as the wall stretch at the end of diastole, and therefore at the maximal resting length of the sarcomere (**Fig. 22.18**). Measurement of wall stress in vivo is difficult because use of the radius of the left ventricle (see the preceding sections) neglects the confounding influence of the complex LV anatomy. Surrogate preload indices include LVEDP or dimensions (the latter being the major and minor axes of the heart in a two-dimensional echocardiographic view). *Afterload*, being the load on the contracting myocardium, is also the wall stress during LV ejection. Increased afterload means that increased intraventricular pressure has to be generated first to open the aortic valve and then during the ejection phase. These increases will translate into increased myocardial wall stress, which can be measured either as an average value or at end-systole.

Peak systolic wall stress reflects the three major components of afterload: peripheral resistance, arterial compliance, and peak intraventricular pressure.[4] Decreased arterial compliance and increased afterload can be anticipated with aortic remodeling and dilation, as in severe systemic hypertension or in elderly patients. The systolic timing of the afterload can also influence LV relaxation. In experimental and human studies, a late systolic load, as when the aorta has stiffened, is associated with impaired LV systolic shortening and diastolic relaxation.[62,63] This is why it is crucial to consider both afterload and preload when evaluating indices of LV function based on the velocity or extent of tissue motion using echocardiography.[63]

Aortic impedance or *elastance* gives another accurate measure of LV afterload (**Fig. 22.18**). The advantage of impedance/elastance compared to wall stress is that this measure is totally independent of heart size or wall thickness. The aortic impedance reflects the ratio of aortic pressure to flow across different frequency harmonics. During systole, when the aortic valve is open, an increased afterload will communicate itself to the ventricles by increasing wall stress. In LV failure, aortic impedance is augmented not only by peripheral vasoconstriction (high systemic vascular resistance), but also by decreases in aortic compliance (ability of aorta to “yield” during systole), especially with aging. The problem with the clinical measurement of aortic impedance is that it is expressed in the frequency domain, which is cumbersome to relate to time-domain measures of LV function. An alternative index of LV afterload is the *arterial elastance* (Ea), estimated by the relationship between end-systolic LV pressure and stroke volume (**Fig. 22.18**). Ea is derived from the Windkessel model of the arterial system, which includes upstream characteristic impedance (Zc) and a downstream resistance and capacitor that are situated in parallel. Thus, Ea incorporates both mean resistive components of load along with heart rate and aortic compliance.

Heart Rate and Force-Frequency Relationship

Treppe or Bowditch Effect

An increased heart rate progressively enhances the force of ventricular muscle contraction, even in isolated papillary muscle preparations and isolated myocytes, the *Bowditch staircase phenomenon.*[4] Alternative names are the *treppe* (German, “steps”) phenomenon, positive inotropic effect of activation, or force-frequency relationship (**Fig. 22.19A**). Conversely, a decreased heart rate has a negative staircase effect. However, at a very high heart rate, force progressively decreases. These effects at the myocyte level are largely attributable to changes in Na^+ and Ca^{2+} in the myocyte. At a higher heart rate, there is more Na^+ and Ca^{2+} entry per unit time and less time for the cell to extrude these ions, which results in higher $[Na^+]_i$ and cellular and SR Ca^{2+} content.[1] The increase in SR Ca^{2+} content increases the amount of Ca^{2+} released during the action potential, the primary cause of the increase in contractility at higher heart rates. The elevation in $[Na^+]_i$ also further reduces the efficacy of NCX in extruding Ca^{2+} during the cardiac cycle, thereby leading to further gains in cellular (and SR) Ca^{2+}. A new steady-state Ca^{2+} load will be achieved when the increased Ca^{2+} transients cause Ca^{2+} extrusion by NCX to match the amount of Ca^{2+} influx at each beat (and similarly when Na^+,K^+-ATPase extrudes the amount of Na^+ that enters per beat). This is the definition of steady state, with no net gain or loss of cellular Ca^{2+} (or Na^+) from beat to beat.

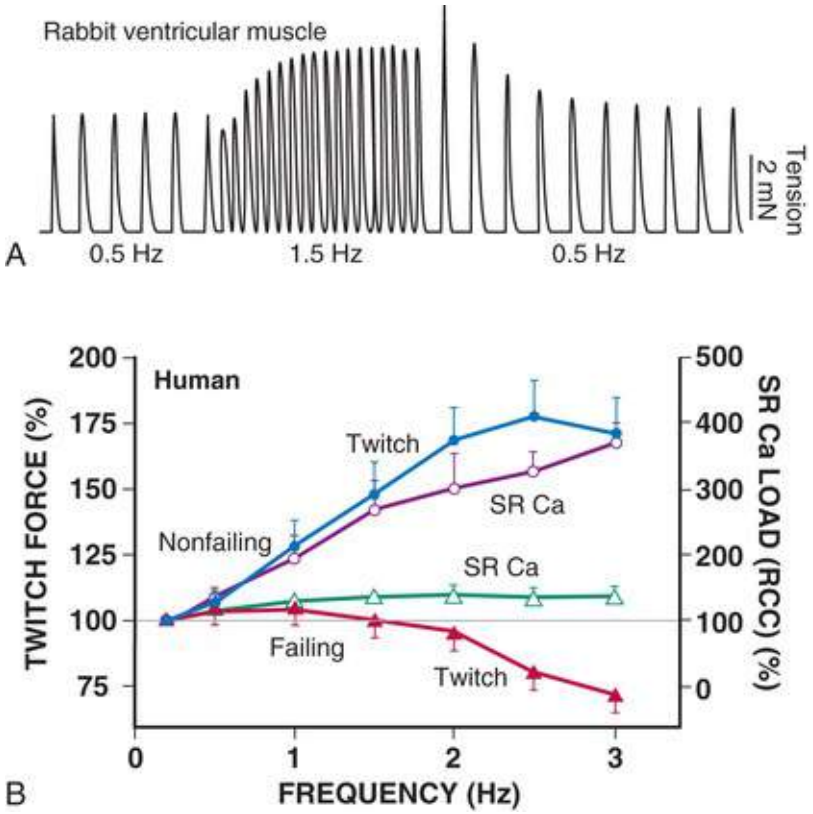

FIGURE 22.19 Heart rate dependence on contraction: Bowditch staircase or *treppe* phenomenon. **A,** An increased stimulation rate increases the force of contraction. The tension developed by rabbit ventricular muscle is shown in mN. During the first shortened diastolic interval the first beat is smaller, an effect caused mainly by refractoriness of the SR Ca^{2+} release channel. As the 1.5-Hz stimulation approaches a steady state, the contraction is progressively increased, an effect attributable to the gain in myocyte Na^{+} and Ca^{2+} and enhanced SR Ca^{2+} content. When the diastolic interval is prolonged (first beat at 0.5 Hz), the first beat is especially large because the SR Ca^{2+} load is still elevated and there is more time for the RyR to recover from refractoriness. The larger Ca^{2+} transient then drives higher extrusion of Ca^{2+} from the cell as the initial 0.5-Hz steady state is eventually achieved. **B,** With an increasing heart rate, normal nonfailing ventricular muscle exhibits a progressive increase in SR Ca^{2+} content (*SR Ca*) and a positive force-frequency relationship that peaks at approximately 2.5 Hz. The decline at 3 Hz is caused by reduced fractional SR Ca^{2+} release. In failing human ventricular muscle, the SR fails to increase its Ca^{2+} content appreciably at higher heart rates; this results in a negative force-frequency relationship (which is dominated by the refractoriness, but here is not compensated by increased SR Ca^{2+}). SR Ca^{2+} in these experiments was assessed by rapid-cooling contractures (*RCC*). (From Bers DM. Excitation-Contraction Coupling and Cardiac Contractile Force. Dordrecht, Netherlands: Kluwer Academic; 2001.)

To the extent that the SR can take up this extra Ca^{2+} load at a higher heart rate, diastolic $[Ca^{2+}]_i$ and stiffness remain low. This is helped by an increase in the rate of SR Ca^{2+} uptake at a higher heart rate (known as “frequency-dependent acceleration of relaxation”) mediated by faster SR Ca^{2+} uptake function (although the mechanism is not fully resolved). However, if SR Ca^{2+}-ATPase and NCX are unable to remove Ca^{2+} sufficiently from the cytoplasm during the time between beats, an increase in diastolic $[Ca^{2+}]_i$ and force/stiffness will occur. Systolic function is also limited at increasing heart rates. The primary reason at physiologic heart rates is that the SR Ca^{2+} release process has refractoriness that is reminiscent of that seen with voltage-gated Na^{+} and Ca^{2+} channels. Thus, at higher heart rates, even when a normal action potential and Ca^{2+} current signal occur, the fraction of SR Ca^{2+} released can be reduced (**Fig. 22.19B**). In a sense, the resulting Ca^{2+} transient and contraction at increasing heart rates can be seen as the product of the increasing SR Ca^{2+} content times the declining fractional SR Ca^{2+} release, with the former factor being dominant (especially at more moderate heart rate) but the latter being progressively limiting.

In the intact heart this scenario is complicated by alterations in filling time and consequent changes in

preload. That is, at higher heart rates there will also be a reduced filling time that will limit preload (EDV), and thus a negative Frank-Starling effect will modulate the positive and negative inotropic effects to limit the overall strength of LV contraction. In addition, higher aortic elastance (Ea) at increased heart rates will also increase cardiac afterload and limit the ability of the left ventricle to eject blood. Thus, both fundamental myocyte and hemodynamic properties combine to influence net cardiac function at increased heart rates.

Premature ventricular complexes (PVCs) or *extrasystoles* can also modulate contraction in understandable ways. When a PVC occurs during the time when SR Ca^{2+} release is partially refractory and the left ventricle has not been refilled, the strength of that PVC will be very weak and may even fail to open the aortic valve. However, because the PVC had low SR Ca^{2+} release, less Ca^{2+} current inactivation and less Ca^{2+} extrusion from the cell occur and result in much higher SR Ca^{2+} release at the next (postextrasystolic) beat following the usual compensatory pause (because of AV node refractoriness during the next sinus node beat). Similarly, by the time the postextrasystolic beat occurs, the much smaller LV ejection and continued LV filling result in greater preload, reduced afterload, and a larger Ca^{2+} transient. These cellular and hemodynamic effects combine to cause an extremely strong, postextrasystolic potentiation beat that a person can often sense as the heart "skipping a beat."

Physiologic Force-Frequency Relationship and Optimal Heart Rate

When the heart rate increases under physiologic conditions, it is usually accompanied and partially mediated by sympathetic beta-adrenergic activation at myocytes throughout the heart. As discussed earlier, this will increase Ca^{2+} current influx, the rate of SR Ca^{2+} uptake, and the amount of SR Ca^{2+} released during the beat, which greatly amplifies the inotropic and lusitropic effects associated with alteration of the heart rate without sympathetic activation. However, the beta-adrenergic system also enhances Na^+,K^+-ATPase activity to limit the rise in $[Na^+]_i$ that occurs at the higher heart rate, and this would temper the overall inotropic effect. Normally, peak contractile force at a fixed muscle length (isometric contraction) increases, and a peak is reached at about 150 to 180 beats/min[1,4] (**Fig. 22.19B**). In situ, the optimal heart rate is also dependent on the previous hemodynamic factors and a functioning sympathetic system, so the exact value of the heart rate when cardiac output starts to decrease rather than increase is more difficult to specify and likely varies among people. Pacing rates of up to 150 beats/min can be tolerated, whereas higher rates cannot because of the development of AV block. In contrast, during exercise, indices of LV function still increase up to a maximum heart rate of about 170 beats/min, presumably because of enhanced contractile function and peripheral vasodilation.[4] The critical heart rate associated with a fall-off in LV function likely occurs at lower values in diseased hearts, but this is not well understood.

Myocardial Oxygen Uptake

Myocardial O_2 demand can be increased by the heart rate (HR), preload, or afterload (**Fig. 22.20**), factors that can all precipitate myocardial ischemia in those with coronary artery disease (CAD). Because myocardial O_2 uptake ultimately reflects the rate of mitochondrial metabolism and thus ATP production, any increase in ATP requirement will be reflected in increased O_2 uptake. In general, factors increasing wall stress will increase O_2 uptake. Increased afterload causes increased systolic wall stress, which requires greater O_2 uptake. Increased diastolic wall stress, resulting from increased preload (EDV), will also require more oxygen because the greater stroke volume must be ejected against the afterload. In

states of enhanced contractile function, the rate of change in wall stress is increased. Because systolic blood pressure (SBP) is an important correlate of afterload, a practical index of O_2 uptake is SBP × HR, the *double product*. The concept of wall stress in relation to O_2 uptake also explains why heart size is such an important determinant of myocardial O_2 uptake (because a larger radius increases wall stress).

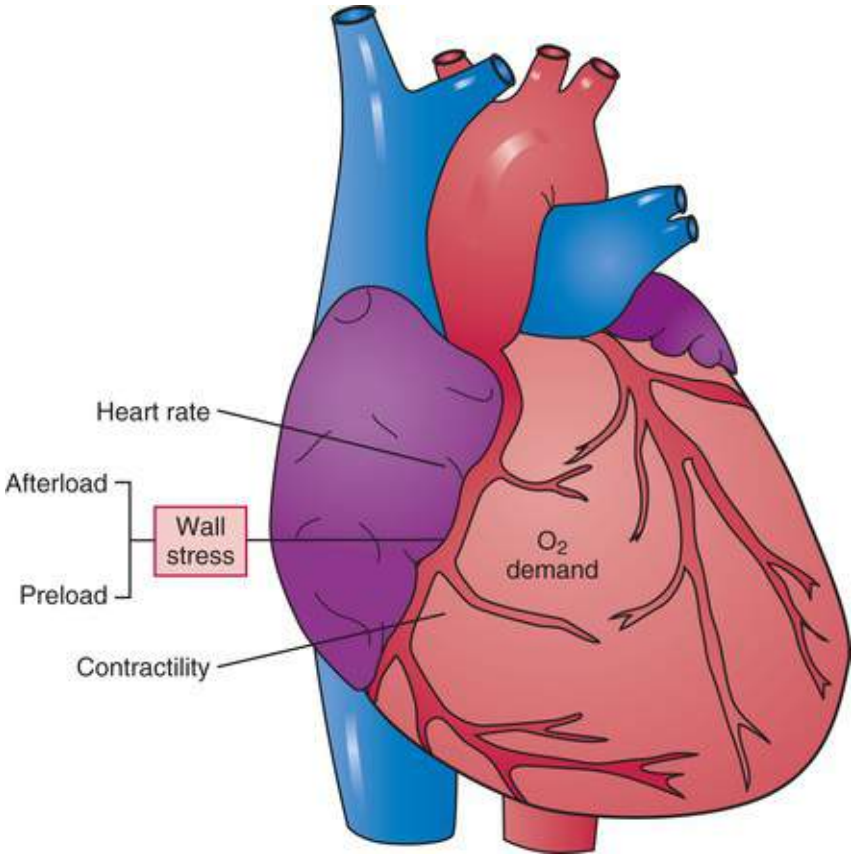

FIGURE 22.20 Major determinants of the O_2 demand of the normal heart: heart rate, wall stress, and contractile function. (Modified with permission from Opie LH. Heart Physiology, from Cell to Circulation. Philadelphia: Lippincott Williams & Wilkins; 2004. Figure copyright L.H. Opie, © 2004.)

Work of the Heart

External work (pressure × volume) is done by the heart, with stroke volume (or cardiac output) being the volume moved against arterial blood pressure. *Volume work* (associated with increased stroke volume) requires less oxygen than *pressure work* does (increased pressure or heart rate), and one might suppose that external work is not an important determinant of myocardial O_2 uptake. However, three determinants of myocardial O_2 uptake are involved: preload (because this helps determine stroke volume), afterload (in part determined by blood pressure), and heart rate. *Minute work* can be defined as the product of systolic blood pressure, stroke volume, and heart rate (SBP × SV × HR). Not surprisingly, heart work is related to O_2 uptake. This *pressure-work index* takes into account both the double product (SBP × HR) and HR × SV (i.e., cardiac output). The *pressure-volume area* is another index of cardiac work or O_2 uptake, but requires invasive monitoring for accurate measurements (**see Fig. 22.18**). External cardiac work can account for up to 40% of the total myocardial O_2 uptake.

Internal Work (Potential Energy).

Total O_2 consumption is related to the total work of the heart (area *abcd* in **Fig. 22.21**), which means that both external work (area *abce*) and the volume-pressure triangle joining the end-systolic volume-pressure point to the origin (area *cde*; marked PE).[64] Although this area has been called internal work, more strictly it should be called the "potential energy" that is generated within each contraction cycle but not converted to external work. Such potential energy at the end of systole (point *c*) may be likened to the potential energy of a compressed spring.

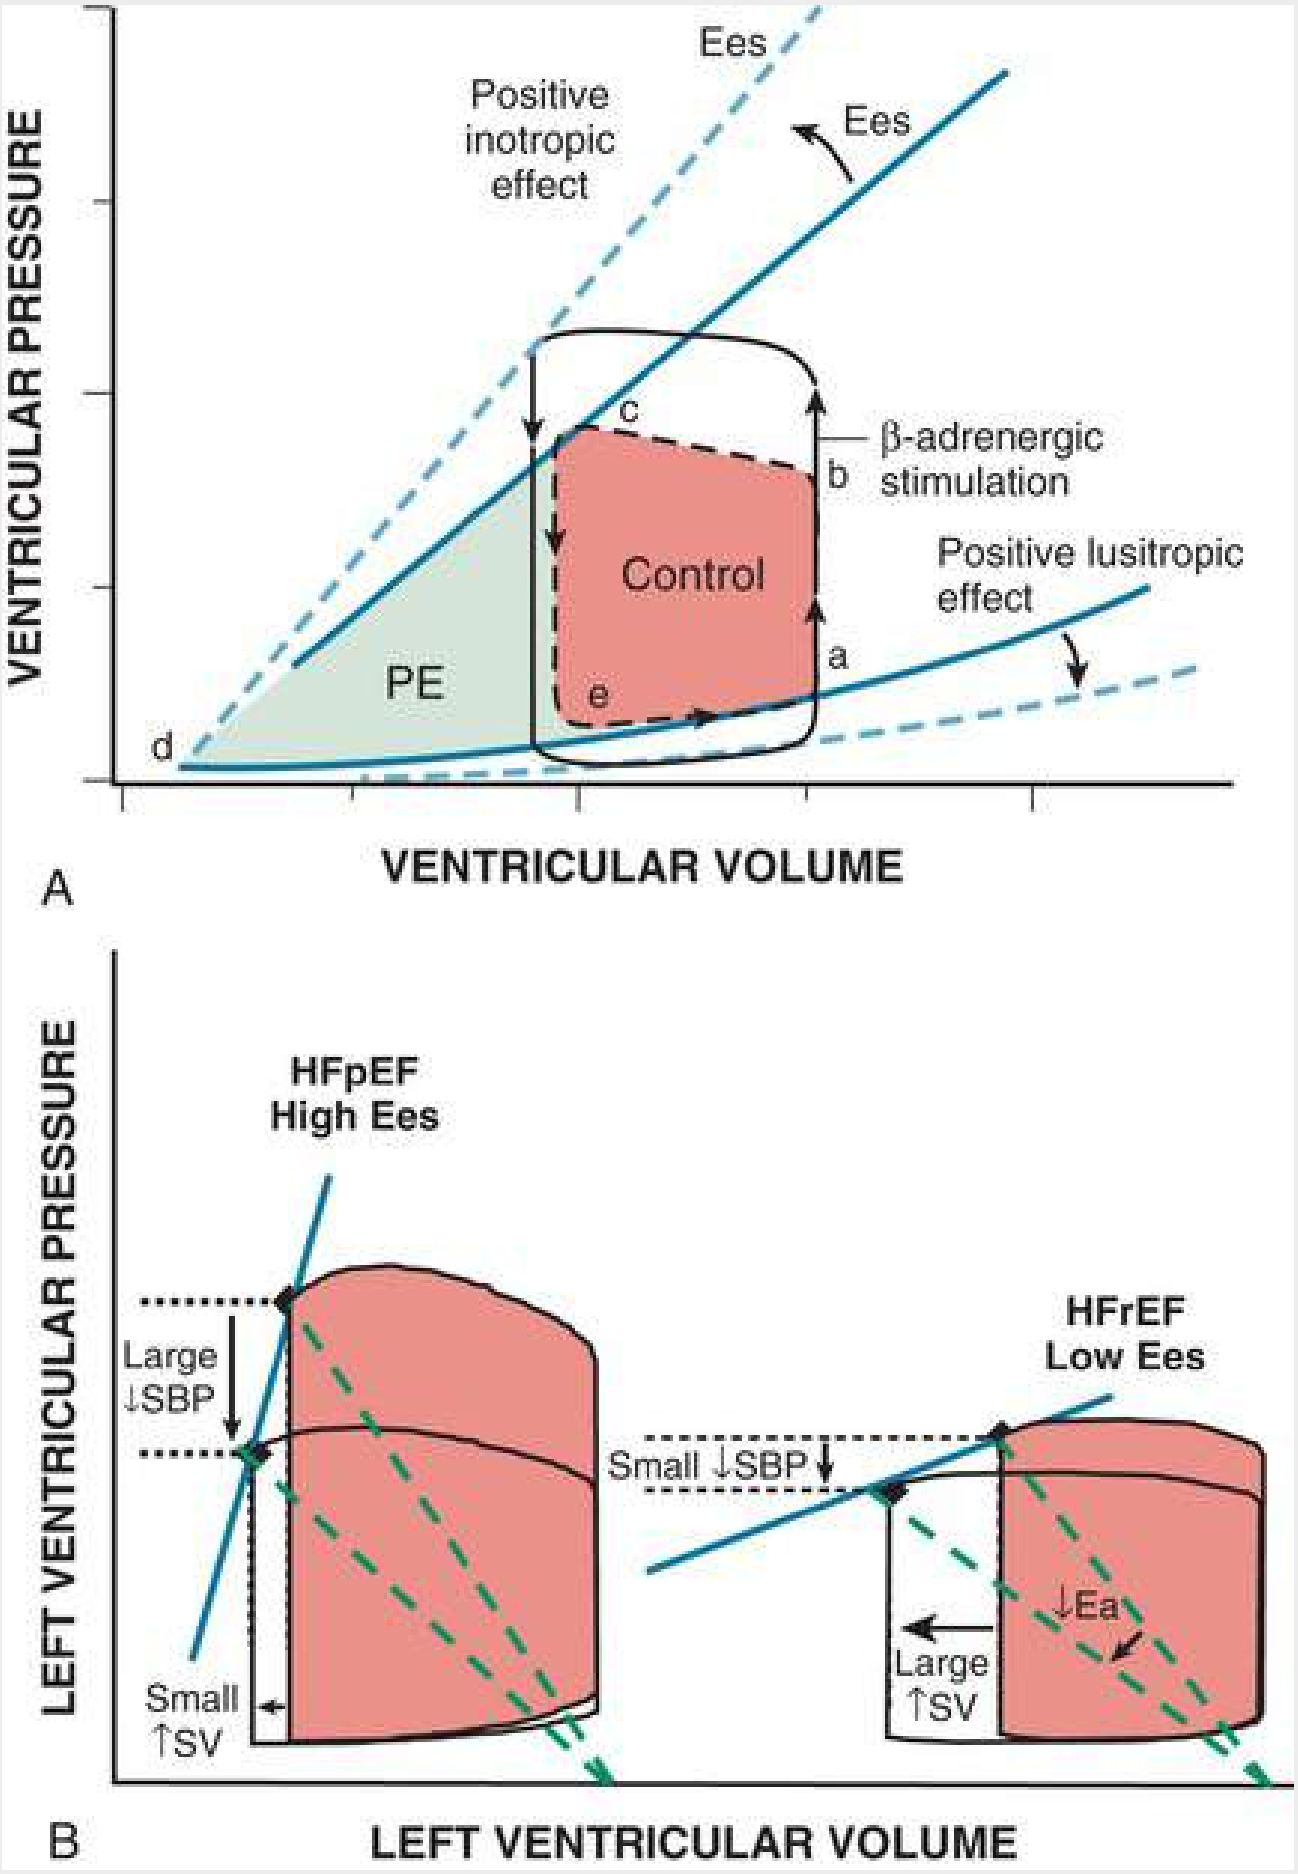

FIGURE 22.21 Pressure-volume loop of the left ventricle. **A,** Note the effects of beta-adrenergic catecholamines with both positive inotropic (increased slope of line *Ees*) and increased lusitropic (relaxant) effects. *Ees* is slope of the pressure-volume relationship. The total pressure-volume area (for the control area, see *abcd*) is closely related to myocardial O_2 uptake. The area *cde* is the component of work spent in generating potential energy (*PE*). **B,** Representative LV pressure-volume loops in a patient with heart failure and preserved ejection fraction (HFpEF, left) and heart failure with reduced ejection

fraction (HFrEF, right) demonstrating the differential effects of vasodilator therapy. In HFpEF, the end-systolic pressure volume relationship is steep, Ees is high, and reductions in arterial afterload or elastance (*Ea*) from acute vasodilator therapy (in this case, nitroprusside infusion) lead to dramatic reductions in systolic blood pressure (*SBP*) and modest increases in stroke volume (*SV,* defined by the width of the pressure-volume loop). In the patient with HFrEF, contractility is depressed, Ees is low, and the end-systolic pressure volume relationship is accordingly shallow. Thus the same degree of vasodilation (reduction in Ea) causes much less reduction in SBP and much more increase in forward SV. (**A**, Modified from Opie LH. Heart Physiology, from Cell to Circulation. Philadelphia: Lippincott, Williams & Wilkins; 2004. Figure copyright L.H. Opie, © 2004; **B,** modified from Schwartzenberg S et al. J Am Coll Cardiol 2012; PMID 22281246.)

Efficiency of work is the relationship between the work performed and myocardial O_2 uptake.[4] Metabolically, efficiency is increased by promotion of glucose rather than fatty acids as the major myocardial fuel. Conversely, heart failure decreases the efficiency of work, although the basis is not fully understood. Because as little as 12% to 14% of O_2 uptake may be converted to external work,[4] it is probably the "internal work" that becomes less demanding. Ion fluxes ($Na^+/K^+/Ca^{2+}$) account for approximately 20% to 30% of the ATP requirement of the heart, so most ATP is spent on actin-myosin interaction and much of that on the generation of heat rather than on external work. An increased initial muscle length sensitizes the contractile apparatus to Ca^{2+}, thereby theoretically increasing the efficiency of contraction by diminishing the amount of Ca^{2+} flux required.

Measurements of Contractile Function

Force-Velocity Relationship and Maximum Contractile Function in Muscle Models

If contractility is truly independent of load and the heart rate, unloaded heart muscle stimulated at a fixed rate should have a maximum value of contractile function for any given magnitude of the cytosolic Ca^{2+} transient. This value, the V_{max} of muscle contraction, is defined as the *maximal velocity of contraction* when there is no afterload to prevent maximal rates of cardiac ejection.[4] Beta-adrenergic stimulation increases V_{max}, and converse changes are found in failing myocardium. V_{max} is also termed V_0 (maximum velocity at zero load). As the load increases, the velocity of shortening decreases. A limitation of this relatively simple concept is that V_{max} cannot be measured directly but must be extrapolated from the *force-velocity relationship* to the velocity axis intercept. The other extreme condition is zero muscle shortening, with all the energy going into the development of pressure (P_0) or force (F_0). This situation is an example of *isometric shortening*.

Isometric Versus Isotonic Contraction

Data for P_0 are obtained under isometric conditions (length unchanged). When muscle is allowed to shorten against a steady load, the conditions are *isotonic* (*tonic,* "contractile force").[4] Thus the force-velocity curve may be a combination of initial isometric conditions followed by isotonic contraction and then abrupt and total unloading to measure V_{max}. Although isometric conditions can be found in the whole heart (e.g., during isovolumic contraction), isotonic conditions are rare because afterload is constantly changing during the ejection period, and complete unloading is impossible. However, as shortening progresses during ejection, the maximal P_0 declines. and velocity is lower for any given nonzero load. Therefore the force-velocity relationship is heuristically useful, but measurements in vivo are limited.

Pressure-Volume Loops

Accordingly, measurements of pressure-volume loops are among the best of the current approaches for assessment of the contractile behavior of the intact heart (**see Figs. 22.18 and 22.21**). A crucial measurement is the *end-systolic elastance* (Ees) from the pressure-volume relationship.[4] When the loading conditions are changed, alterations in the slope of this line joining the different E_s points (the end-systolic pressure-volume relationship) are generally a good load-independent index of the contractile performance of the heart. In clinical practice, the need to change the loading conditions and the requirement for invasive monitoring for the full pressure-volume loop lessen the usefulness of this index. Measurement of LV volume adequately and continuously throughout the cardiac cycle is not easy. During a positive inotropic intervention, the pressure-volume loop reflects a smaller end-systolic volume and a higher end-systolic pressure, so the slope of the pressure-volume relationship (E_s) has moved upward and to the left (**Fig. 22.21**). When the positive inotropic intervention consist of beta-adrenergic stimulation, the enhanced relaxation (lusitropic effect) results in a lower pressure-volume curve during ventricular filling than in controls.

Ventricular Function in Heart Failure (see also Chapter 23).
In patients with heart failure and reduced ejection fraction (HFrEF), the ventricle is dilated, EF is low, and contractility is severely depressed.[65] As such, the pressure-volume loop is shifted to the far right on the volume axis, and the end-systolic pressure-volume relationship (ESPVR, contractility) is very shallow (**Fig. 21.21**). In this setting, a reduction in arterial afterload (Ea) produces modest reductions in blood pressure despite often dramatic increases in stroke volume. This heightened "afterload dependence" of the LV in HFrEF serves as the hemodynamic basis for aggressive use of vasodilators in this disease. In contrast, patients with heart failure and preserved EF (HFpEF) display an increased Ees (steep ESPVR). In this patient, the same degree of afterload reduction (decrease in Ea) using a vasodilator causes a much more dramatic drop in blood pressure, with little improvement in forward stroke volume.

Limitations of the Concept of Contractility

Despite all the previous procedures that can be adopted in an attempt to measure true contractility (or the inotropic state), the concept has at least two serious defects: (1) the absence of any noninvasive index that can be measured unequivocally and (2) the impossibility of separating the cellular and chamber-level mechanisms of changes in contractile function from those of load or the heart rate.[4] Thus an increased heart rate, by the changes in Na^+ and Ca^{2+} handling noted earlier, gives rise to increased cytosolic Ca^{2+} transients, and contraction is clearly an inotropic effect. However, the simultaneous changes in preload and afterload also involve Frank-Starling effects, which complicates this picture in the clinical setting. Similarly, increased preload involves increased fiber stretch, which in turn causes enhanced myofilament Ca^{2+} sensitivity, a factor that in a sense is built into the Frank-Starling effect. However, additional changes in myofilament Ca^{2+} sensitivity (e.g., during acidosis or alpha-adrenergic activation) would be attributed to inotropic changes. *So there is a clear overlap between contractility, which should be independent of load or heart rate, and the effects of load and heart rate on the cellular mechanisms.*[3,4] Even though this does not undermine the importance of the intrinsic mechanistic distinctions between contractility/inotropy and Frank-Starling mechanisms, the distinction can be blurred by the clinical context and available measurements. For example, in humans with atrial fibrillation and constantly

varying ventricular frequency, contractility inferred from pressure-volume loops constantly changes from beat to beat. It is then more difficult to infer a “true” change in LV contractility versus operation of the Frank-Starling mechanism because of varying diastolic filling times.[4]

Left Ventricular Relaxation and Diastolic Dysfunction

Normal diastolic function allows the ventricle to fill adequately during rest and exercise, without an abnormal increase in LA pressure.[60] The phases of diastole are isovolumic pressure decline and filling. The filling phase is divided into early rapid filling, diastasis, and atrial systole. Early rapid filling contributes 70% to 80% of LV filling in normal individuals. Early diastolic filling is driven by the LA-to-LV pressure gradient, which is dependent on a complex interplay of factors, including myocardial relaxation, LV elastic recoil, LV diastolic stiffness, left atrial (LA) pressure, ventricular interaction, pericardial constraint, pulmonary vein properties, and mitral orifice area. Diastasis occurs in mid-diastole when LA and LV pressure is usually almost equal. It contributes less than 5% of LV filling, and its duration shortens with tachycardia. In normal persons, atrial systole contributes 15% to 25% of LV diastolic filling without raising mean LA pressure. This contribution depends on the PR interval, atrial inotropic state, atrial preload, atrial afterload, autonomic tone, and heart rate. **Chapter 26** further details the basic mechanisms of LV relaxation, as well as measurements of LV relaxation. In addition to being important in heart failure, abnormalities in diastolic relaxation and stiffness develop as part of normal aging, and this cardiac aging process seems to be accelerated in the presence of obesity.[66]

Right Ventricular Function

Most of the forgoing principles and discussions also apply to the right ventricle, and the differences are not discussed in any detail here. RV myocytes are fundamentally the same as those in the left ventricle, with some minor, mainly quantitative differences in their ion channel, electrophysiology, Ca^{2+} handling, and myofilament properties. The most important functional differences are in the chamber geometry related to Laplace's law and the normal levels of pressure developed (lower pressure in the right ventricle and pulmonary circulation).[67] The right ventricle has a larger radius of curvature, which would tend to increase wall tension, but it normally develops much lower pressure, which greatly reduces wall tension (wall tension = [radius × pressure]/[2 × thickness]). RV wall thickness is also lower such that the normal characteristics of RV shape and size are functionally matched to the different prevailing conditions on the right ventricle. The right ventricle is poorly suited to eject against high pressures, as in pulmonary hypertension, and this heightened afterload-dependence is further accentuated in patients with heart failure.[68]

Atrial Function

The left atrium has five main functions.[4,69] First and best known, the left atrium functions as a blood-receiving reservoir chamber. Second, it also is a contractile chamber that by presystolic contraction helps complete LV filling with an atrial kick. Third, the left atrium functions as a conduit that empties its contents into the left ventricle down a pressure gradient after the mitral valve opens. Fourth, it is a *blood volume sensor* in the heart and releases atrial natriuretic peptide (ANP) in response to stretch so that ANP-induced diuresis can help restore blood volume to normal. Notably, in congestive heart failure, when the renin-angiotensin system causes fluid retention and exacerbates the elevation in LA pressure and

volume, ANP secretion is elevated. Fifth, the left atrium contains receptors for the afferent arms of various reflexes, including mechanoreceptors that increase the sinus discharge rate, thereby contributing to the tachycardia of exercise as venous return increases (Bainbridge reflex).[3,4]

The atrial pressure-volume loop is very different in shape from that of the ventricles in that it resembles a figure 8. During atrial pacing, preload is increased and the atria are distended, so the volume part of the loop is small, and the pressure part of the loop is much enlarged.[67] The atria have a number of differences in structure and function from the ventricles, including smaller myocytes with fewer T tubules, a shorter action potential duration, and more fetal myosin isoforms (both heavy and light chains).[70] The more rapid atrial repolarization is caused by increased outward potassium currents, such as I_{to}, and also has faster Ca^{2+} transient kinetics. In general, these histologic and physiologic changes might be related to the decreased need for the atria to generate high intrachamber pressures, rather than being sensitive to changes in volume while retaining enough contractile action to help with LV filling and to respond to inotropic stimuli. *Atrial remodeling* refers to a variety of ionic, structural, contractile, and metabolic changes that are induced by insults such as chronic atrial tachyarrhythmias, including atrial fibrillation,[70] or by left atrial stretch and enlargement. Cellular mechanisms include decreased L-type Ca^{2+} channel activity,[70] increased abnormal collagen,[71] and probably adverse stretch-induced signaling. The results include poor contractile performance and increased initiation and perpetuation of atrial fibrillation. Atrial remodeling and deterioration in left atrial function lead to worsening pulmonary hypertension and secondary right ventricular dysfunction in patients with heart failure.[72]

Future Perspectives

During the last 20 years we have gained tremendous molecular and cellular insight into a much richer, quantitatively detailed understanding of the individual steps in the overall excitation-contraction-relaxation process. In addition, there is a greatly enhanced understanding about how all these processes interact at the cellular and tissue level, how they are regulated by numerous interacting signaling pathways, and what goes wrong during certain cardiac pathologies. This is a very complex system, and diseases such as heart failure are also extremely complex. In the coming 5 years we can expect further clarification of all these systems, likely with a better understanding of signaling in local microdomains and protein complexes. At present, however, we must use this rich mechanistic knowledge to test novel therapeutic strategies for heart failure (e.g., SERCA2 overexpression, RyR inhibitors, GRK2 inhibitors, myofilament enhancers). This work may provide novel effective therapies but will also help us better understand how the fundamental systems impacted by these approaches integrate into the behavior of the whole system. This emphasizes how critical it is to integrate our knowledge of these many systems that dynamically regulate contraction and relaxation over multiple physical scales (molecules to cell to heart to animal) and time scales (milliseconds to seconds, minutes, hours, days, and years), as well as in multiple disciplinary and methodologic perspectives, to help bring the entire system to a higher level of understanding. In this way the therapeutic strategies that we must also continue to test are likely to improve.

Pathophysiology of Heart Failure

Gerd Hasenfuss, Douglas L. Mann

Overview

Despite repeated attempts to discover a unique pathophysiologic mechanism that precisely explains the clinical syndrome of heart failure (HF), no single conceptual paradigm has withstood the test of time. Although clinicians initially viewed HF as a problem of excessive salt and water retention that was caused by abnormalities of renal blood flow (the so-called cardiorenal model) and/or abnormal pumping capacity of the heart (the cardiocirculatory or hemodynamic model),[1] these models do not adequately explain the relentless disease progression that occurs in this syndrome.

This chapter focuses on the molecular and cellular changes that underlie heart failure with a reduced ejection fraction (HFrEF), with an emphasis on the role of neurohormonal activation and left ventricular (LV) remodeling as the primary determinants for disease progression in HF. The hemodynamic, contractile, and wall motion disorders in HF are discussed in the chapters on echocardiography (**see Chapter 14**), cardiac catheterization (**Chapter 19**), radionuclide imaging (**Chapter 16**), and clinical assessment of the patient with HF (**Chapter 21**). **Chapter 26** discusses the pathogenesis of HF with preserved ejection fraction.

Pathogenesis

As shown in **Fig. 23.1A**, heart failure may be viewed as a progressive disorder that is initiated after an *index event* either damages the heart muscle, with a resultant loss of functioning cardiac myocytes or,

alternatively, disrupts the ability of the myocardium to generate force, thereby preventing the heart from contracting normally. This index event may have an abrupt onset, as in the case of a myocardial infarction (MI); it may have a gradual or insidious onset, as in the case of hemodynamic pressure or volume overloading, or it may be hereditary, as in the case of many of the genetic cardiomyopathies. Regardless of the nature of the inciting event, the feature that is common to each of these index events is that they all, in some manner, produce a decline in pumping capacity of the heart. In most instances, patients will remain asymptomatic or minimally symptomatic after the initial decline in pumping capacity of the heart, or symptoms develop only after the dysfunction has been present for some time. Although the precise reasons why patients with LV dysfunction remain asymptomatic have not been established with certainty, one potential explanation is that a number of compensatory mechanisms that become activated in the setting of cardiac injury or depressed cardiac output appear to modulate LV function within a physiologic/homeostatic range, such that the patient's functional capacity is preserved or is depressed only minimally. With progression to symptomatic HF, however, the sustained activation of neurohormonal and cytokine systems leads to a series of end-organ changes within the myocardium referred to collectively as *left ventricular remodeling*. As discussed later, LV remodeling is sufficient to lead to disease progression in HF independent of the neurohormonal status of the patient.

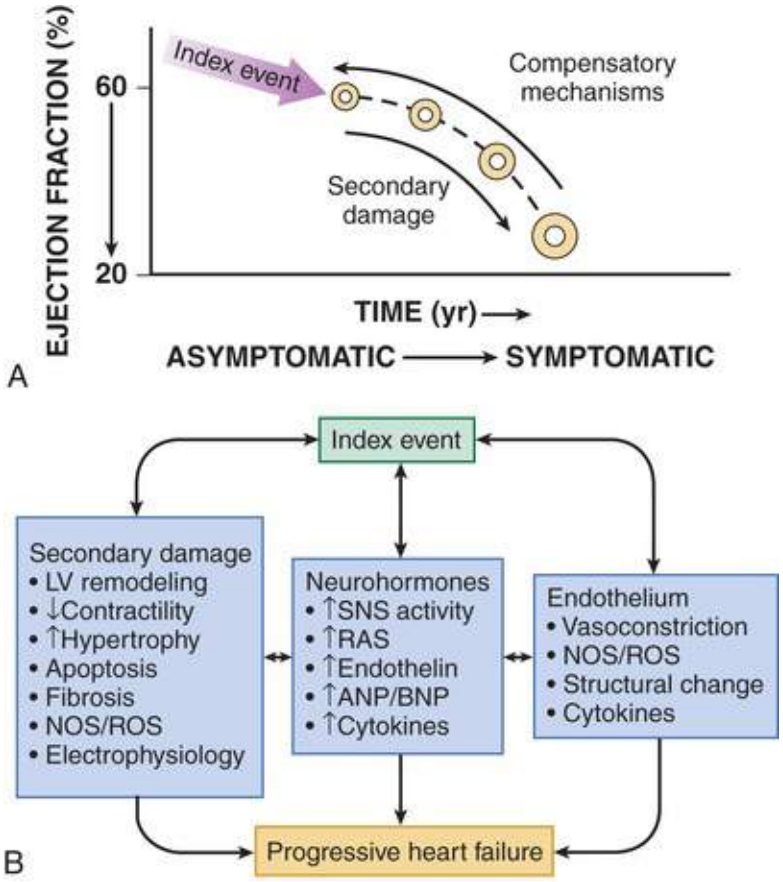

FIGURE 23.1 Pathogenesis of heart failure. **A,** Heart failure begins after a so-called index event produces an initial decline in pumping capacity of the heart. **B,** After this initial decline in pumping capacity, a variety of compensatory mechanisms are activated, including the adrenergic nervous system, the renin-angiotensin system (RAS), and the cytokine systems. In the short term, these systems are able to restore cardiovascular function to a normal homeostatic range, with the result that the patient remains asymptomatic. With time, however, the sustained activation of these systems can lead to secondary end-organ damage within the ventricle, with worsening LV remodeling and subsequent cardiac decompensation. As a result of these changes, patients undergo the transition from asymptomatic to symptomatic heart failure. ANP/BNP, Atrial/brain-type natriuretic peptide; NOS, nitric oxide synthase; ROS, reactive oxygen species; SNS, sympathetic nervous system. (From Mann DL: Mechanisms and models in HF: a combinatorial approach. Circulation 199;100:99; and Kaye DM, Krum H. Drug discovery for heart failure: a new era or the end of the pipeline? Nat Rev Drug Discov 2007;6:127.)

Heart Failure as a Progressive Model

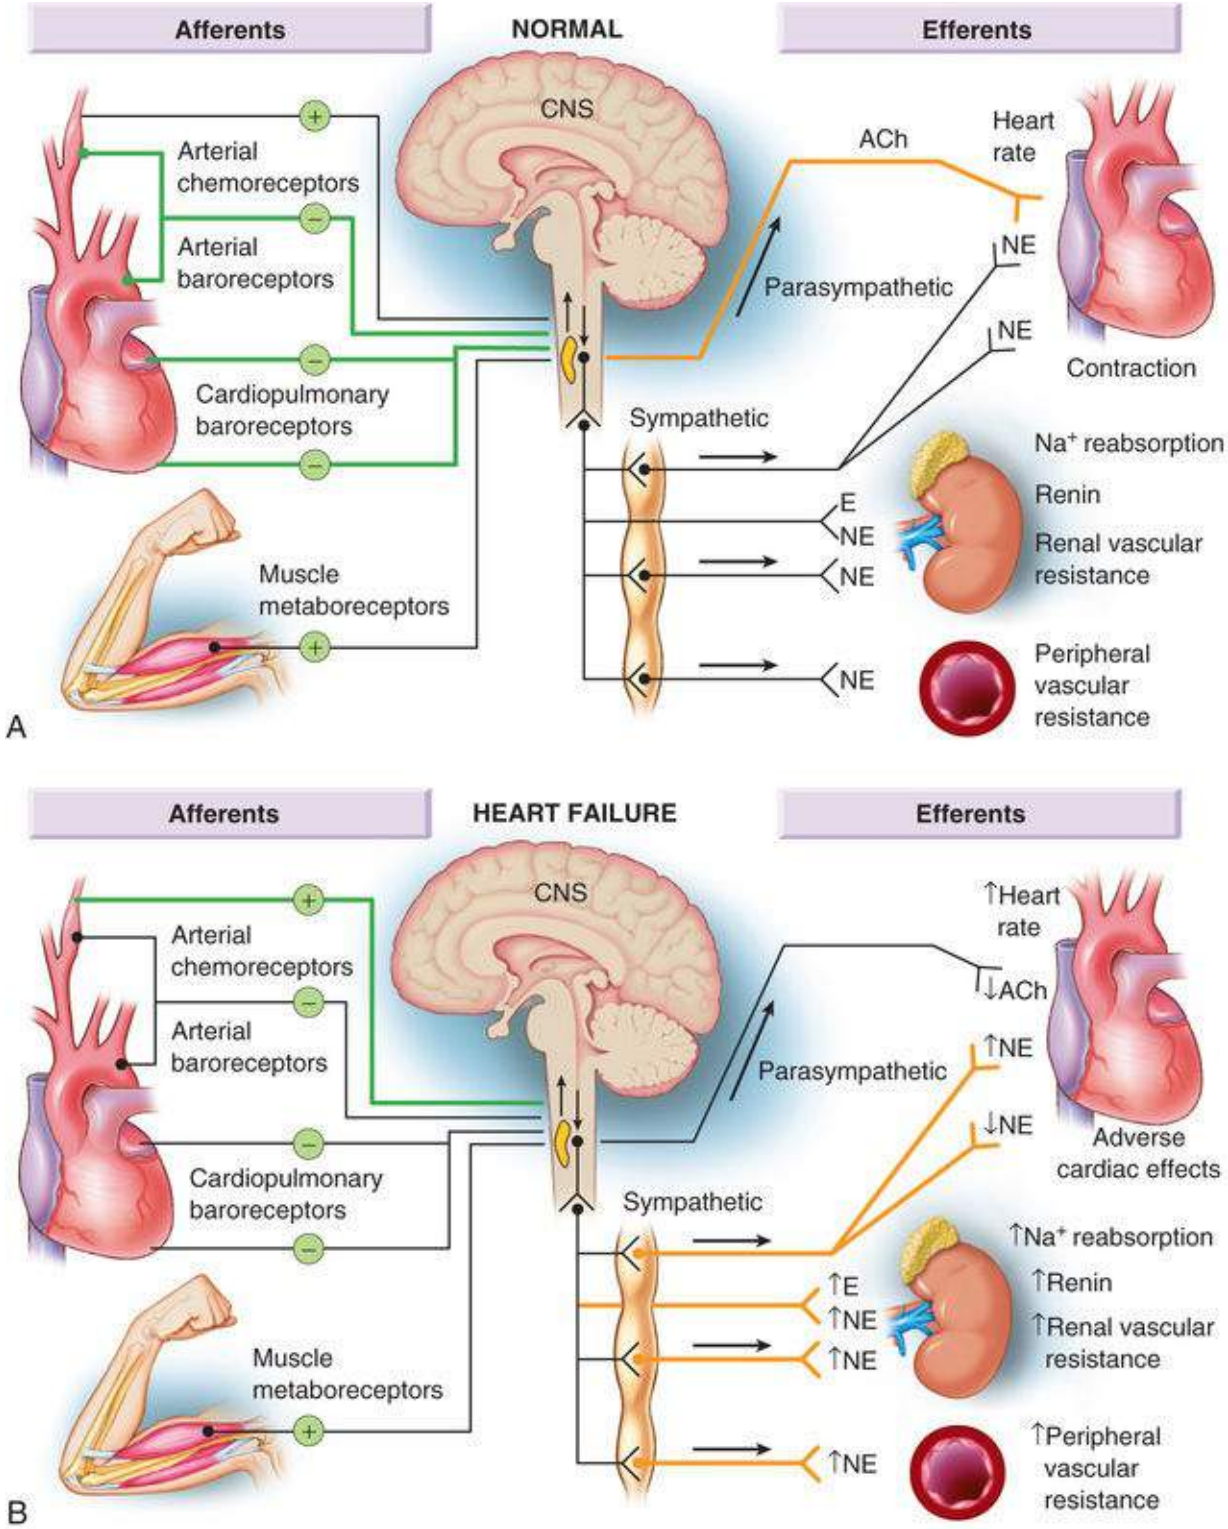
Neurohormonal Mechanisms

A growing body of experimental and clinical evidence suggests that HF progresses as a result of the overexpression of biologically active molecules that are capable of exerting deleterious effects on the heart and circulation[2] (**Fig. 23.1B**). The portfolio of compensatory mechanisms that have been described thus far includes activation of the adrenergic nervous systemic system and the renin-angiotensin system (RAS), which are responsible for maintaining cardiac output through increased retention of salt and water; peripheral arterial vasoconstriction and increased contractility; and inflammatory mediators that are responsible for cardiac repair and remodeling. It bears emphasis that *neurohormone* is largely a historical term, reflecting the original observation that many of the molecules that were elaborated in HF were produced by the neuroendocrine system and thus acted on the heart in an endocrine manner. It has since become apparent, however, that a great many of the so-called classic neurohormones such as norepinephrine (NE) and angiotensin II are synthesized directly within the myocardium by myocytes and

thus act in an autocrine and paracrine manner. Nonetheless, the important unifying concept that arises from the neurohormonal model is that the overexpression of portfolios of biologically active molecules contributes to disease progression by virtue of the deleterious effects these molecules exert on the heart and circulation.

Activation of Sympathetic Nervous System

The decrease in cardiac output in HF activates a series of compensatory adaptations that are intended to maintain cardiovascular homeostasis. One of the most important adaptations is activation of the sympathetic (adrenergic) nervous system (SNS), which occurs early in the course of HF. Activation of the SNS in HF is accompanied by a concomitant withdrawal of parasympathetic tone (**eFig. 23.1**). Although these disturbances in autonomic control initially were attributed to loss of the inhibitory input from arterial or cardiopulmonary baroreceptor reflexes, increasing evidence indicates that excitatory reflexes also may participate in the autonomic imbalance that occurs in HF.[3] In healthy persons, “high-pressure” carotid sinus and aortic arch baroreceptors and “low-pressure” cardiopulmonary mechanoreceptors provide inhibitory signals to the central nervous system (CNS) that repress the sympathetic outflow to the heart and peripheral circulation. Under normal conditions, inhibitory inputs from high-pressure carotid sinus and aortic arch baroreceptors and the low-pressure cardiopulmonary mechanoreceptors are the principal inhibitors of sympathetic outflow, whereas discharge from the nonbaroreflex peripheral chemoreceptors and from muscle *metaboreceptors* are the major excitatory inputs to sympathetic outflow. The vagal limb of the baroreceptor heart rate reflex also is responsive to arterial baroreceptor afferent inhibitory input. Healthy persons display low sympathetic discharge at rest and have a high heart rate variability. In patients with HF, however, inhibitory input from baroreceptors and mechanoreceptors decreases and excitatory input increases, with the net result of a generalized increase in sympathetic nerve traffic and blunted parasympathetic nerve traffic, leading to loss of heart rate variability and increased peripheral vascular resistance.[3]



EFIGURE 23.1 Compensated and decompensated heart failure (HF), as indicated by the presence or absence of urinary sodium retention, together with symptoms and signs of expanded intravascular and extravascular volume. **A,** In compensated HF with mild to moderate reductions in renal perfusion, natriuretic peptides, such as atrial natriuretic peptide (ANP) released by distended atria, stimulate sodium excretion (decreasing reabsorption, *minus sign*) so that the urinary sodium-potassium (Na^+/K^+) ratio is greater than 1.0. **B,** In decompensated HF, moderate to severe reductions in renal perfusion activate the renin-angiotensin-aldosterone system (RAAS), overriding the action of natriuretic peptides to stimulate nearly complete urinary sodium reabsorption (*plus sign*), resulting in a urinary sodium-potassium ratio less than 1.0. *Ach,* Acetylcholine; *CNS,* central nervous system; *E,* epinephrine; *NE,* norepinephrine. (From Weber KT. Aldosterone in congestive heart failure. N Engl J Med 2001;345:1689; and Weber KT, Villareal D. Aldosterone and antialdosterone therapy in congestive heart failure. Am J Cardiol 1993;71[suppl 3A]:11A.)

As a result of the increase in sympathetic tone, there is an increase in circulating levels of NE, a potent adrenergic neurotransmitter. The elevated levels of circulating NE result from a combination of increased

release of NE from adrenergic nerve endings and its consequent “spillover” into the plasma, as well as reduced uptake of NE by adrenergic nerve endings. In patients with advanced HF, the circulating levels of NE in resting patients are two to three times those found in normal persons. Indeed, plasma levels of NE predict mortality in patients with HF. Whereas the normal heart usually extracts NE from the arterial blood, in patients with moderate HF the coronary sinus NE concentration exceeds the arterial concentration, indicating increased adrenergic stimulation of the heart. However, as HF progresses there is a significant decrease in the myocardial concentration of NE. The mechanism responsible for cardiac NE depletion in severe HF is not clear and may relate to an “exhaustion” phenomenon resulting from the prolonged adrenergic activation of the cardiac adrenergic nerves in HF. In addition, there is decreased activity of myocardial tyrosine hydroxylase, which is the rate-limiting enzyme in the synthesis of NE. In patients with cardiomyopathy, iodine 131 (^{131}I)–labeled metaiodobenzylguanidine (MIBG), a radiopharmaceutical that is taken up by adrenergic nerve endings, is not taken up normally, suggesting that NE reuptake is also depressed.

Increased sympathetic activation of the beta$_1$-adrenergic receptor results in increased heart rate and force of myocardial contraction, with a resultant increase in cardiac output (**see Chapter 22**). In addition, the heightened activity of the adrenergic nervous system leads to stimulation of myocardial alpha$_1$-adrenergic receptors, which elicits a modest positive inotropic effect, as well as peripheral arterial vasoconstriction (**Fig. 23.2**). Although NE enhances both contraction and relaxation and maintains blood pressure, myocardial energy requirements are augmented, which can intensify ischemia when myocardial oxygen (O_2) delivery is restricted. The augmented adrenergic outflow from the CNS also may trigger ventricular tachycardia or even sudden cardiac death, particularly in the presence of myocardial ischemia. Thus, activation of the SNS provides short-term support that has the potential to become maladaptive over the long term. Moreover, increasing evidence suggests that apart from the deleterious effects of sympathetic activation, parasympathetic withdrawal also may contribute to the pathogenesis of HF. Withdrawal of parasympathetic nerve stimulation has been associated with decreased nitric oxide (NO) levels, increased inflammation, increased sympathetic activity, and worsening LV remodeling. Several clinical trials with vagal nerve stimulation did not meet their primary endpoint but have shown encouraging trends in several secondary endpoints.[4]

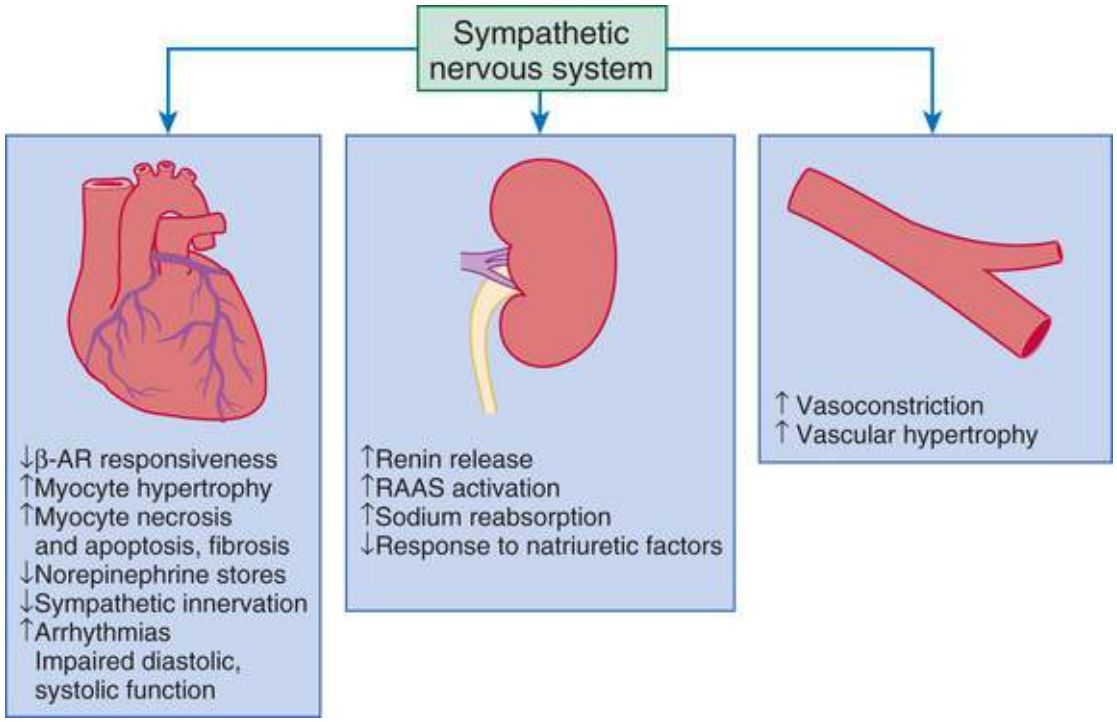


FIGURE 23.2 Activation of the sympathetic nervous system. Increased sympathetic nervous system (SNS) activity may contribute to the pathophysiology of congestive heart failure by multiple mechanisms involving cardiac, renal, and vascular function. In the heart, increased SNS outflow may lead to desensitization beta-adrenergic receptors (β-ARs), myocyte hypertrophy, necrosis, apoptosis, and fibrosis. In the kidneys, increased SNS activation induces arterial and venous vasoconstriction, activation of the renin-angiotensin-aldosterone system (RAAS), increase in salt and water retention, and an attenuated response to natriuretic factors. In the peripheral vessels, neurogenic vasoconstriction and vascular hypertrophy are induced by increased SNS activity. (From Nohria A, Cusco JA, Creager MA. Neurohormonal, renal and vascular adjustments in heart failure. In Colucci WS, editor. Atlas of Heart Failure. 4th ed. Philadelphia: Current Medicine; 2008, p 106.)

Activation of the Renin-Angiotensin System

In contrast with the SNS, the components of the RAS are activated comparatively later in HF. The presumptive mechanisms for RAS activation in HF include renal hypoperfusion, decreased filtered sodium reaching the macula densa in the distal tubule, and increased sympathetic stimulation of the kidney, leading to increased renin release from juxtaglomerular apparatus. As shown in **Fig. 23.3**, renin cleaves four amino acids from circulating angiotensinogen, which is synthesized in the liver, to form the biologically inactive decapeptide angiotensin I. Angiotensin-converting enzyme (ACE) cleaves two amino acids from angiotensin I to form the biologically active octapeptide (1-8) angiotensin II. Most ACE activity (approaching 90%) in the body is found in tissues; the remaining 10% is found in a soluble (non–membrane-bound) form in the interstitium of the heart and vessel wall. The importance of tissue ACE activity in HF is suggested by the observation that ACE messenger RNA (mRNA) and ACE-binding sites and ACE activity are increased in explanted human hearts.[5] Angiotensin II also can be synthesized using renin-independent pathways through the enzymatic conversion of angiotensinogen to angiotensin I by kallikrein and cathepsin G (**Fig. 23.3A**). The tissue production of angiotensin II also may occur along ACE-independent pathways, through the activation of chymase. This latter pathway may be of major importance in the myocardium, particularly when the levels of renin and angiotensin I are increased by the use of ACE inhibitors. Angiotensin II itself can undergo further proteolysis to generate three biologically active fragments: angiotensin III (2-8) angiotensin IV (3-8) and angiotensin 1-7 (**Fig. 23.3B**).

FIGURE 23.3 **A,** The systemic and tissue components of the RAS. Several tissues, including myocardium, vasculature, kidney, and brain, have the capacity to generate angiotensin II independent of the circulating RAS. Angiotensin II produced at the tissue level may play an important role in the pathophysiology of heart failure. ACE, Angiotensin-converting enzyme; Ang, angiotensin. **B,** Angiotensin II degradation pathways. Angiotensin II is degraded by angiotensin-converting enzyme 2 (ACE2) to form Ang-(1–7), which subsequently can be degraded by ACE to form Ang-(1–5). Other pathways of angiotensin II degradation include aminopeptidase A to Ang-(2–8), dipeptidyl-aminopeptidase I–III to Ang IV, and neprilysin and various peptidases to other small peptide products. Ang-(2–8) and Ang IV may also be reversibly interchanged via aminopeptidase N. **C,** Action of angiotensin II type 1 (AT_1) and type 2 (AT_2) receptors and MAS-mediated signaling. NO, Nitric oxide. Devil and angel in the renin-angiotensin system. Hypertens Res 2009;32:533-6.)

Angiotensin II exerts its effects by binding to two G protein–coupled receptors (GPCRs), the angiotensin type 1 (AT_1) and angiotensin type 2 (AT_2) receptors. The predominant angiotensin receptor in the vasculature is the AT_1 receptor. Although both AT_1 and AT_2 receptor subtypes are present in human myocardium, the AT_2 receptor predominates in a 2 : 1 molar ratio. Cellular localization of the AT_1 receptor in the heart is most abundant in nerves distributed in the myocardium, whereas the AT_2 receptor is localized more specifically in fibroblasts and the interstitium. Activation of the AT_1 receptor leads to vasoconstriction, cell growth, aldosterone secretion, and catecholamine release, whereas activation of the AT_2 receptor leads to vasodilation, inhibition of cell growth, natriuresis, and bradykinin release (**Fig. 23.3C**). Studies have shown that the AT_1 receptor and mRNA levels are downregulated in failing human hearts, whereas AT_2 receptor density is increased or unchanged, so that the ratio of AT_1 to AT_2 receptors decreases.[6] The MAS receptor is a GPCR that is expressed primarily in the brain and testes but also in the heart (**Fig. 23.3C**).

Angiotensin II has several important actions that are critical to maintaining short-term circulatory homeostasis. The sustained expression of angiotensin II is maladaptive, however, leading to fibrosis of the heart, kidneys, and other organs. Angiotensin II can also lead to worsening neurohormonal activation by enhancing the release of NE from sympathetic nerve endings, as well as stimulating the zona glomerulosa of the adrenal cortex to produce aldosterone. Analogous to angiotensin II, aldosterone provides short-term support to the circulation by promoting the reabsorption of sodium in exchange for potassium, in the distal segments of the nephron. However, the sustained expression of aldosterone may exert harmful effects by provoking hypertrophy and fibrosis within the vasculature and the myocardium, contributing to reduced vascular compliance and increased ventricular stiffness. In addition, aldosterone provokes endothelial cell dysfunction, baroreceptor dysfunction, and inhibition of NE uptake, any of which may lead to worsening HF. The mechanism of action of aldosterone in the cardiovascular system appears to involve oxidative stress, with resultant inflammation in target tissue. Although the exact role of angiotensin III (2-8) angiotensin IV (3-8) and angiotensin 1-7 in HF are not known, experimental studies suggest that angiotensin 1-7 counteracts the effects of angiotensin II, and attenuates LV remodeling.[2] In contrast, angiotensin III directly stimulates the zona glomerulosa of the adrenal glands to produce aldosterone,[2] which promotes sodium resorption in the distal collecting duct of the kidney. Angiotensin III also has an important role in vasopressin release in the brain, which controls water retention in the distal collecting duct of the kidney. Angiotensin III in the brain can also modulate cardiac nervous sympathetic hyperactivity, as well as LV remodeling after MI.[2]

Oxidative Stress.

Reactive oxygen species (ROS) are a normal byproduct of aerobic metabolism. In the heart, the potential sources for ROS include the mitochondria, xanthine oxidase, and nicotinamide-adenine dinucleotide phosphate (NADPH) oxidase (**Fig. 23.4**). ROS can modulate the activity of a variety of intracellular proteins and signaling pathways, including essential proteins involved in myocardial excitation-contraction coupling, such as ion channels, sarcoplasmic reticulum (SR) calcium release channels, and myofilament proteins, as well as signaling pathways that are coupled to myocyte growth.[7] "Oxidative stress" occurs when the production of ROS exceeds the buffering capacity of antioxidant defense systems, leading to an excess of ROS within the cell. Substantial evidence indicates that the level of oxidative stress is increased both systemically and in the myocardium of patients with HF. Oxidative stress in the heart may be caused by reduced antioxidant capacity and increased production of ROS, which may arise secondary to mechanical strain of the myocardium, neurohormonal stimulation (angiotensin II, alpha-adrenergic agonists, endothelin-1 [ET-1]), or inflammatory cytokines (tumor necrosis factor [TNF], interleukin [IL]-1). Excessive mitochondria-derived ROS in cardiac myocytes have been demonstrated in experimental models of HF and may contribute to contractile dysfunction in advanced HF. Increased xanthine oxidase expression and activity have been reported in canine rapid pacing–induced HF and patients with end-stage HF. Moreover, increased expression and activity of myocardial NADPH oxidases have been demonstrated in both experimental and human HF.[7] In cultured cardiac myocytes, ROS stimulate myocyte hypertrophy, reexpression of fetal gene programs, and apoptosis. ROS also can modulate fibroblast proliferation and collagen synthesis and trigger increased matrix metalloproteinase (MMP) abundance and activation. ROS also can affect the peripheral vasculature in HF by decreasing the bioavailability of NO. These and other observations have led to the suggestion that strategies to reduce ROS may be of therapeutic value in patients with HF. However, xanthine oxidase inhibition with allopurinol to reduce oxidative stress in hyperuremic patients with HF did not improve clinical status or cardiac function in a recent trial.[8]

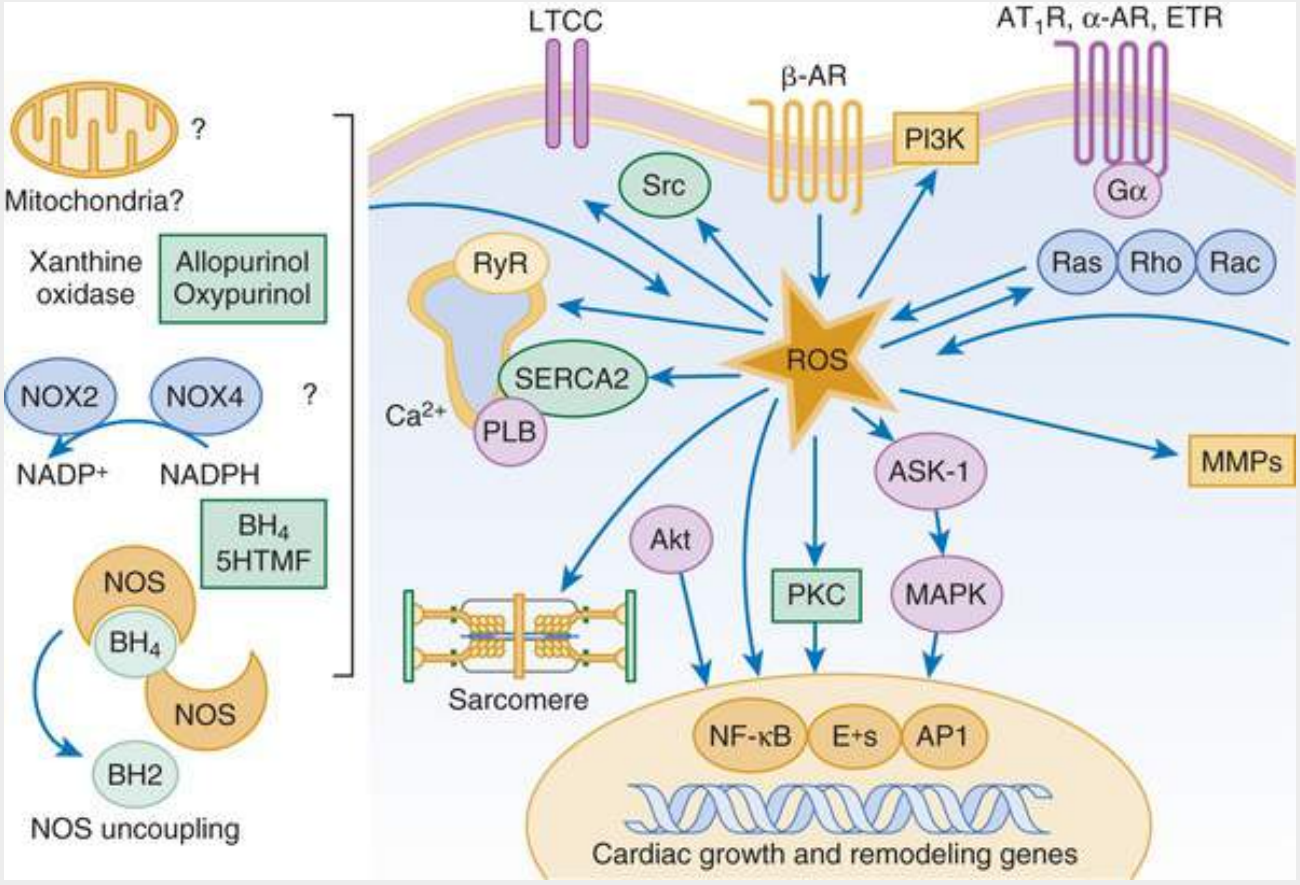

FIGURE 23.4 Cellular sources of ROS and ROS signaling in cardiac hypertrophy. ROS-generating systems are shown on the *left* and include xanthine oxidase, NADPH oxidases (NOX2, NOX4), NOS, and mitochondrial complexes. (Modified from McKinsey TA, Kass DA. Small-molecule therapies for cardiac hypertrophy: moving beneath the cell surface. Nat Rev Drug Discov 2007;6:617.)

The importance of aldosterone, independent of angiotensin II, has been demonstrated by clinical trials (**see Chapter 25**) showing that low-dose spironolactone increased the survival of patients with New York Heart Association (NYHA) Class II to IV systolic HF, as well as improved survival after MI, independent of changes in volume or electrolyte status.[9]

Neurohormonal Alterations of Renal Function

One of the signatures of advancing HF is increased salt and water retention by the kidneys. Traditional theories have ascribed this increase to either “forward” failure, which attributes sodium retention to inadequate renal perfusion as a consequence of impaired cardiac output, or “backward” failure, which emphasizes the importance of increased venous pressure in favoring transudation of salt and water from the intravascular to the extracellular compartment. These mechanisms have largely been supplanted by the concept of decreased *effective arterial blood volume*, which postulates that despite blood volume expansion in HF, inadequate cardiac output sensed by baroreceptors in the vascular tree leads to a series of compensatory neurohormonal adaptations that resemble the homeostatic response to acute blood loss.[2] As illustrated in **Fig. 23.5**, a falling cardiac output or redistribution of the circulating blood volume is sensed by baroreceptors in the left ventricle, aortic arch, carotid sinus, and renal afferent arterioles. The

loss of inhibitory input from arterial or cardiopulmonary baroreceptor reflexes leads to sustained activation of the SNS and the RAS. An implantable barostimulation device that activates the carotid baroreceptors to decrease sympathetic activation and increase vagal tone improved quality of life and exercise capacity in patients with symptomatic HF.[4] The ongoing BeAT-HF (Barostim Therapy for Heart Failure) trial will determine whether baroreceptor activation therapy will favorably impact cardiovascular mortality and HF mortality at study completion (efficacy endpoint) and major adverse neurologic and cardiovascular events at 6 months.

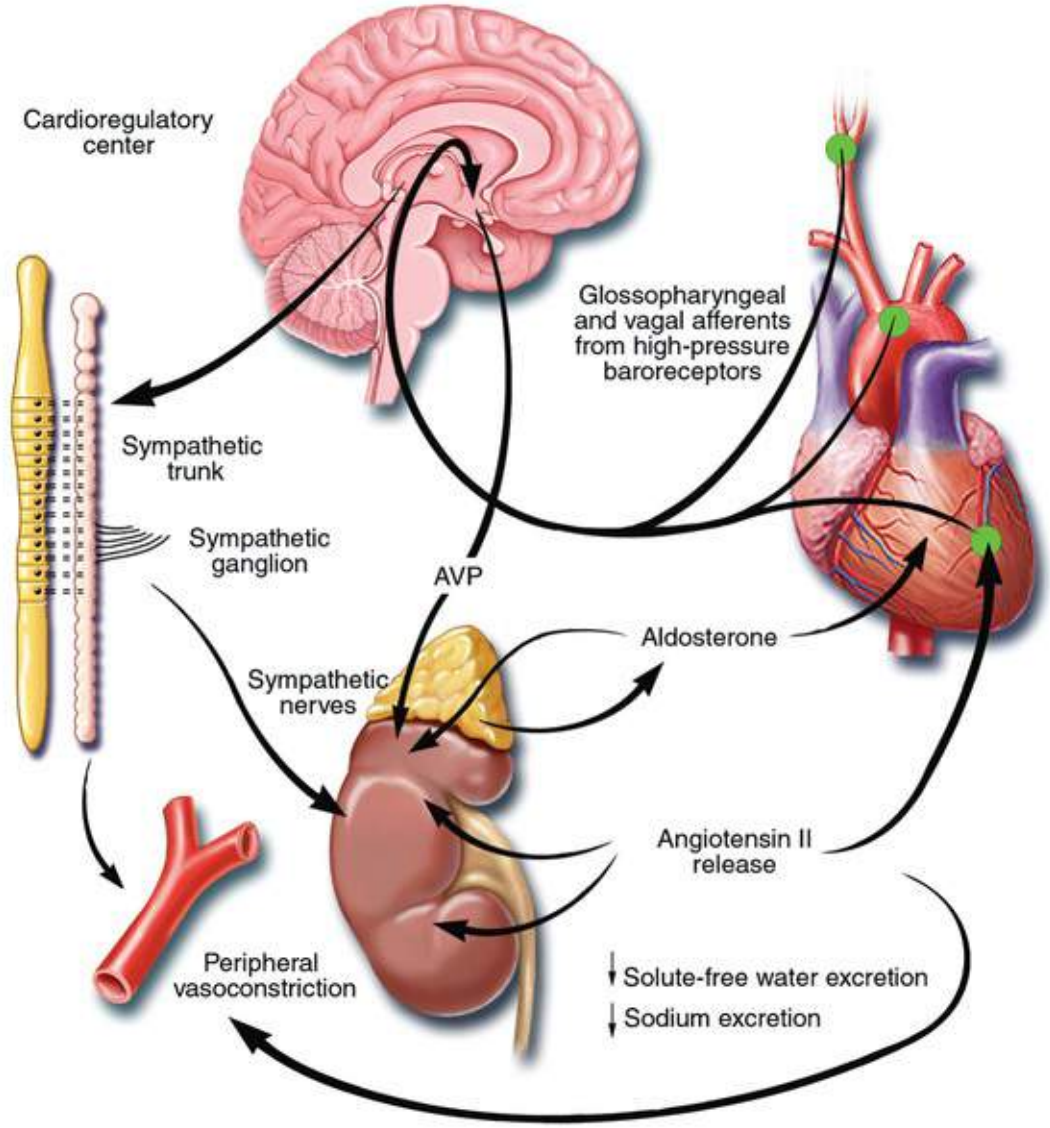

FIGURE 23.5 Unloading of high-pressure baroceptors (*circles*) in the left ventricle, carotid sinus, and aortic arch generates afferent signals that stimulate cardioregulatory centers in the brain, resulting in the activation of efferent pathways in the sympathetic nervous system. The SNS appears to be the primary integrator of the neurohumoral vasoconstrictor response to arterial underfilling. Activation of renal sympathetic nerves stimulates the release of arginine vasopressin (*AVP*). Sympathetic activation also causes peripheral and renal vasoconstriction, as does angiotensin II. Angiotensin II constricts blood vessels and stimulates the release of aldosterone from the adrenal gland, and it also increases tubular sodium reabsorption and causes remodeling of cardiac myocytes. Aldosterone also may have direct cardiac effects, in addition to increasing the reabsorption of sodium and the secretion of potassium (K^+) and hydrogen ($H^{+)}$ ions in the collecting duct. The *black arrows* designate circulating hormones. (Modified from Schrier RW, Abraham WT. Hormones and hemodynamics in heart failure. N Engl J Med 1999;341:577.)

There is little evidence to suggest that a primary renal abnormality is responsible for the initial sodium

retention in heart; however, there is mounting evidence that secondary changes in the kidney contribute importantly to volume overload as HF progresses. Volume overload in HF is multifactorial and is secondary, at least in part, to several factors that have the potential to cause increased sodium reabsorption, including activation of the SNS, activation of RAS, reduced renal perfusion pressures, and blunting of renal responsiveness to natriuretic peptides. Increased renal sympathetic nerve–mediated vasoconstriction leads to decreased renal blood flow, as well as increased renal tubular sodium and water reabsorption throughout the nephron. Renal sympathetic stimulation also can lead to the nonosmotic release of arginine vasopressin (AVP) from the posterior pituitary, which reduces the excretion of free water and contributes to worsening peripheral vasoconstriction, as well as increased endothelin (ET) production.[2] Increased renal venous pressure can also lead to renal interstitial hypertension, with the development of tubular injury and renal fibrosis.

Arginine Vasopressin.
AVP is a pituitary hormone that plays a central role in the regulation of free water clearance and plasma osmolality (**see Fig. 23.5**). Under normal circumstances, AVP is released in response to an increase in plasma osmolality, leading to increased retention of water from the collecting duct. Of note, circulating AVP is elevated in many patients with HF, even after correction for plasma osmolality (i.e., nonosmotic release),[2] and may contribute to the hyponatremia that occurs in HF. The cellular effects of AVP are mediated mainly by interactions with three types of receptors, termed V_{1a}, V_{2a}, and V_2. The V_{1a} receptor, the most widespread subtype, is found primarily in vascular smooth muscle cells. The V_{1b} receptor has a more limited distribution and is located mainly in the CNS. The V_2 receptors are found primarily in the epithelial cells in the renal collecting duct and the thick ascending limb. AVP receptors are members of the GPCRs. The V_{1a} receptors mediate vasoconstriction, platelet aggregation, and stimulation of myocardial growth factors, whereas V_{1b} modulates adrenocorticotropic hormone (ACTH) secretion from the anterior pituitary. The V_2 receptor mediates antidiuretic effects by stimulating adenyl cyclase to increase the rate of insertion of water channel−containing vesicles into the apical membrane. Because the vesicles contain preformed functional water channels, termed *aquaporins*, their localization in the apical membranes in response to V_2 stimulation increases the water permeability of the apical membrane, leading to water retention. The “vaptans,” vasopressin receptor antagonists with V_{1a} (relcovaptan) or V_2 (tolvaptan, lixivaptan) selectivity or nonselective V_{1a}/V_2 activity (conivaptan), have been shown to reduce body weight and reduce hyponatremia in clinical trials (**see Chapters 24 and 25**).

Increased renal sympathetic activity leads to increased renin production by the kidneys, with a resultant sustained activation of RAS, despite an expanded extracellular volume. Angiotensin II facilitates retention of sodium and water by multiple renal mechanisms, including a direct proximal tubular effect, as well as through activation of aldosterone, which leads to increased sodium resorption in the distal tubule. Angiotensin II also stimulates the thirst center of the brain and provokes the release of AVP and aldosterone, both of which can lead to further dysregulation of salt and water homeostasis.

A number of counterregulatory neurohormonal systems become activated in HF in order to offset the deleterious effects of the vasoconstricting neurohormones (**eTable 23.1**). Metabolites of vasodilatory prostaglandins, including prostaglandin E_2 (PGE_2) and prostacyclin (PGI_2), are elevated in patients with HF. In addition to being a vasodilator, PGE_2 enhances renal sodium excretion and modulates the

antidiuretic action of AVP. One class of the most important counterregulatory neurohormonal systems that become activated in HF are the natriuretic peptides, including atrial natriuretic peptide (ANP) and brain (B-type) natriuretic peptide (BNP). Under physiologic conditions, ANP and BNP function as natriuretic hormones that are released in response to increases in atrial and myocardial stretch, often secondary to excessive sodium intake. Once released, these cardiac peptides act on the kidney and peripheral circulation to unload the heart, through increased excretion of sodium and water, while inhibiting the release of renin and aldosterone (**Fig. 23.6**). In the setting of RAS activation, the release of ANP and BNP may serve as an important counterregulatory mechanism that maintains sodium and water homeostasis. However, for reasons that are not entirely clear, the renal effects of the natriuretic peptides appear to become blunted with advancing HF, leaving the effects of RAS unopposed.[10] Potential reasons for this blunting include low renal perfusion pressure, relative deficiency or altered molecular forms of the natriuretic peptides, and decreased levels of natriuretic peptide receptors.

Natriuretic Peptides.

The natriuretic peptide system consists of five structurally similar peptides: ANP, urodilatin (an isoform of ANP), BNP, C-type natriuretic peptide (CNP), and dendroaspis natriuretic peptide (DNP) (**Fig. 23.6A**).[11] ANP, a 28–amino acid peptide hormone, is produced principally in the cardiac atria, whereas BNP, a 32–amino acid peptide originally isolated from porcine brain, was later identified as a hormone that was primarily produced in the cardiac ventricles.[11] Both ANP and BNP are secreted in response to increasing cardiac wall tension; however, other factors such as neurohormones (e.g., angiotensin II, ET-1, catecholamines) or physiologic factors (e.g., age, sex, renal function) may also play a role in their regulation. The biosynthesis, secretion, and clearance of BNP differs from ANP, suggesting that these two natriuretic peptides have discrete physiologic and pathophysiologic roles. Whereas ANP is secreted in short bursts in response to acute changes in atrial pressure, the activation of BNP is regulated transcriptionally in response to chronic increases in atrial/ventricular pressure. ANP and BNP initially are synthesized as prohormones that are subsequently proteolytically cleaved, respectively, by corin and furin, to yield large, biologically inactive N-terminal fragments (NT-ANP and NT-BNP) and smaller, biologically active peptides (i.e., ANP and BNP). ANP has a relatively short half-life of approximately 3 minutes, whereas BNP has a plasma half-life of approximately 20 minutes. CNP, which is located primarily in the vasculature, also is released as a prohormone that is cleaved into biologically inactive form (NT-CNP) and a 22–amino acid, biologically active form (i.e., CNP).

Fig. 23.6B illustrates the signaling pathway of the natriuretic peptide system. The natriuretic peptides stimulate the production of the intracellular second-messenger cyclic guanosine monophosphate (cGMP), via binding to the natriuretic peptide A receptor (NPR-A), which preferentially binds ANP and BNP, and the natriuretic peptide B receptor (NPR-B), which preferentially binds CNP. Both NPR-A and NPR-B

are coupled to particulate guanylate cyclase. Activation of NPR-A and NPR-B results in natriuresis, vasorelaxation, inhibition of renin and aldosterone, inhibition of fibrosis, and increased lusitropy. The natriuretic peptide C receptor (NPR-C) is not linked to cGMP and serves as a clearance receptor for the natriuretic peptides.

All three natriuretic peptides are degraded by two major mechanisms: NPR-C–mediated internalization, followed by lysosomal degradation and enzymatic degradation by neutral endopeptidase (NEP) 24.11 (neprilysin), which is widely expressed in multiple tissues, where it often is colocalized with ACE. Both ACE and NEP are membrane-bound zinc-containing metallopeptidases involved in the metabolism of a variety of biologic peptides[12] (**Fig. 23.6C**). NEP preferentially cleaves small peptides on the N-terminal side of hydrophobic residues. It has a wide range of tissue distribution, including vascular endothelium, smooth muscle cells, myocytes, fibroblasts, kidney tubule cells, and nerve cells. NEP degrades multiple peptides, including natriuretic peptides (**Fig. 23.6D**), angiotensin I, angiotensin II, ET-I, adrenomedullin, opioids, bradykinin, chemotactic peptides, enkephalins, and amyloid-β peptide (Aβ). NEP inhibition of degradation of natriuretic peptides results in vasorelaxation, natriuresis, inhibition of hypertrophy, and fibrosis. On the other hand, inhibition of degradation of other vasoactive peptides, such as angiotensin II, angiotensin 1-7, and ET, opposes the vasodilatory effects of natriuretic peptides. Accordingly, NEP inhibition has variable effects on blood pressure. NEP inhibition increases urinary kinin levels, which may contribute to its natriuretic effects. NEP plays an important role in clearance of amyloid peptides in the brain. In particular, NEP is of major relevance for degrading the amyloid-beta peptides (Aβ), which play a significant role in neurotoxicity, and formation of amyloid plaques from Aβ aggregates in complex with other proteins is a hallmark of Alzheimer disease. Overexpression of neprilysin ameliorated the development of Alzheimer disease, and disruption of the neprilysin gene induces cognitive dysfunction in a mouse model of Alzheimer disease. Because of the potentially beneficial effects of natriuretic peptides in HF, NEP inhibition was pursued as a rational approach for HF therapy. The early use of omapatrilat, a dual vasopeptidase inhibitor that inhibits both ACE and NEP, was not shown to be more effective than ACE inhibition alone in HF patients.[12] However, the use of a combined AT_1 receptor antagonist and a neprilysin inhibitor (valsartan/sacubitril, LCZ696) was shown to have a favorable impact on HF outcome, including quality of life, exercise capacity, and more importantly, HF hospitalization and total mortality, in the PARADIGM-HF trial (**see Chapter 25**).

The biologic importance of the natriuretic peptides in renal sodium handling has been demonstrated in multiple studies employing NPR antagonists, as well as overexpression of ANP or BNP. In experimental HF models, either acute blockade of NPR-A and NPR-B or chronic genetic disruption of NPR-A blunts the renal natriuretic response to acute volume expansion, demonstrating the renal protective action of natriuretic peptide activation. The infusion of a recombinant human ANP and BNP exerts beneficial hemodynamic effects, characterized by decreases in arterial and venous pressures, increase in cardiac output, and suppression of neurohormonal activation in humans, resulting in their clinical development as therapeutic agents for human HF (**see Chapter 24**). In addition to their important biologic role, the natriuretic peptides have provided important diagnostic and prognostic information in HF (**see Chapter 21**).

Neurohormonal Alterations in the Peripheral Vasculature

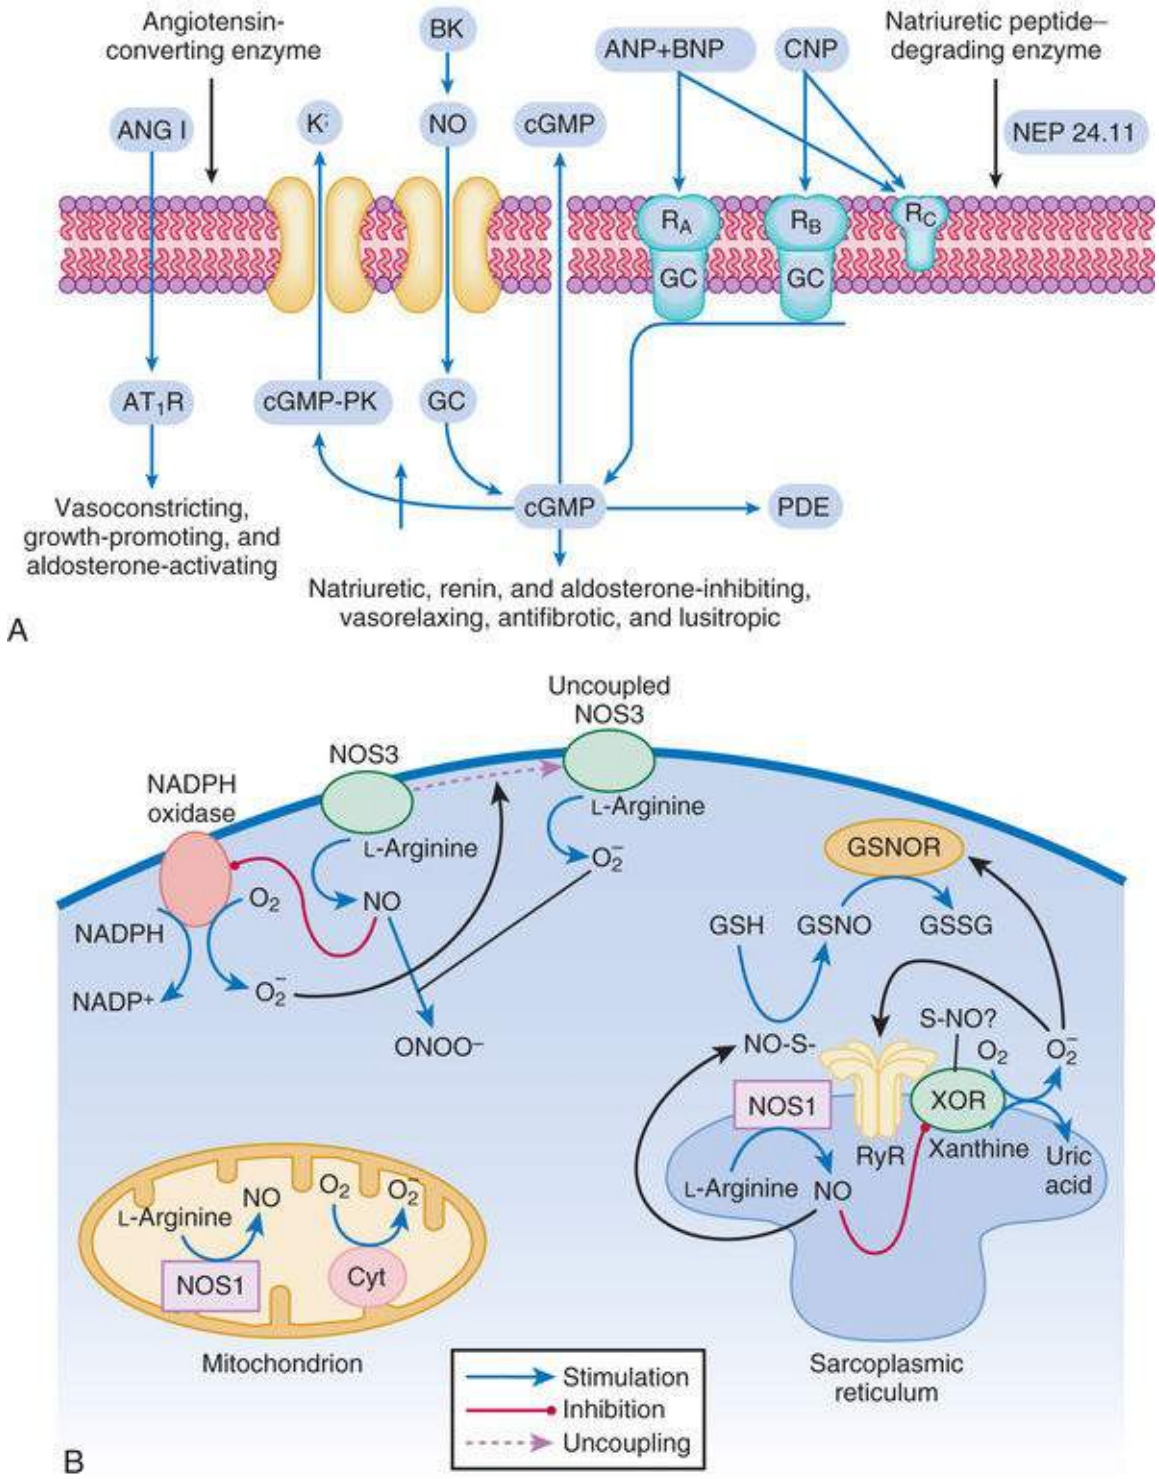
In patients with heart failure, the complex interactions between the autonomic nervous system and local autoregulatory mechanisms tend to preserve circulation to the brain and heart while decreasing blood flow to the skin, skeletal muscles, splanchnic organs, and kidneys. This intense visceral vasoconstriction

during exercise helps to divert the limited cardiac output to exercising muscle but contributes to hypoperfusion of the gut and kidneys. The most powerful stimulus for peripheral vasoconstriction is sympathetic activation, which releases the potent vasoconstrictor NE. Other vasoconstrictors that contribute to maintaining circulatory homeostasis include angiotensin II, ET, neuropeptide Y, urotensin II, thromboxane A_2, and AVP (**see eTable 23.1**). The increased sympathetic adrenergic stimulation of the peripheral arteries and the increased concentrations of circulating vasoconstrictors contribute to the arteriolar vasoconstriction and to the maintenance of arterial pressure. The sympathetic stimulation of the veins contributes to an increase in venous tone, which helps to maintain venous return and ventricular filling and to support cardiac performance by Starling's law of the heart (**see Chapter 22**). Additional content on this topic is presented in the online supplement for this chapter (Vasoconstricting Peptides in Heart Failure).

As noted, the vasoconstricting neurohormones activate counterregulatory vasodilator responses, including release of natriuretic peptides, NO, bradykinin, adrenomedullin, apelin, and vasodilating PGI_2 and PGE_2 (**see eTable 23.1**). Under normal circumstances, the continuous release of NO (endothelium-derived relaxing factor) from the endothelium counteracts the vasoconstricting factors and allows for appropriate vasodilatory responses during exercise. As HF advances, however, the endothelial cell–mediated vasodilatory responsiveness is lost, which contributes to the excessive peripheral arterial vasoconstriction that is emblematic of advanced HF. Of interest, the vasodilator response can be restored by the administration of L-arginine, a precursor of endothelium-derived NO.

Nitric Oxide

The free radical gas NO is produced by three isoforms of NO synthase (NOS). All three isoforms are present in the heart, including NOS1 (neuronal NOS [nNOS]), NOS2 (inducible NOS [iNOS]) and NOS3 (so-called endothelial-constitutive NOS [eNOS]). NOS1 has been detected in cardiac conduction tissue, in intracardiac neurons, and in the SR of cardiac myocytes. NOS2 is an inducible isoform that is not normally expressed in the myocardium but is synthesized de novo in virtually all cells in the heart in response to inflammatory cytokines. NOS3 is expressed in coronary endothelium and endocardium and in the sarcolemma and T-tubule membranes of cardiac myocytes. NOS1 and NOS3 can be activated by calcium or calmodulin, whereas the induction of NOS2 is calcium independent. NO activates soluble guanylate cyclase (**see eFig. 23.2A**). Under normal circumstances, the continuous release of NO (endothelium-derived relaxing factor) from the endothelium counteracts the vasoconstricting factors and allows for appropriate vasodilatory responses during exercise. This activation leads to the production of cyclic guanosine monophosphate (cGMP), which in turn activates protein kinase G (PKG) and cascade of different signaling events. In normal persons, NO released by endothelial cells mediates vasodilation in the peripheral vasculature through cGMP mediated relaxation of vascular smooth muscle. In patients with HF, endothelium-dependent NO-mediated dilation of the peripheral vasculature is blunted, which has been attributed to decreased NOS3 expression and activity.



EFIGURE 23.2 **A,** Cellular actions in signaling of the natriuretic peptide system; *Ang I,* Angiotensin I; *AT_1R,* angiotensin type 1 receptor; *BK,* bradykinin; *GC,* guanylate cyclase; *NEP,* neutral endopeptidase; *PDE,* phosphodiesterase; *PK,* protein kinase; *R_A*, *R_B,* and *R_C,* particulate guanylate cyclase A, B, and C receptors. **B,** Interaction of oxidative and nitrosative pathways in heart failure. The principal sources of ROS in the cardiomyocyte are xanthine oxidoreductase (*XOR*), NADPH oxidase, and the mitochondria. NO is produced by nNOS1, situated in the SR and in the mitochondria, and by eNOS (situated in the caveolae in the cell membrane). XOR and NOS1 colocalize in the SR, and this allows the inhibition of XOR by NOS1, possibly through *S*-nitrosylation In turn, XOR reduces *S*-nitrosoglutathione (*GSNO*), leading to the regeneration of glutathione (*GSH*), the enzyme that reduces SNO moieties in proteins and preserves the *S*-nitrosylation equilibrium. In SR, NOS1 regulates the activity of the ryanodine receptor (*RyR*) through *S*-nitrosylation; by contrast, XOR-generated superoxide (O_2^-) irreversibly activates RyR, precluding this regulatory action of NO. In the cell membrane, NOS3 suppresses NADPH activity, whereas NADPH-produced O_2^- can induce NOS3 uncoupling resulting in O_2^- production and reduced NO synthesis. O_2^- interacts with NO and generates peroxynitrite ($ONOO^-$). *Cyt,* Cytochrome; *GSSG,* oxidized GSH; *GSNOR,* GSNO reductase. (**A,** From Burnett JC, Costello-Boerrigter L, Boerrigter G. The actions of NO on the myocardium are complex and include both short-term alterations in function and energetics and longer-term effects on structure. NO modulates the activity of several key calcium channels involved in excitation-contraction coupling as well as mitochondrial respiratory complexes. This type of regulation is accomplished by spatial localization of different NOS isoforms in distinct cellular microdomains involved in excitation-contraction coupling. Specifically, NOS1 localizes to the SR in proximity to the ryanodine receptor (RyR) and sarcoendoplasmic reticulum calcium–adenosine triphosphatase (SR Ca^{2+}-ATPase, SERCA2a), and NOS3 is found in sarcolemmal caveolae compartmentalized with cell surface receptors and the L-type Ca^{2+} channel (**eFig. 23.2B**). NO also participates in mitochondrial respiration, the process that fuels excitation-contraction coupling. The different NOS isoforms also may participate in the process of cardiac remodeling. LV remodeling was ameliorated and survival improved after MI in transgenic mice deficient in NOS2.[13] By contrast, overexpression of NOS3 resulted in improved remodeling after MI. These contrasting effects of NOS2 and NOS3 may reflect the differences in amount of NO produced, which is much higher with NOS2. Emerging evidence indicates an imbalance between increasing free radical production and decreased NO generation in HF, which has been termed the "nitroso-redox imbalance".[13] NOS uncoupling secondary to a deficiency of tetrahydrobiopterin may further contribute to the nitroso-redox imbalance.[13] The nitroso-redox imbalance probably contributes to disease progression in HF secondary to increased oxidative stress, as well as loss of the peripheral vasodilatory effects of NO.

Bradykinin.

Kinins are vasodilators that are released from inactive protein precursors (kininogens) through the action of proteolytic enzymes termed *kallikreins*. The biologic actions of the kinins are mediated by binding to B_1 and B_2 receptors. Most cardiovascular actions are initiated by the B_2 receptor, which is distributed widely in tissues, where it binds bradykinin and kallidin. The B_1 receptor binds the metabolites of bradykinin and kallidin. Stimulation of the B_2 receptor leads to vasodilation, which is mediated by the activation of NOS3, phospholipase A_2, and adenylyl cyclase. Studies suggest that bradykinin plays an important role in the regulation of vascular tone in HF.[14] The breakdown of bradykinin is catalyzed by ACE and neprilysin, so these enzymes not only lead to the formation of a potent vasoconstrictor (angiotensin II) but also mediate the breakdown of a vasodilator (bradykinin). The augmentation of bradykinin levels likely contributes to the beneficial actions of ACE inhibitors and NEP inhibitors (**see Chapter 25**).

Adrenomedullin.

Adrenomedullin is a 52–amino acid vasodilatory peptide that originally was discovered in human pheochromocytoma tissue. Subsequently, high levels of adrenomedullin immunoreactivity were detected in cardiac atrium and adrenal and pituitary glands, with lower levels detected in the ventricle, kidney, and vasculature.[15] Adrenomedullin binds to a number of GPCRs, including the calcitonin receptor–like receptor and one specific for the adrenomedullin peptide. Adrenomedullin receptors are present in multiple tissue beds, as well as both endothelial and vascular smooth muscle cells. Circulating concentrations of adrenomedullin are elevated in cardiovascular disease and HF in proportion to the severity of cardiac and hemodynamic impairment. Increasing evidence suggests that adrenomedullin may

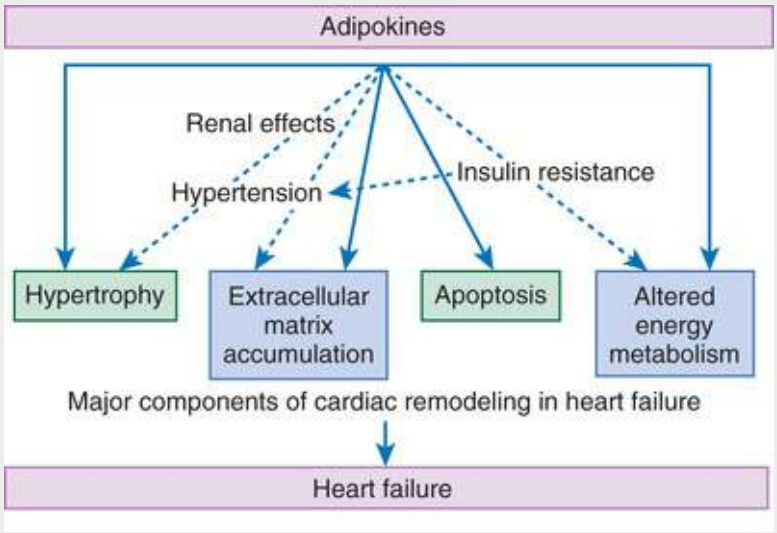
play a compensatory role in HF by offsetting the deleterious effects of excessive peripheral vasoconstriction. Plasma levels of adrenomedullin are elevated in chronic HF and are increased proportionally in response to disease severity. Immunoassays that detect the prohormone form of adrenomedullin have been shown to predict HF-related death in the Biomarkers in Acute Heart Failure (BACH) trial.[16]

Apelin.

Apelin is a vasoactive peptide that is an endogenous ligand for the GPCR APJ. The *APJ* gene encodes a receptor that most closely resembles the angiotensin receptor AT_1. However, the APJ receptor does not bind angiotensin II. In the cardiovascular system, apelin elicits endothelium-dependent, NO-mediated vasorelaxation and reduces arterial blood pressure. In addition, apelin demonstrates potent inotropic activity without stimulating concomitant cardiac myocyte hypertrophy. Apelin also produces diuresis by inhibition of arginine vasopressin activity. In experimental animals, apelin concentrations are significantly lower in failing hearts and are increased after treatment with an angiotensin receptor blocking agent. Furthermore, apelin levels are significantly reduced in patients with HF compared with controls and are significantly increased after cardiac resynchronization. The APJ receptor is a bifunctional GPCR that conveys cytoprotective signals after endogenous ligand stimulation and also acts a mechanosensor to delimit cardiac hypertrophy after hemodynamic pressure overload.[17] CLR325 is a apelin receptor agonist that is currently undergoing phase II clinical evaluation in patients with chronic HF.

Adipokines.

Although adipose tissue was once considered as a simple storage depot for fat, adipose tissue is now known to synthesize and secrete a family of proteins collectively referred to as *adipokines* (**see eFig. 23.3**). Adipokines include adiponectin, TNF, plasminogen activator inhibitor type 1 (PAI-1), transforming growth factor-β, and resistin. *Leptin* is a 16-kDa protein hormone that plays a key role in regulating energy intake and energy expenditure. The product of the ob gene, leptin is predominantly synthesized and secreted by adipocytes, although the heart is also a site of leptin synthesis. The initial role of leptin was thought to be decreasing appetite through hypothalamic stimulation and thus regulation of food intake. However, elevated circulating levels of leptin, which act via a family of receptor (ob.R) isoforms, appear to play an important role in hypertension, hypertrophy, and HF.[18] Leptin may affect myocardial function through direct peripheral effects or through secondary CNS-mediated responses. Lack of leptin and leptin resistance may lead to an accumulation of lipids in nonadipose peripheral tissues, resulting in a variety of “lipotoxic” effects, including cardiac myocyte apoptosis. Several studies suggest that leptin directly induces hypertrophy in both human and rodent cardiac myocytes.[18]



EFIGURE 23.3 Potential direct and indirect effects of adipokines on cardiac remodeling. Various circulating adipokines, the profile of which alters in obesity, may directly (*solid lines*) influence remodeling events known to occur in heart failure: hypertrophy, apoptosis, fibrosis, and metabolic alterations. Another potential mechanism whereby adipokines may influence cardiac structure and function is through indirect effects (*broken lines*) on parameters known to influence cardiac remodeling, such as hypertension, insulin resistance, and renal effects. (From Abel ED, Litwin SE, Sweeney G. Cardiac remodeling in obesity. Physiol Rev 2008;88:389.)

Adiponectin is a 224–amino acid polypeptide that modulates a number of metabolic processes, including glucose regulation and fatty acid oxidation. Although adiponectin initially was thought to be exclusively produced by adipose tissue, recent studies have demonstrated adiponectin expression in the heart. Studies in adiponectin-deficient mice demonstrated progressive cardiac remodeling after hemodynamic pressure overloading, whereas administration of adiponectin diminished the infarct size, apoptosis, and TNF production after myocardial ischemia-reperfusion in both wild-type and adiponectin-deficient mice. Many studies have correlated decreased adiponectin levels with development of obesity-linked HF. Thus, adiponectin has been proposed as a potential biomarker of HF and therapeutic target in its treatment.[18]

Inflammatory Mediators.

The adult heart responds to tissue injury by synthesizing a series of proteins that promote homeostasis, either by activating mechanisms that facilitate tissue repair or, alternatively, by upregulating mechanisms that confer cytoprotective responses within the heart.[19] An ensemble of proinflammatory cytokines, including TNF, IL-1β, and IL-6, serve as the downstream "effectors" of the innate immune system by facilitating tissue repair within the heart. What has been less well understood, until recently, is how these myocardial innate immune responses are coordinated after tissue injury. The relatively recent discovery of a family of receptors termed *Toll-like receptors* (TLRs) and *NOD-like receptors* (NLRs) has greatly increased our understanding of the "upstream" molecular components that regulate the innate immune response.[20] Although the primary role for these molecules is to initiate repair of the injured myocardium, when expressed for protracted periods or at high levels, these molecules are sufficient to recapitulate virtually all aspects of the HF phenotype, by provoking deleterious changes in cardiac myocytes and nonmyocytes, as well as changes in the myocardial extracellular matrix (**summarized in Table 23.1**).[19] Moreover, in experimental models, substantial cross-talk takes place between proinflammatory cytokines and RAS, such that angiotensin II upregulates the expression of TNF through a nuclear factor-κB (NF-κB)–dependent pathway, and the expression of inflammatory mediators leads to upregulation of RAS though increased activation of myocardial ACE and chymase. Circulating levels of proinflammatory cytokines (e.g., TNF, IL-6) are increased in patients with HF and correlate with adverse patient

outcomes.[20] Conversely, the plasma concentrations of anti-inflammatory cytokines (e.g., IL-10) are reduced in patients with HF and are decreased more in direct relation to the severity of the degree of HF, suggesting that the imbalance between pro- and anti-inflammatory cytokine expression may contribute to progression of the disease process.

Left Ventricular Remodeling

Although the neurohormonal concept explains many aspects of disease progression in the failing heart, increasing clinical evidence suggests that current neurohormonal models fail to completely explain the basis for this progression. That is, although neurohormonal antagonists stabilize and in some cases reverse certain aspects of the disease process in HF, in the overwhelming majority of patients, it will progress, although at a slower rate. It has been suggested that the process of LV remodeling is directly related to future deterioration in LV performance and a less favorable clinical course in patients with HF (i.e. “biomechanical model”).[1] LV remodeling is influenced by hemodynamic, neurohormonal, epigenetic,[21] and genetic factors (**eFig. 23.4**), as well as by comorbid conditions. Although the complex changes that occur in the heart during LV remodeling have traditionally been described in anatomic terms, the process of LV remodeling also has an important impact on the biology of the cardiac myocyte, on changes in the volume of myocyte and nonmyocyte components of the myocardium, and on the geometry and architecture of the LV chamber (**Table 23.2**).

EFIGURE 23.4 Role of genetics in the pathogenesis of heart failure. Gene polymorphisms may contribute to disease progression in HF through several mechanisms. Disease susceptibility genes may confer increased risk of disease progression after cardiac injury, whereas modifier genes can increase and/or decrease the impact of susceptibility genes. Finally, gene polymorphisms may modify the response to HF therapies (therapy modifier genes).

Alterations in Biology of Cardiac Myocyte

Numerous studies have suggested that failing human cardiac myocytes undergo a number of important changes that might be expected to lead to a progressive loss of contractile function. These include decreased alpha-myosin heavy chain gene expression with a concomitant increase in beta-myosin heavy chain expression, progressive loss of myofilaments in cardiac myocytes, alterations in cytoskeletal proteins, and alterations in excitation-contraction coupling and in energy metabolism, as well as desensitization of beta-adrenergic signaling (**Table 23.2**).

Cardiac Myocyte Hypertrophy

Two basic patterns of cardiac hypertrophy occur in response to hemodynamic overload (**Fig. 23.7**). In pressure overload hypertrophy (e.g., with aortic stenosis or hypertension), increased systolic wall stress

leads to the addition of sarcomeres in parallel, an increase in myocyte cross-sectional area, and increased LV wall thickening. This pattern of remodeling has been referred to as “concentric” hypertrophy (**Fig. 23.7A**) and has been linked with alterations in Ca^{2+}/calmodulin-dependent protein kinase II–dependent signaling[22] (**Fig. 23.8**). By contrast, in volume overload hypertrophy (e.g., with aortic and mitral regurgitation), increased diastolic wall stress leads to an increase in myocyte length with the addition of sarcomeres in series, thereby engendering increased LV ventricular dilation. This pattern of remodeling has been referred to as “eccentric” hypertrophy (because of the position of the heart in the chest), or a “dilated” phenotype (**see Fig. 23.7A**), and has been linked with protein kinase B (Akt) activation[22] (**see Fig. 23.8**). Patients with HF classically present with a dilated left ventricle with or without LV wall thinning. The myocytes from these failing ventricles have an elongated appearance that is characteristic of myocytes obtained from hearts subjected to chronic volume overload.

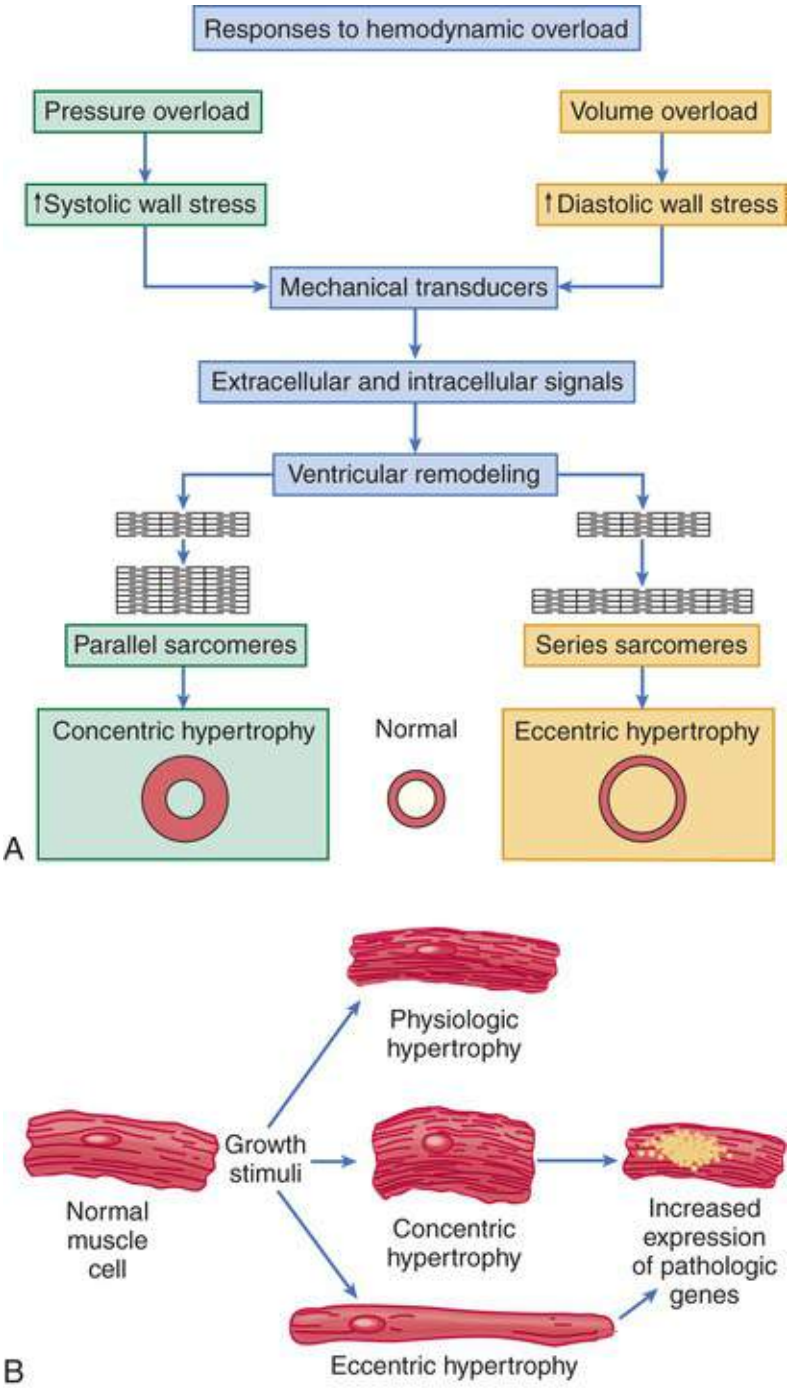

FIGURE 23.7 The pattern of cardiac and cellular remodeling that occurs in response to hemodynamic overloading depends on the nature of the inciting stimulus. **A,** When the overload is predominantly due to an increase in pressure (e.g., with systemic hypertension or aortic stenosis), the increase in systolic wall stress leads to the parallel addition of sarcomeres and widening of the cardiac myocytes, resulting in "concentric" cardiac hypertrophy. When the overload is predominantly due to an increase in ventricular volume, the increase in diastolic wall stress leads to the series addition of sarcomeres, lengthening of cardiac myocytes, and LV dilation, which is referred to as "eccentric" chamber hypertrophy. **B,** Phenotypically distinct changes occur in the morphology of myocytes in response to the type of hemodynamic overload that is superimposed. When the overload is predominantly due to an increase in pressure, the increase in systolic wall stress leads to the parallel addition of sarcomeres and widening of the cardiac myocytes. When the hemodynamic overload is predominantly due to an increase in ventricular volume, the increase in diastolic wall stress leads to the series addition of sarcomeres with consequent lengthening of cardiac myocytes. The expression of maladaptive embryonic genes is increased in both eccentric and concentric hypertrophy, but not in physiologic myocyte hypertrophy as occurs with exercise (see Table 23.2). (**A,** From Colucci WS, editor. Heart Failure: Cardiac Function and Dysfunction. 2nd ed. Philadelphia: Current Medicine; 1999, p 4.2. **B,** Modified from Hunter JJ, Chien KR. Signaling pathways for cardiac hypertrophy and failure. N Engl J Med 1999;341:1276.)

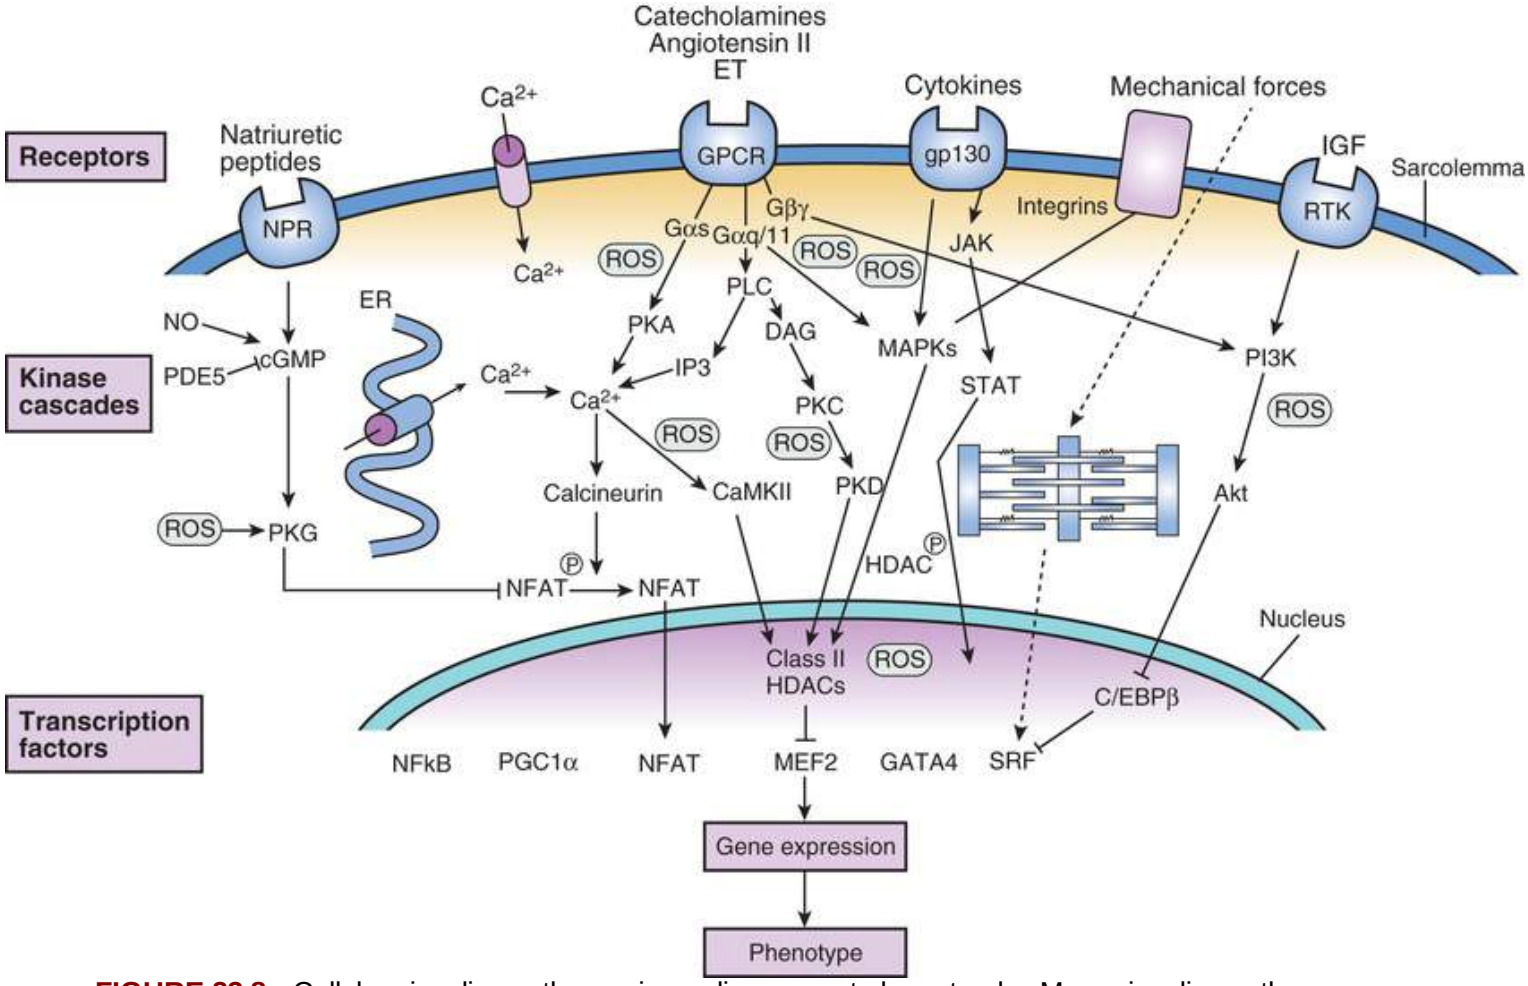

FIGURE 23.8 Cellular signaling pathways in cardiac myocyte hypertrophy. Many signaling pathways have the potential to regulate the growth of cardiac cells acting through an increasingly complex network of intracellular signaling cascades. Agonists for α-adrenergic, angiotensin, and endothelin (*ET*) receptors couple to phospholipase C (*PLC*) and calcium influx channels by way of G proteins. Activation of PLC results in the generation of two second messengers, inositol triphosphate (*IP3*) and diacylglycerol (*DAG*). IP3 causes the release of calcium from intracellular stores, and DAG activates protein kinase C (*PKC*). Changes in intracellular calcium stores can activate Ca^{2+}/calmodulin-dependent kinases (*CaCMKII*), as well as calcineurin, which can affect gene expression in multiple ways. PKC and G proteins can affect gene expression by activating mitogen-activated protein kinase (*MAPK*) cascades. Histone deacetylase complexes (*HDACs*) are emerging as important negative regulators of genes involved in cardiac hypertrophy. Cytokines and peptide growth factors, such as insulin-like growth factor (*IGF*), can be elaborated by various cells within the heart and may act in an autocrine or paracrine manner. These growth factors activate cellular receptors that usually possess receptor tyrosine kinase (*RTK*) activity and are coupled to a cascade of protein kinase. Mechanical deformation of cardiac myocytes through matrix-integrin interactions can lead to activation or modulation of several signaling pathways, at least in part through autocrine action of released agonists such as angiotensin. Both NO and oxidative stress may be induced after stimulation of signaling pathways and modulate the activity of kinase cascades and transcription factors leading to alterations in contractile phenotype, growth, and death in myocytes. *Akt,* Protein kinase B; *C/EBPβ,* CCAAT/enhancer binding protein-β; *ER,* endoplasmic reticulum; *GATA4,* GATA-binding protein; *gp130,* glycoprotein 130; *GPCR,* G protein–coupled receptor; *JAK,* Janus kinase; *MEF2,* myocyte enhancer factor; *NFAT,* nuclear factor of activated T cells; *NFκB,* nuclear factor-kappaB cells; *NPR,* natriuretic peptide receptor; *P,* phosphorylation; *PDE5,* phosphodiesterase type 5; PGC1α, peroxisome proliferator–activated receptor gamma, coactivator 1 alpha; *PKA, PKD, PKG,* protein kinases A, D, G; *STAT,* signal transducer and activator of transcription; *SRF,* serum response factor. (From Shah AM, Mann DL. In search of new therapeutic targets and strategies for heart failure: recent advances in basic science. Lancet 2011;378:704.)

Cardiac myocyte hypertrophy also leads to changes in the biologic phenotype of the myocyte that are secondary to reactivation of portfolios of genes normally not expressed postnatally. The reactivation of these fetal genes, the so-called fetal gene program, also is accompanied by decreased expression of a number of genes that are normally expressed in the adult heart. As discussed later, activation of the fetal

gene program may contribute to the contractile dysfunction that develops in the failing myocyte. As shown in **Fig. 23.8**, the stimuli for the genetic reprogramming of the myocyte include mechanical stretch/strain of the myocyte, neurohormones (e.g., NE, angiotensin II), inflammatory cytokines (e.g., TNF, IL-6), other peptides and growth factors (e.g., ET), and ROS (e.g., superoxide, NO). These stimuli occur both locally within the myocardium, where they exert autocrine/paracrine effects, and systemically, where they exert endocrine effects.

The early stage of cardiac myocyte hypertrophy is characterized morphologically by increases in the number of myofibrils and mitochondria, as well as enlargement of mitochondria and nuclei. At this stage, the cardiac myocytes are larger than normal, but with preservation of cellular organization. As hypertrophy continues, there is an increase in the number of mitochondria, as well as the addition of new contractile elements in localized areas of the cell. Cells subjected to longstanding hypertrophy show more obvious disruptions in cellular organization, such as extremely enlarged nuclei with highly lobulated membranes, accompanied by the displacement of adjacent myofibrils with loss of the normal registration of the Z-bands. The late stage of hypertrophy is characterized by loss of contractile elements (myocytolysis) with marked disruption of Z-bands and severe disruption of the normal parallel arrangement of the sarcomeres, accompanied by dilation and increased tortuosity of T tubules.

Alterations in Excitation-Contraction Coupling

As discussed in **Chapter 22**, excitation-contraction coupling refers to the cascade of biologic events that begins with the cardiac action potential and ends with myocyte contraction and relaxation (**see Fig. 22.1**). Impaired contraction and relaxation of the failing heart is most prominent at high heart rates, which results in a depressed force-frequency relationship. This has been demonstrated both in isolated strips of human myocardium and in clinical observations of patients (**Fig. 23.9**). Normally, higher contraction frequency increases cardiac performance because of a frequency-dependent augmentation of intracellular Ca^{2+} transients. By contrast, in the failing myocardium, a decline in force generation is seen with higher heart rates that is secondary to a decrease in amplitude of intracellular Ca^{2+}, a prolonged decline of the Ca^{2+} transient, and increased levels of diastolic calcium. The reduced intracellular Ca^{2+} transient is secondary to depletion of Ca^{2+} from the SR, the result of three major defects in calcium cycling that occur in the failing heart: (1) increased Ca^{2+} leak through ryanodine receptors (RyRs), (2) impaired sarcoplasmic reticulum (SR) Ca^{2+} uptake from reduced SERCA2a (SR calcium pump) protein levels and function, and (3) increased expression and function of the sarcolemmal Na^{+}/Ca^{2+} exchanger (NCX).

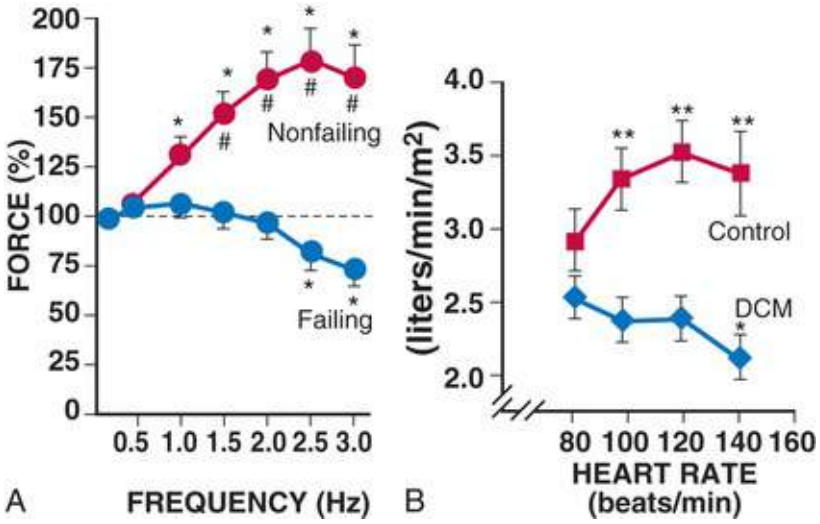

FIGURE 23.9 Relationship between contraction frequency and cardiac performance (force-frequency relation) in heart failure. **A,** Relationship between stimulation frequency and force generation of isolated muscle strip preparations from nonfailing and failing human hearts. In nonfailing myocardium, contractile force increases up to a stimulation rate of approximately 2.5 Hz (150 beats/min), whereas contractile force does not significantly increase in failing myocardium. (* indicates $P < 0.05$ versus 0.25 Hz; # indicates $P < 0.05$ between failing and nonfailing myocardium.) **B,** Cardiac index versus heart rate in patients with and without HF. Heart rate was changed by temporary pacing during cardiac catheterization, and cardiac output was measured by thermodilution. In patients without HF, cardiac index increases with higher heart rates up to 120 beats/min, but it declines continuously in patients with HF. (* indicates $P < 0.05$ and ** $P < 0.01$ versus lowest pacing rate.) *DCM,* Dilated cardiomyopathy. (**A,** Modified from Pieske B et al. Ca^{2+} handling and sarcoplasmic reticulum Ca^{2+} content in isolated failing and nonfailing human myocardium. Circ Res 1999;85:38; **B,** modified from Hasenfuss G et al. Influence of the force-frequency relationship on haemodynamics and left ventricular function in patients with non-failing hearts and in patients with dilated cardiomyopathy. Eur Heart J 1994;15:164.)

Increased Ca^{2+} Leak

Ca^{2+} enters the cell during the action potential through L-type calcium channels and triggers a release of a much larger amount of calcium from the SR through RyRs. Although controversy surrounds the expression levels of RyRs in HF, as well as the coupling of RyRs to L-type Ca^{2+} channels, there is general agreement that the diastolic Ca^{2+} leak in HF is the result of RyRs opening during diastole.[23] The resultant release of calcium from the SR event is referred to as a "Ca^{2+}-spark." The pathophysiologic mechanism underlying the diastolic Ca^{2+} leak in HF has been attributed to increased phosphorylation of the RyR by protein kinase A (PKA), Ca^{2+}/calmodulin-dependent protein kinase II (CaMKII), and decreased binding of the RyR stabilizing protein calstabin (FKBP12.6). Experimental studies suggest that PKA-dependent phosphorylation of the RyR may provoke Ca^{2+} leak by destabilizing the association between calstabin and FKB (**see Chapter 22**). Interestingly, in dogs, beta-adrenergic blockers prevent the development Ca^{2+} leak by restoring RyR stabilization by FKBP12.6.[24] This observation has led to the suggestion that the increase in contractile function following treatment with beta blockers is secondary to RyR stabilization. The role of excess PKA-dependent RyR phosphorylation in the etiology of HF appears somewhat paradoxical, in that the β-receptor is downregulated in HF. One current proposal is that there are microdomains in close proximity to the RyR where there is increased PKA phosphorylation and more cyclic adenosine monophosphate (cAMP) and decreased activity of the type 4 phosphodiesterase (PDE4D3).[25] Besides its contribution to reduced SR Ca^{2+} content, increased leak seems to be relevant for arrhythmias in HF. This results from activation of NCX: Ca^{2+} leaking out of the SR activates NCX to remove Ca^{2+} from the cytosol in exchange of Na^+. Since NCX is electrogenic (3 Na^+ versus 1 Ca^{2+}), this results in a net inward current generating the so-called delayed afterdepolarizations (DADs) as a trigger of arrhythmias. Drugs with the ability to bind to and stabilize the RyR (referred to as RYCALS), such as

the diltiazem derivative JTV 519, have been shown to attenuate experimental HF and arrhythmias[24] and are currently being developed as a novel therapeutic class of drugs in the treatment of HF.

Sarcoplasmic Reticulum Ca^{2+} Reuptake and Sarcolemmal Ca^{2+} Elimination

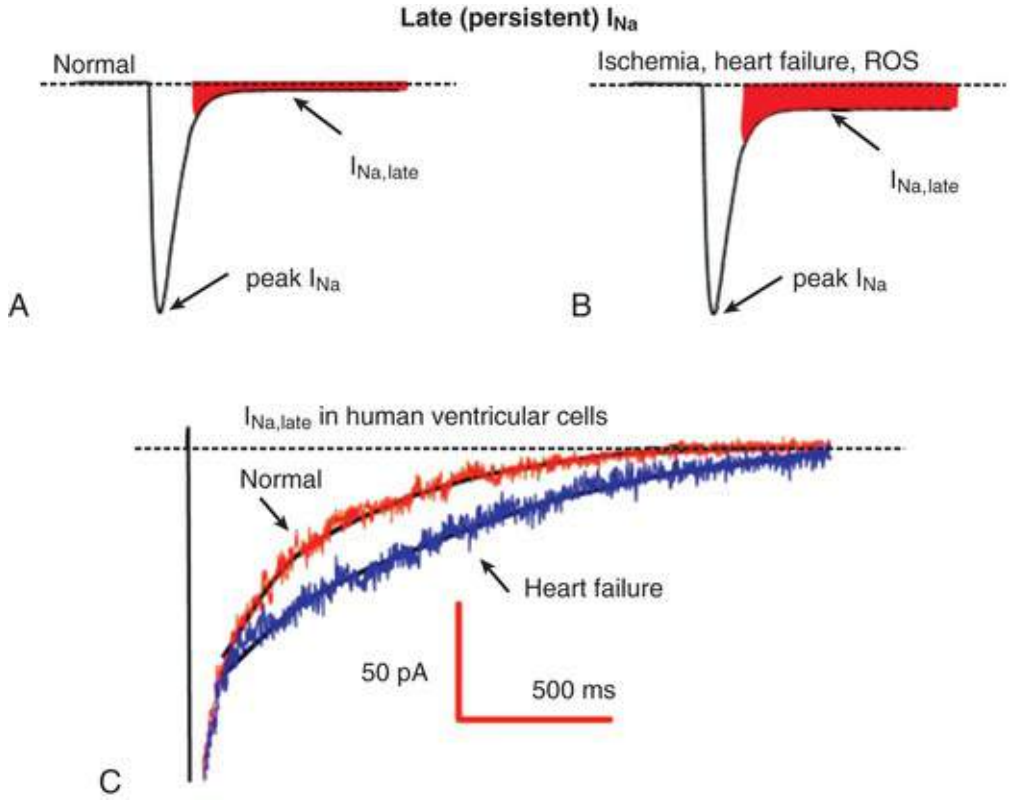
Relaxation of the contractile proteins occurs after dissociation of Ca^{2+} from troponin C and Ca^{2+} elimination from the cytosol. In the human heart, there are two main mechanisms responsible for elimination of Ca^{2+} from the cytosol: SR uptake of Ca^{2+} by the SERCA2a Ca^{2+} pump and transsarcolemmal Ca^{2+} elimination through NCX. Under normal conditions, approximately 75% of Ca^{2+} is taken up by the SR and 25% extruded from the cell through NCX. In HF there is decreased uptake of Ca^{2+} by the SR secondary to decreased SERCA2a protein levels and SERCA2a function. In addition, phosphorylation of phospholamban (PLB) is reduced in the failing heart, resulting in increased PLB-dependent inhibition of the SR Ca^{2+} pump.[24] The decrease of SR Ca^{2+} uptake in the failing heart results in a relative increase of transsarcolemmal Ca^{2+} elimination by the NCX, which is most likely secondary to increased expression of NCX protein.

Restoring deficient SERCA2a by gene transfer has been shown to improve contractile function and restore electrical stability experimentally. However, the recent CUPID trial failed to show clinical benefit of SERCA2a gene transfer in patients with HF, whereas the gene transfer procedure itself seems to be safe.[26] Although the increase in NCX activity may result in increased Ca^{2+} elimination from the myocyte, thereby preserving diastolic calcium levels and preventing diastolic dysfunction when SR calcium uptake is reduced, increased NCX activity may further reduce SR Ca^{2+} accumulation/content and may therefore reduce Ca^{2+} activation of contractile proteins.[24] As noted, electrogenic NCX activity induces DADs and arrhythmias.

Action Potential Duration and Sodium Handling

Several factors contribute to the prolongation of the action potential duration, which is a ubiquitous finding in failing hearts.[27] The transient outward potassium current (Ito) and the inward rectifier potassium current (Ik1) both are reduced in HF. In addition, the increased inward Na^+ current through the NCX and persistent activity of the sodium channel also may contribute to prolongation of the action potential. The latter mechanism, also termed the "late sodium current," may be important in the pathogenesis of cardiac arrhythmias in HF. As discussed in **Chapter 22**, the voltage-gated Na^+ channels are activated on depolarization of the cell membrane, leading to rapid influx of Na^+ that is responsible for the fast upstroke of the action potential (**see eFig. 23.5**). Under normal conditions, Na^+ channels inactivate a few milliseconds after depolarization. However, it is now recognized that some Na^+ channels remain open (or reopen), leading to a small but persistent influx of Na^+ throughout the plateau of the action potential, which generates a "late" sodium current (I_{Na}).[28] Late I_{Na} is sufficient to lead to a substantial influx of Na^+ into the cell in HF, with consequent prolongation of the action potential and early afterdepolarizations (EADs), which may be a significant source of increased arrhythmias in HF. High levels of intracellular Na^+ also may lead to cellular acidosis secondary to increased sodium-proton exchange activity. Increased intracellular Na^+ also influences the driving forces for the NCX, thereby reducing Ca^{2+} extrusion through the forward mode of the NCX, which when combined with reduced activity of the SERCA2a pump, may be a cause of the elevated diastolic cytosolic calcium levels and disturbed diastolic function in HF. Inhibition of the late Na^+ current with the inhibitor ranolazine can improve disturbed diastolic function in isolated myocardium from failing human hearts and also may exhibit antiarrhythmic properties.[29] Of note, the different contributions to altered Ca^{2+} handling may vary significantly from patient to patient, which

may explain the heterogeneity of different HF phenotypes. If SERCA2a expression is decreased and intracellular sodium is high, both systolic and diastolic function will be impaired. By contrast, higher NCX expression with moderately elevated intracellular Na^+ will result in excess transsarcolemmal calcium elimination, and diastolic function will rather be preserved. However, this may be associated with increased arrhythmias secondary to increased NCX activity.[24]

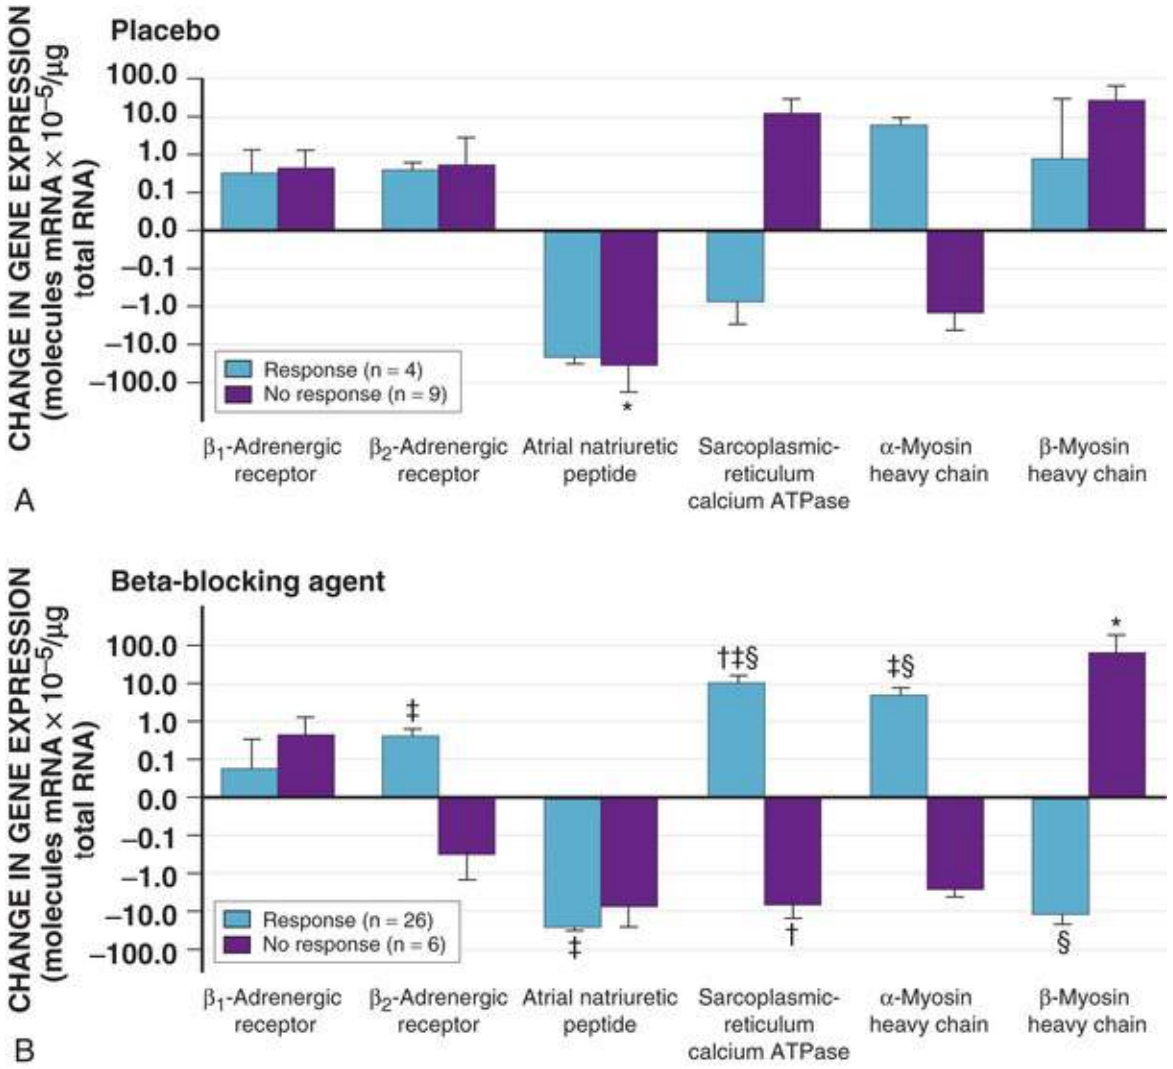


EFIGURE 23.5 Sodium current under normal and disease conditions. **A,** Depiction of Na^+ current in nonfailing myocardium. Under normal conditions, Na^+ channels inactivate a few milliseconds after depolarization and net Na^+ influx is small. **B,** Pathologic conditions (ischemia, HF, ROS) alter Na^+ current. Channels remain open (or reopen), and a persistent influx of Na^+ generates the so-called late Na^+ current ($I_{Na,late}$). This causes a substantial influx of Na^+, which contributes to elevated Na^+ concentrations under conditions of HF. **C,** Original recordings of Na^+ currents from human ventricular isolated cells. Persistent opening of Na^+ channels in the myocyte from a failing heart results in a larger Na^+ influx relative to that for the myocyte from the normal heart. (From Maltsev VA, Silverman N, Sabbah HN, et al. Eur J Heart Fail 2007;9:219.)

Abnormalities in Contractile and Regulatory Proteins

Early studies showed that the activity of myofibrillar ATPase was reduced in the hearts of patients who died of HF. Furthermore, reductions in the activity of myofibrillar ATPase, actomyosin ATPase, or myosin ATPase have been demonstrated in several animal models of HF. Subsequent studies showed that these abnormalities in ATPase activity could be explained by a shift to the fetal isoform of myosin heavy chain (MHC) in cardiac hypertrophy and failure. In rodents the predominant MHC is the “fast” V1 isoform (alpha-MHC [MYHC6]), which has high ATPase activity. With pressure-induced hypertrophy or after MI in rodents, reexpression of the “slow” V3 fetal isoform of MHC that has low ATPase activity (beta-MHC [MYHC7]) and decreased expression of the V1 isoform have been observed. Although translating this information to human HF proved to be more challenging, because the predominant MHC isoform in humans is the slower V3 isoform (MYHC7), polymerase chain reaction (PCR) techniques have shown

that MYHC6 accounts for approximately 33% of MHC mRNA in normal human myocardium, whereas MYHC6 mRNA abundance decreases to approximately 2% in failing hearts. Furthermore, when myocardial biopsy was performed in patients receiving beta blockers, reciprocal changes were observed in the levels of MYHC6 (increase) and MYHC7 (decrease) mRNA, and an increase in the MYHC6/MYHC7 ratio was noted in those who demonstrated an improvement in LV function. However, these changes in myosin isoform shifts did not occur in HF patients who showed no improvement in LV function with beta blockers (**eFig. 23.6**). Thus the decreased expression of MYHC6 may play a significant role in the pathophysiology of dilated cardiomyopathy (DCM).



EFIGURE 23.6 Changes in myocardial mRNA expression and beta-adrenergic receptor protein levels. **A, B,** Changes between baseline and the end of the 6-month study in the abundance of myocardial mRNA for six contractility-regulating or hypertrophy-regulating proteins in patients who received either placebo or a beta-blocking agent. The changes in patients who had an improvement in LV ejection fraction (a "response," defined as an increase by at least 5 ejection fraction [EF] units) were compared with the changes in patients who did not demonstrate such a response. Gene expression is shown as molecules of mRNA per microgram of total RNA on a logarithmic scale. The *asterisk* indicates $P < 0.10$ for the change between the baseline value and the value measured at 6 months by the paired *t*-test; †, $P < 0.05$ for the comparison with the placebo group by the test for interaction; ‡, $P < 0.05$ for the change between the baseline value and the value measured at 6 months by the paired *t*-test; and §, $P < 0.05$ for the comparison with patients who did not have a response. Each panel shows results for patients with complete data for the indicated mRNA and receptor protein measurements. (From Lowes BD et al. Myocardial gene expression in dilated cardiomyopathy treated with beta blocking agents. N Engl J Med 2002;346:1357.)

Another important modification of contractile proteins that contributes to contractile dysfunction is

proteolysis of the myofilaments themselves (myocytolysis). Myocardial biopsy samples from patients with advanced LV dysfunction show a significant reduction in the volume of myofibrils per cell, which may contribute to the development of cardiac decompensation.

Alterations in the expression and/or activity of myofilament regulatory proteins also have been proposed as a potential mechanism for the decrease in cardiac contractile function in HF (**Table 23.3**), including the myosin light chains, the troponin-tropomyosin complex, and titin. Changes in myosin light chain isoforms have been observed in the atria and ventricles of patients whose hearts have been subjected to mechanical overload. Although changes in the abundance and/or isoforms of troponins TnI and TnC have not been reported in HF, isoform shifts have been reported in TnT (**see Chapter 22**). In normal adult myocardium, TnT is expressed as a single isoform (cTnT3). In myocardium samples from patients with end-stage HF, however, both the fetal cTnT1 and the cTnT4 isoforms are expressed at increased levels, which might be expected to lead to a decrease in maximal active tension. Changes in the titin isoform from N2B, which is expressed postnatally and is stiffer, to N2BA, the more distensible fetal isoform, have been associated with increased compliance in hearts from patients with HF.[30]

TABLE 23.3

Changes in the Biology of the Failing Myocyte

PROTEIN	CHANGE IN HUMAN HEART FAILURE
Plasma Membrane	
L-type calcium channels	Decreased*†
Sodium/calcium exchanger	Increased*†
Sodium pump	Reexpression of fetal isoforms
$Beta_1$-adrenergic receptor	Decreased*†
$Beta_2$-adrenergic receptor	Increased*
$Alpha_1$-adrenergic receptor	Increased*
Contractile Proteins	
Myosin heavy chain (MHC)	Reversion to fetal isoform (↓MYHC6/MYHC7)
Myosin light chain (MLC)	Reversion to fetal isoform

Abnormalities in Cytoskeletal Proteins

The cytoskeleton of cardiac myocytes consists of actin, the intermediate filament desmin, the sarcomeric protein titin (**see Chapter 22**), and alpha- and beta-tubulin, which form the microtubules by polymerization. Vinculin, talin, dystrophin, and spectrin constitute a separate group of membrane-associated proteins. In numerous experimental studies, a role for cytoskeletal and membrane-associated proteins has been implicated in the pathogenesis of HF. In patients with DCM, titin is downregulated, and

the cytoskeletal proteins desmin and membrane-associated proteins such as vinculin and dystrophin are upregulated. Proteolytic digestion of the dystrophin molecule has been identified as a possible reversible cause of HF. Loss of integrity of the cytoskeleton and its linkage of the sarcomere to the sarcolemma and extracellular matrix would be expected to lead to contractile dysfunction at the myocyte level, as well as at the myocardial level.

Beta-Adrenergic Desensitization

Ventricles obtained from HF patients demonstrate a marked reduction in beta-adrenergic receptor density, isoproterenol-mediated adenyl cyclase stimulation, and the contractile response to beta-adrenergic agonists.[31] The downregulation of beta-adrenergic receptors is likely mediated by increased levels of NE in the vicinity of the receptor (**see eFig. 23.6**). In patients with DCM, this reduction in receptor density involves primarily the $beta_1$-receptor protein and mRNA and is proportional to the severity of HF. In contrast, the level of $beta_2$-adrenergic receptor protein and mRNA are unchanged or increased. In addition, there are increases in the expression of beta-adrenergic receptor kinase 1 (βARK1, also called G protein–coupled receptor kinase 2 [GRK2]), a member of the family of GPCR kinases, in failing human hearts. As noted in **Chapter 22**, βARK phosphorylates the cytoplasmic loops of both $beta_1$- and $beta_2$-adrenergic receptors and increases the affinity of these receptors for a scaffolding protein termed *beta-arrestin* (**see Fig. 22.14**). The binding of beta-arrestins to the cytoplasmic tail of the beta receptor not only uncouples the receptor from heterotrimeric G proteins, but also targets the receptor for internalization in clathrin-coated vesicles. Although this internalization fosters receptor dephosphorylation and serves as a prelude to recycling the beta receptor to the surface for reactivation, at some point receptor entry via endocytosis is not followed by recycling, but rather leads to receptor trafficking to lysosomes and receptor degradation. Increased βARK (GRK2) activity may therefore contribute to the desensitization of both $beta_1$ and $beta_2$ receptors in patients with HF. Desensitization of the beta receptors can be both beneficial and deleterious in HF. By reducing LV contractility, desensitization may be deleterious. However, by reducing energy expenditure of the energy-starved myocardium and protecting the myocyte from the deleterious effects of sustained adrenergic stimulation, this adaptive response is beneficial. Interestingly, lymphocyte GRK2 protein levels were shown to be independent predictors of cardiovascular mortality in patients with HF and added prognostic and clinical value over demographic and clinical variables.[32]

Alterations in the Myocardium

The changes that occur in failing myocardium may be categorized broadly into those that occur in the volume of cardiac myocytes and those that occur in the volume and composition of the extracellular matrix. For changes in the myocyte component of the myocardium, increasing evidence suggests that progressive myocyte loss, through necrotic, apoptotic, or autophagic cell death pathways, may contribute to progressive cardiac dysfunction and LV remodeling. Myocardial regeneration is discussed in **Chapter 30**.

Necrosis.
Although necrosis initially was thought to be a “passive” form of cell death, emerging evidence indicates that necrotic cell death also is “regulated.”[33] The relative proportion of unregulated versus regulated

necrotic death in the heart is not currently known; however, regulated necrosis is an important component of MI, HF, and cerebrovascular accident (stroke). The hallmark features of necrosis are loss of plasma membrane integrity and depletion of cellular adenosine triphosphate (ATP). Dysfunction of the plasma membrane in necrotic cells leads to cell swelling and rupture. There is also swelling of organelles such as the mitochondria. In the heart, increased plasma membrane permeability allows Ca^{2+} to leak into the cell, exposing the contractile proteins to very high concentrations of this activator, which in turn initiates extreme interactions between the myofilaments (contraction bands), further contributing to disruption of the cellular membrane. Necrotic myocyte death occurs in ischemic heart disease, myocardial injury, toxin exposure (e.g., daunorubicin; **see Chapter 81**), infection, and inflammation. Neurohormonal activation also can lead to necrotic cell death. For example, concentrations of NE available within myocardial tissue, as well as circulating levels in patients with advanced HF, are sufficient to provoke myocyte necrosis in experimental model systems. Moreover, excessive stimulation with angiotensin II, ET, or TNF has been shown to provoke myocyte necrosis in experimental models.

In contrast with apoptosis, the rupture of cell membranes with cell necrosis releases intracellular contents, so-called danger-associated molecular patterns (DAMPS), which evoke an intense inflammatory reaction, leading to the influx of granulocytes, macrophages, and collagen-secreting fibroblasts into the area of injury. The final result is a fibrotic scar, which may alter the structural and functional properties of the myocardium.[34] The regulated cell death pathways that have been studied thus far include TNF signaling through the type 1 TNF receptor (TNFR1) and opening of the mitochondrial permeability transition pore (MPTP) in the inner mitochondrial membrane, resulting in loss of the electrical potential difference ($\Delta\psi m$) across the inner mitochondrial membrane, leading to ATP depletion (**Fig. 23.10A**).

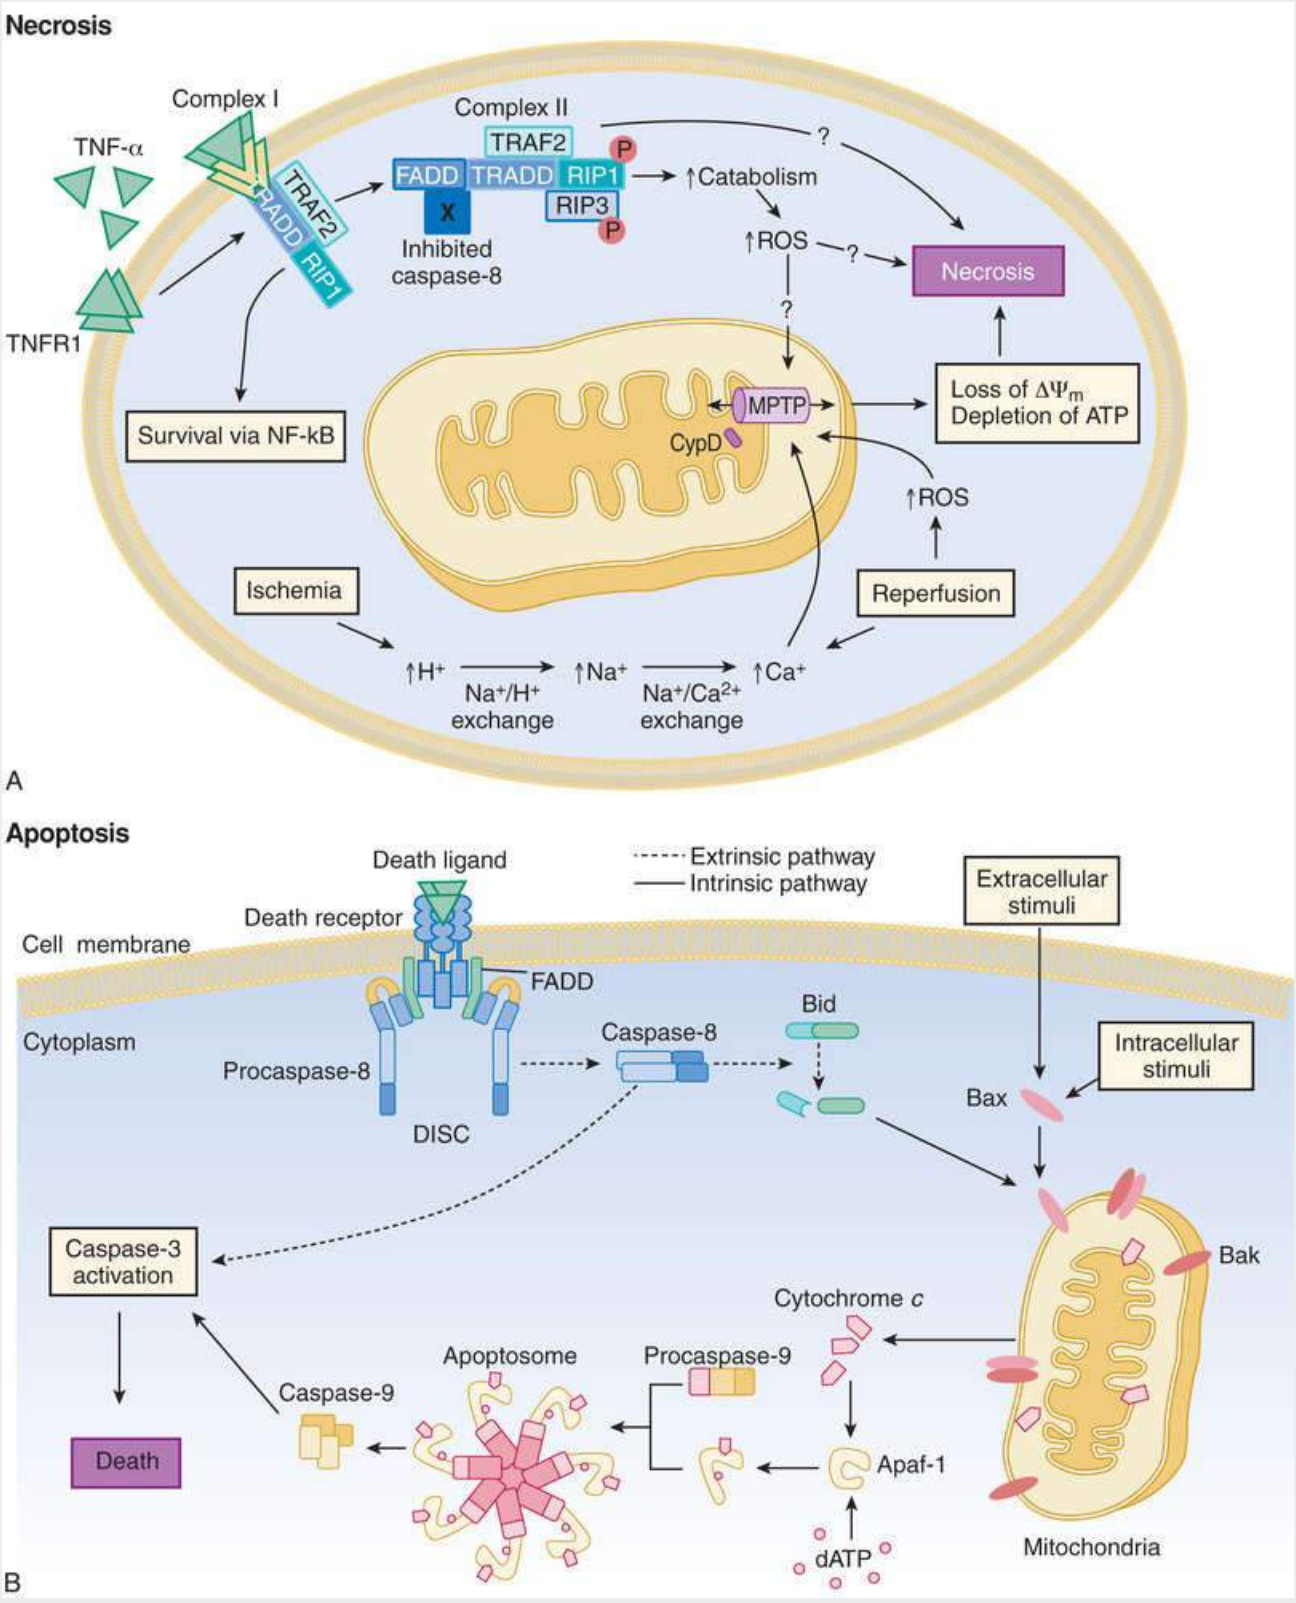

FIGURE 23.10 Apoptotic and necrotic cell death pathways. **A,** Necrosis. Information about regulated signaling in necrosis is currently limited to two pathways. The first involves death receptors, as exemplified by TNFR1 (tumor necrosis factor-α receptor 1). Depending on context, activation of TNFR1 can promote cell survival or either apoptotic or necrotic cell death. These choices are mediated by multiprotein complexes I and II. The binding of TNF-α to TNFR1 stimulates formation of complex I, which contains TNFR1, TRADD, RIP1, TRAF2, and cIAP1/2. Death effects of TNFR1 signaling are mediated via complex II, which forms after endocytosis of complex I, the dissociation of TNFR1, and the deubiquitination of RIP1 by CYLD and A20 (*not shown*). A second necrosis pathway involves the mitochondrial permeability transition pore (*MPTP*) in the inner mitochondrial membrane and its regulation by cyclophilin D (*CypD*). This pore may be opened by increased Ca^{2+}, oxidative stress, decreased ATP generation, and other stimuli that operate during ischemia-reperfusion and heart failure. Ischemia-reperfusion can lead to increased Ca^{2+} and ROS, as depicted. MPTP opening results in profound alterations in mitochondrial structure and function, which results in decreased ATP generation. **B,** Apoptosis is mediated by an extrinsic pathway involving cell surface death receptors and by an intrinsic pathway that uses the

mitochondria and endoplasmic reticulum (ER). The extrinsic pathway is activated by binding of death ligand to its receptor, which triggers formation of the DISC (death-inducing signaling complex). Caspase-8 is activated by forced proximity within the DISC and then cleaves and activates downstream procaspases. Caspase-8 also can cleave the BH3-only protein Bid, which translocates to the mitochondria to trigger apoptotic mitochondrial events. The intrinsic pathway is activated by diverse biologic, chemical, and physical stimuli. These signals are transduced to the mitochondria and ER (*not shown*) by proapoptotic Bcl-2 proteins: Bax (a multidomain protein) and BH3-only proteins. These death signals trigger the release of apoptogens from the mitochondria into the cytosol, including cytochrome *c*, which triggers the formation of a second multiprotein complex, the apoptosome, in which procaspase-9 undergoes activation. Caspase-9 then cleaves and activates downstream procaspases. Downstream caspases cleave several hundred cellular proteins to bring about the apoptotic death of the cell. *FADD,* Fas-associated protein with death domain; *RIP1, RIP3,* receptor-interacting proteins 1, 3; *TRADD,* tumor necrosis factor receptor type 1–associated death domain protein; *TRAF2,* TNF receptor–associated factor. (Modified from Whelan RS, KaplinskiyV, Kitsis RN. Cell death in the pathogenesis of heart disease: mechanisms and significance. Annu Rev Physiol 2010;72:19.)

Apoptosis.

Apoptosis, or programmed cell death, is an evolutionarily conserved process that allows multicellular organisms to selectively remove cells through a highly regulated program of cell suicide. Apoptosis is mediated by two pathways (**Fig. 23.10B**). The extrinsic pathway utilizes cell surface receptors, whereas the intrinsic pathway involves the mitochondria and endoplasmic reticulum (ER), and each of these pathways leads to caspase activation. In addition, connections between the pathways amplify signals, increasing the efficiency of killing. The intrinsic pathway is responsible for transducing most apoptotic stimuli, including those caused by inadequate nutrients or survival factors, hypoxia, oxidative stress, nutrient stress, proteotoxic stress, DNA damage, and chemical and physical toxins. These stimuli ultimately converge at the mitochondria to trigger the release of apoptogenic proteins, such as cytochrome *c*, and at the ER to stimulate the release of luminal Ca^{2+}.[35] Apoptosis plays important roles in development and in postnatal life, when it is critical for tissue homeostasis and surveillance for damaged or transformed cells. However, under pathologic circumstances, such as acute ischemia and in DCM, the apoptotic program can be triggered inappropriately, resulting in inadvertent cell death that can lead to organ failure. In contrast with the cell swelling that characterizes necrosis, during apoptosis the cell shrinks and eventually breaks up into small, membrane-surrounded fragments. The latter often contain bits of condensed chromatin referred to as *apoptotic bodies*. Maintenance of plasma membrane integrity until late in the apoptotic process allows the dying cell to be engulfed by macrophages, which prevents the release of the reactive intracellular contents, thereby preventing an inflammatory reaction.

Cardiac myocyte apoptosis has been shown to occur in failing human hearts.[36] Indeed, many of the factors implicated in the pathogenesis of HF, including catecholamines acting through $beta_1$-adrenergic receptor, angiotensin II, ROS including NO, inflammatory cytokines (e.g., TNF), and mechanical strain, have been shown to trigger apoptosis in vitro. Moreover, activation of either the extrinsic or the intrinsic cell death pathway provokes progressive LV dilation and decompensation in transgenic mice.[37] Nonetheless, the exact physiologic significance and consequence(s) of apoptosis in human HF have been difficult to determine because of the uncertainty about the actual rate of cardiac myocyte apoptosis in the failing human heart.[36] The aggregate clinical and experimental data, however, suggest that apoptosis is likely to play an important role in HF.

Autophagy.

Autophagy refers to the homeostatic cellular process of sequestering organelles, proteins, and lipids in a double-membrane vesicle inside the cell (*autophagosome*), where the contents are subsequently delivered to the lysosome for degradation. Unlike necrosis and apoptosis, autophagy is primarily a survival mechanism that regulates the quality and abundance of intracellular proteins and organelles. The

three types of autophagy are macroautophagy, microautophagy, and chaperone-mediated autophagy. The term *autophagy* generally refers to macroautophagy unless otherwise specified. When autophagy involves the total destruction of the cell, it is referred to as *autophagic cell death.* Recent studies have demonstrated the existence of autophagic cell death in hypertrophied, failing, and hibernating myocardium.[35] Approximately 0.3% of the cardiac myocytes in explanted hearts from patients with HF exhibited autophagic cell death,[38] whereas the predominant form of cell death in pressure-overloaded human hearts was mainly by autophagy and oncosis.[39] Recent studies, however, have clearly demonstrated that autophagy has a variety of physiologic roles in the heart, and that impaired clearance of autophagosomes (impaired autophagic flux) may be deleterious, rather than the process of autophagy per se.[40]

Although the distinction between necrosis and apoptosis is apparent in certain circumstances, it often is less clear in the failing heart. Indeed, similar mechanisms can operate in both types of cell death. Thus, instead of the existence of distinct types of cell death in HF, a more likely scenario is a continuum of cell death responses that contribute to progressive myocyte loss and disease progression.

Alterations in the extracellular matrix (ECM) constitute the second important myocardial adaptation that occurs during cardiac remodeling. The myocardial ECM consists of a basement membrane, a fibrillar collagen network that surrounds the myocytes, proteoglycans and glycosaminoglycans, and specialized proteins such as matricellular proteins. The major fibrillar collagens in the heart are types I and III, with a type I/III ratio of approximately 1.3 : 1 to 1.9 : 1. The organization of myocardial fibrillar type I and type III collagen ensures the structural integrity of adjoining myocytes and is essential for maintaining alignment of myofibrils within the myocyte through the interaction of collagen and integrins and the cytoskeletal proteins (**Fig. 23.11A**). *Matricellular proteins* are a class of nonstructural ECM proteins exerting regulatory functions, most likely through their interactions with cell surface receptors, the structural proteins, and soluble extracellular factors such as growth factors and cytokines. *Osteopontin* (OPN [Eta-1]) is a matricellular protein that is expressed in various cell types, including cardiac myocytes and fibroblasts and myofibroblasts (**Fig. 23.11B**). Because of its localization and molecular properties, OPN is likely to be involved in the communication between the ECM and cardiac myocytes, which implies a role in cardiac remodeling after hemodynamic overloading. OPN is markedly upregulated in animal models of cardiac hypertrophy and failure and myocardial ischemia and in the hearts of patients with DCM. OPN is elevated in the peripheral circulation of patients in direct relation to HF disease severity.[41]

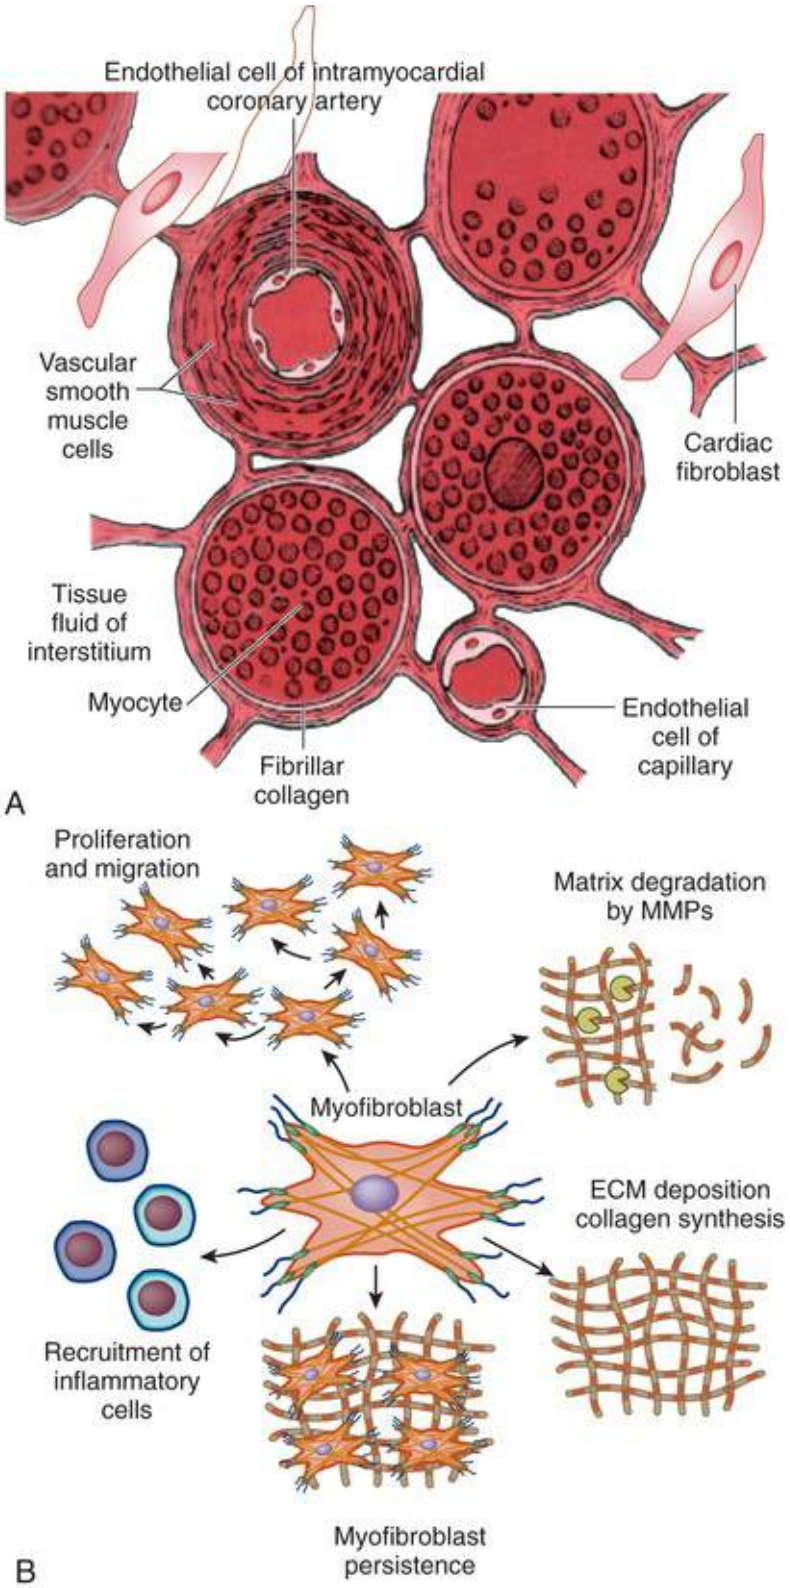

FIGURE 23.11 Extracellular matrix in heart failure. **A,** Although myocytes are the major components of heart on the basis of mass, they represent only a minority on the basis of number. Nonmyocyte cellular constituents of the myocardium include fibroblasts, smooth muscle cells, and endothelial cells. Myocytes and nonmyocytes are interconnected by a complex of connective tissue and extracellular matrix (ECM). Components of ECM include collagens, proteoglycans, glycoproteins (e.g., fibronectin), several peptide growth factors, and proteases (e.g., plasminogen activators) and collagenases (e.g., MMPs). **B,** Interactions among cardiac fibroblasts, myocytes, and ECM. In response to biomechanical stress, peptide growth factors in ECM and adjacent cardiac fibroblasts release an ensemble of peptide growth factors that activate hypertrophic signaling pathways in cardiac myocytes. Activated cardiac myofibroblasts express elevated levels of various proinflammatory and profibrotic factors that directly contribute to inflammatory cell infiltration and fibroblast proliferation, secrete high levels of matrix metalloproteinases (MMPs) and other ECM-degrading enzymes that facilitate fibroblast migration, and contribute to the deposition of collagen and other ECM proteins, leading to scar formation. (**A,** Modified from Weber KT, Brilla CG. Pathological hypertrophy and cardiac interstitium. Circulation 1991;83:1849; **B,** from Travers JG et al. Cardiac Fibrosis: The Fibroblast Awakens. Circ Res 2016;118:1021-40. Copyright 2016 American Heart Association.)

During cardiac remodeling, important alterations in the ECM include changes in fibrillar collagen synthesis and degradation (**Fig. 23.12**) and in the degree of collagen cross-linking, as well as loss of collagen struts that connect the individual cardiac myocytes.[42] Markers of collagen turnover have been shown to be increased in patients with DCM compared with age-matched controls.[43] In patients with idiopathic or ischemic DCM, serum N-terminal peptide type III collagen propeptide (PIIINP) levels have been shown to be independent predictors of mortality.[44] In the RALES trial (**see Chapter 25**), serum C-terminal peptide type I collagen propeptide (PIP) and PIIINP were decreased in the spironolactone-treated patients but not in the placebo group, suggesting that aldosterone may play an important role in ECM synthesis. Moreover, it is becoming increasingly apparent that the three-dimensional organization of the ECM plays an important role in regulating cardiac structure and function in HF.[45]

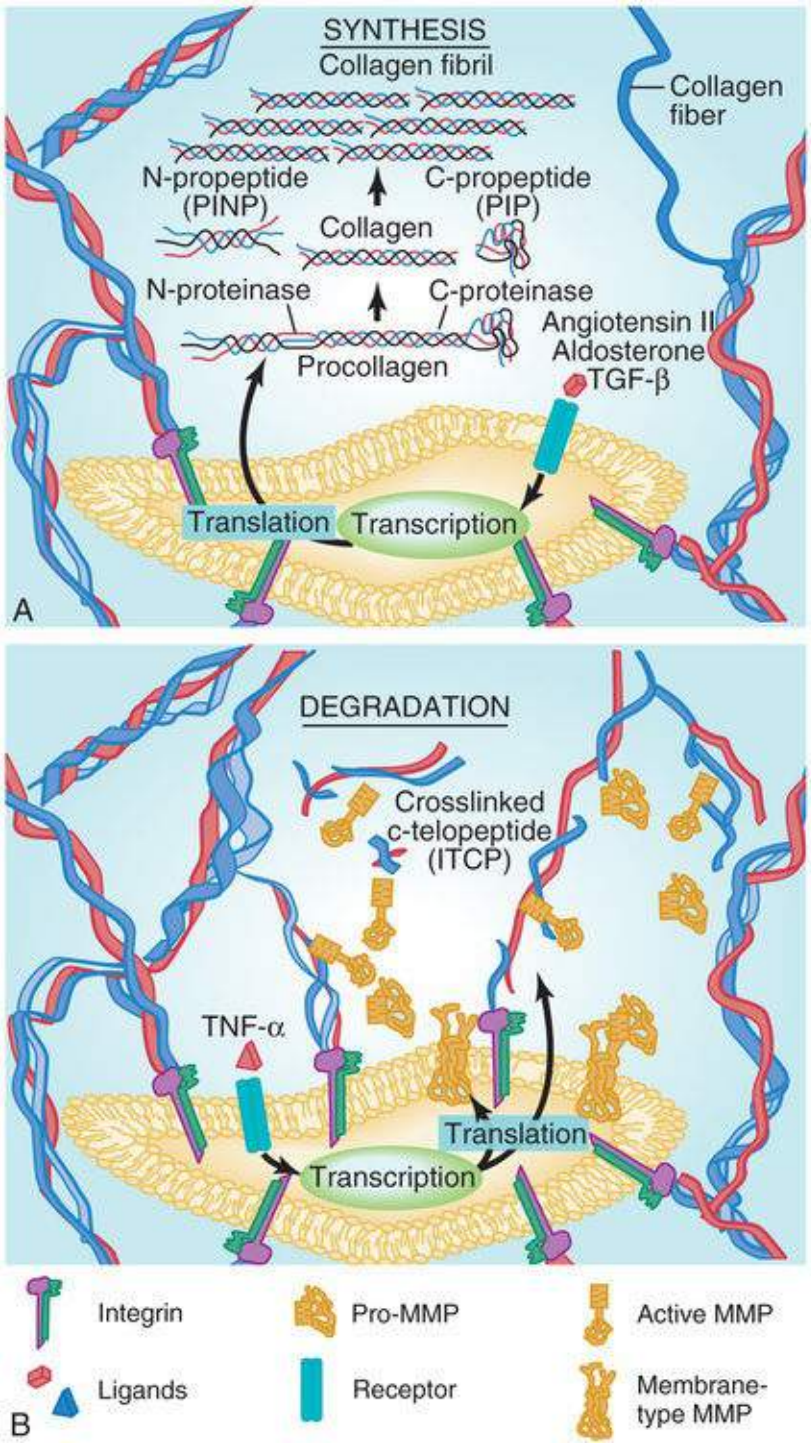

FIGURE 23.12 Collagen synthesis and degradation. **A,** Intracellular signals generated by neurohormonal and/or mechanical stimulation of cardiac fibroblasts results in transcription and translation of nascent collagen proteins containing aminoterminal (N-terminal) and carboxyl terminal (C-terminal) propeptides that prevent collagen from assembling into mature fibrils. Once secreted into the interstitium, these propeptides are cleaved by N- and C-proteinases, yielding two procollagen fragments and a mature triple-stranded collagen molecule. In the case of collagen type I, these propeptides are referred to as N-terminal peptide type I collagen propeptide (PINP) and C-terminal peptide type I collagen propeptide (PIP). Removal of the propeptide sequences allows the secreted collagen molecule to integrate into growing collagen fibrils, which can then further assemble into collagen fibers. After the collagen fibrils form in the extracellular space, their tensile strength is greatly strengthened by the formation of covalent cross-links between the lysine residues on the collagen molecules. **B,** The degradation of the collagen matrix within the myocardium entails a number of biochemical events involving several protease systems. Degradation of collagen fibrils occurs through catalytic cleavage of the three collagen alpha chains at a single locus by interstitial collagenase, yielding 36-kDa and 12-kDa collagen telopeptides that maintain their helical structure and thus are resistant to further proteolytic degradation. The large 36-kDa telopeptide spontaneously denatures into nonhelical gelatin derivatives, which in turn are completely degraded by interstitial gelatinases. The small 12-kDa pyridinoline cross-linked C-terminal telopeptide resulting from the cleavage of collagen type I (ICTP) is found in intact in blood, where it appears to be derived from tissues, with a stoichiometric ratio of 1 : 1 between the number of collagen type I molecules degraded and that of ITCP released. (From Deschamps AM, Spinale FG. Extracellular matrix. In Walsh RA, editor. Molecular Mechanisms of Cardiac Hypertrophy and Failure. Boca Raton, Fla: Taylor & Francis; 2005, pp 101-116.)

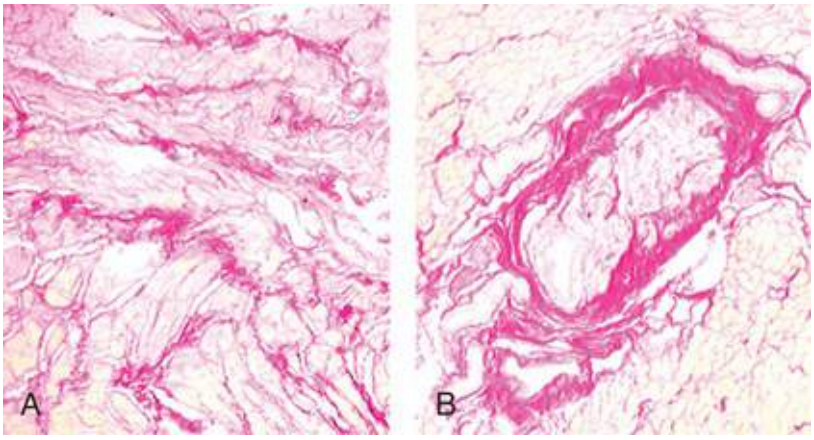
Cardiac Fibroblasts and Mast Cells.

The cardiac fibroblast, which accounts for almost 90% of nonmyocyte cells in the heart, is the primary cell type that is responsible for the secretion of a majority of ECM components in the heart, such as collagens I, III, and IV and laminin and fibronectin. In response to mechanical stress and neurohormonal activation, a subset of fibroblasts undergoes phenotypic conversion to myofibroblasts that are characterized by increased expression of α-smooth muscle actin and enhanced secretory activity. Recent studies have shown that myofibroblasts, which are responsible for the collagen secretion and contraction/realignment of the nascent collagen fibers, arises from tissue-resident fibroblasts that become activated after tissue injury.[46] Myofibroblasts migrate into the area surrounding tissue and play an important role in the final scar formation. Cardiac myofibroblasts also may regulate the phenotype of cardiac myocytes through multiple paracrine signaling pathways (**Fig. 23.11B**). Several lines of evidence suggest that that cardiac fibroblasts and myocytes release proteins that regulate neighboring cells.[47] The proteins that have been implicated thus far include transforming growth factor-β1 (TGF-β1), fibroblast growth factor-2 (FGF2), members of the IL-6 family, and the recently discovered cytokine IL-33. Increasing evidence also suggests that mast cells, which are bone marrow–derived cells that "home" to and reside in the myocardium, also play an important role in remodeling of the ECM. Myocardial mast cells are located mainly around blood vessels and between myocytes, where they are capable of releasing profibrotic cytokines and growth factors that influence ECM remodeling. In experimental studies, mast cells that are recruited to the heart during inflammation were responsible for TGF-β1–mediated fibroblast activation, myocardial fibrosis, and LV diastolic dysfunction.[48]

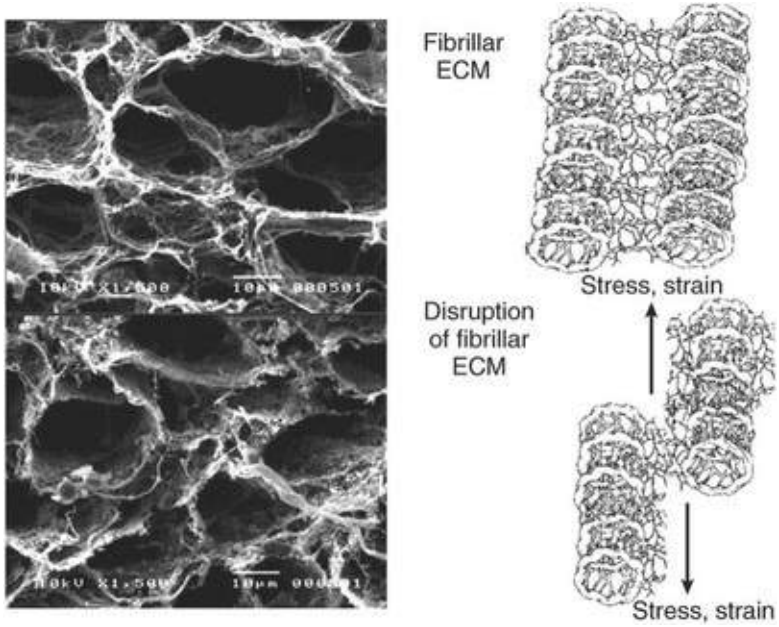
As noted earlier, one of the histologic signatures of advancing HF is the progressive increase in collagen content of the heart (myocardial fibrosis). Studies in failing human myocardium have shown a quantitative increase in collagen types I, III, VI, and IV, along with fibronectin, laminin, and vimentin, and a decrease in the type I/III collagen ratio in patients with ischemic cardiomyopathy. Moreover, clinical studies show a progressive loss of cross-linking of collagen in the failing heart, as well as loss of connectivity of the collagen network with individual myocytes, which would be expected to result in

profound alterations in LV structure and function. Furthermore, loss of cross-linking of the fibrillar collagen has been associated with progressive LV dilation after myocardial injury. The accumulation of collagen can occur on a “reactive” basis around intramural coronary arteries and arterioles (perivascular fibrosis) or in the interstitial space (interstitial fibrosis) and does not require myocyte cell death (**eFig. 23.7**). Alternatively, collagen accumulation can occur as a result of microscopic scarring, which develops in response to cardiac myocyte cell necrosis. This scarring or “replacement fibrosis” is an adaptation to the loss of parenchyma and is therefore critical to preserve the structural integrity of the heart. The increased fibrous tissue would be expected to lead to increased myocardial stiffness, which presumably would result in decreased myocardial shortening for a given degree of afterload. In addition, myocardial fibrosis may provide the structural substrate for atrial and ventricular arrhythmias, thus potentially contributing to inhomogeneous activation, bundle branch block, and dyssynchrony, as well as sudden death (**see Chapter 42**). Although the full complement of molecules responsible for fibroblast activation is not known, many of the classic neurohormones (e.g., angiotensin II, aldosterone) and cytokines (ET, TGF-β, cardiotrophin-1) that are expressed in HF are sufficient to provoke fibroblast activation. Indeed, the use of ACE inhibitors, beta blockers, and aldosterone receptor antagonists has been associated with a decrease in myocardial fibrosis in experimental HF models.[49]



EFIGURE 23.7 Myocardial fibrosis. Histologic section of a human myocardial biopsy specimen showing interstitial **(A)** and perivascular **(B)** fibrosis using picrosirius red staining. (Modified from Lopez B et al. Biochemical assessment of myocardial fibrosis in hypertensive heart disease. Hypertension 2001;38:1222.)

Although the fibrillar collagen matrix initially was thought to form a relatively static complex, it is now recognized that these structural proteins can undergo rapid turnover. A major development in understanding the pathogenesis of cardiac remodeling was the discovery that a family of collagenolytic enzymes, the *matrix metalloproteinases* (MMPs), is activated within the failing myocardium. Conceptually, ECM disruption would be expected to lead to LV dilation and wall thinning as a result of mural realignment of myocyte bundles and within the LV wall (**as depicted in eFig. 23.8**), as well as LV dysfunction as a result of dyssynchronous contraction of the left ventricle. Although the precise biochemical triggers responsible for activation of MMPs are not known, TNF and other cytokines and peptide growth factors expressed within the failing myocardium are capable of activating MMPs.



EFIGURE 23.8 Disruption of the fibrillar extracellular matrix (ECM). **Left,** Scanning electron micrographs of normal human myocardial ECM in which the myocardium has been subjected to corrosion digestion to provide full relief of the collagen ECM. The scaffolding around where the myocytes are positioned is evident and underscores the complexity of the fibrillar collagen matrix. **Right,** Schematic representation depicting the collagen matrix and the potential effects of mechanical load and proteolytic digestion of fibrillar collagen support. The geometric alignment of myocytes is disrupted, with loss of the rigid architecture of the matrix. (Electron micrographs from Rossi MA. Connective tissue skeleton in the normal left ventricle and in hypertensive left ventricular hypertrophy and chronic chagasic myocarditis. Med Sci Monit 2001;7:820; schematic representation of ECM disruption, courtesy Dr. Francis G. Spinale.)

However, the biology of matrix remodeling in HF is likely to be much more complex than the simple presence or absence of MMP activation, because degradation of the matrix also is controlled by glycoproteins termed *tissue inhibitors of matrix metalloproteinases*. TIMPs are capable of regulating the activation of MMPs by binding to and preventing these enzymes from degrading the collagen matrix of the heart. The TIMP family at present consists of four distinct members, TIMP-1, -2, -3, and -4, each of which is constitutively expressed in the heart by fibroblasts as well as myocytes. TIMPs are secreted proteins that act as the natural inhibitors of active forms of all MMPs, although the efficiency of MMP inhibition varies among the different members. The extant literature suggests that MMP activation can lead to progressive LV dilation, whereas TIMP expression favors progressive myocardial fibrosis. Additional content on this topic is presented in the online supplement for this chapter (Matrix Metalloproteinases and Tissue Inhibitors of Metalloproteinases).

Noncoding RNAs.

Once considered “transcriptional noise,” noncoding RNAs have emerged as potential biomarkers as well as therapeutic targets in HF. The noncoding portion of the genome is actively transcribed, generating thousands of regulatory short and long noncoding RNAs that are capable of regulating gene networks. Noncoding RNAs are classified based on their length. Small noncoding RNAs are less than 200 nucleotides in size and include both small interfering RNAs (siRNAs) and microRNAs (miRNAs). Transcripts larger than 200 nucleotides are called long noncoding RNAs (lncRNAs). MicroRNAs are involved in virtually all cellular processes. The lncRNAs also regulate gene and protein levels but through more complicated and diverse mechanisms.

Experimental studies have shown that microRNAs have a profound effect on cardiac remodeling.

MicroRNAs are noncoding RNAs that pair with specific “target” mRNAs and negatively regulate their expression through translational repression or mRNA degradation (gene silencing). The binding specificity of microRNAs depends on complementary base pairing of the approximately 6 nucleotide (nt) region at the 5′ end of the microRNA with the 3′ untranslated region (UTR) of the corresponding mRNA target. As shown in **Fig. 23.13A**, binding of microRNAs to their cognate target mRNAs typically leads to decreased expression of target genes. Individual microRNAs modulate the expression of collections of mRNA targets that often have related functions, thereby governing complex biologic processes. Recent studies have suggested that microRNAs contribute to adverse or pathologic remodeling in experimental HF models.[50] As shown in **Fig. 23.13B**, microRNAs regulate key components of the remodeling process, including cardiac myocyte biology, cell fate, ECM remodeling, and neurohormonal activation. Given that microRNAs are coordinately upregulated in response to stress signals, and that microRNAs regulate the expression levels of gene networks that determine the “heart failure phenotype,” it is tempting to speculate that microRNAs, acting singly or in combination, may be responsible for modulating the transition from adaptive to pathologic cardiac remodeling. Moreover, it is possible that certain microRNAs may themselves become therapeutic targets using chemically modified oligonucleotides to target specific microRNAs and disrupt the binding between a specific microRNA and a specific mRNA target.[50]

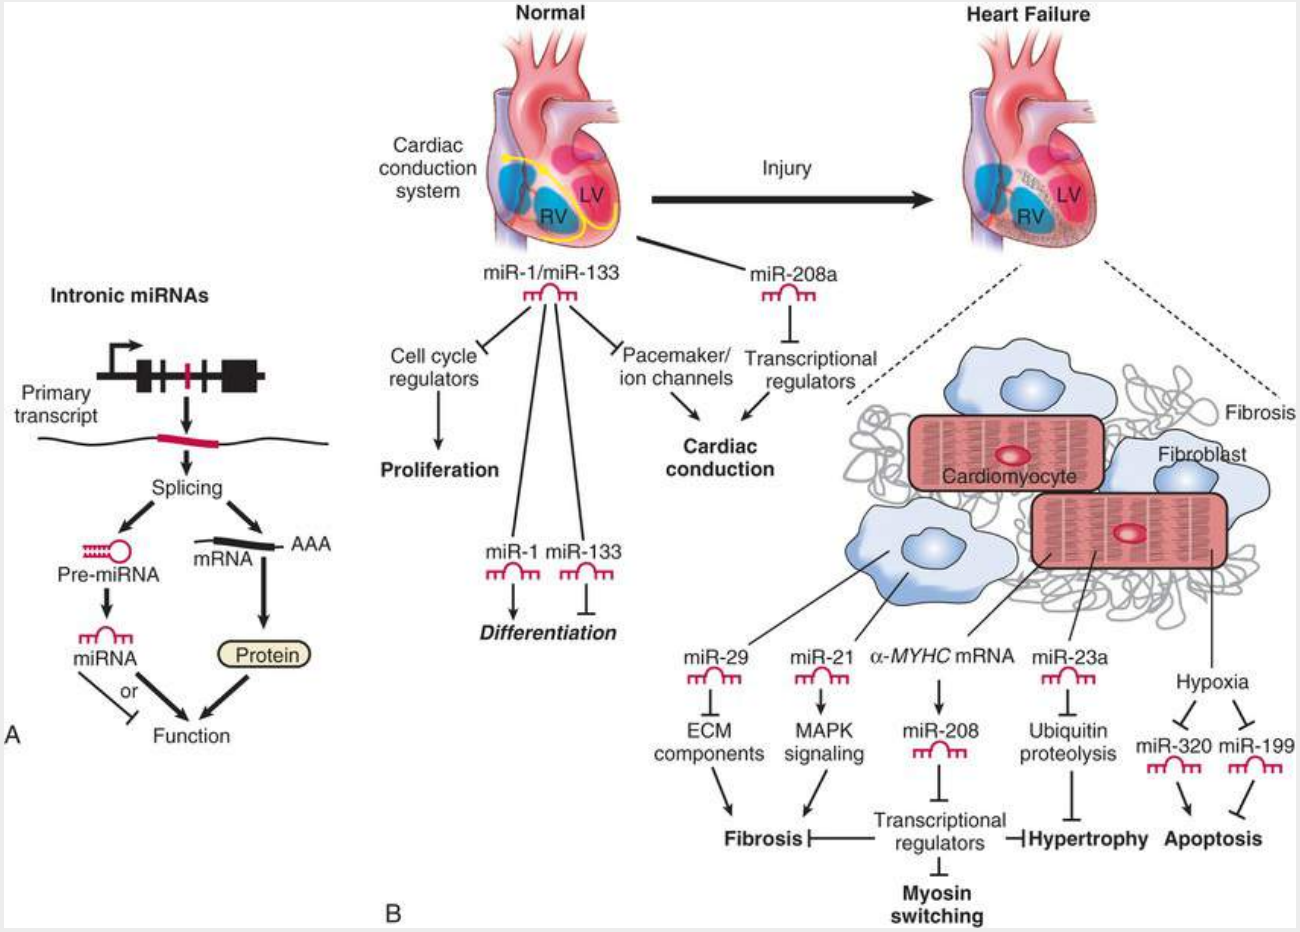


FIGURE 23.13 MicroRNAs (miRNAs) and the heart. **A,** The potential modes of miRNA-based regulation of gene expression are illustrated. Intronic microRNAs are encoded within an intron of a host gene. Messenger RNA splicing generates a protein coding transcript and a microRNA stem-loop. A common mechanism of miRNA function involves the modest repression of several mRNAs in a common biologic process by a single miRNA, most commonly through transcriptional silencing, or through enhanced mRNA degradation. Intronic miRNAs often regulate similar processes to that of the protein encoded by the host gene. *AAA,* Polyadenylated tail of the transcript; pre-miRNA, precursor miRNA. **B,** Functional role of miRNAs in the normal and failing heart. A normal heart and a hypertrophic/failing heart are shown in schematic form, depicting miRNAs that contribute to normal function or pathologic remodeling. All *arrows* denote the normal action of each component or process. The miRNAs miR-1 and miR-133 are involved in the development of a normal heart **(left)** by regulating proliferation, differentiation, and cardiac conduction. After cardiac injury **(right),** various miRNAs contribute to pathologic remodeling and the progression to heart failure: miR-29 blocks fibrosis by inhibiting the expression of ECM components, whereas miR-21 promotes fibrosis; miR-208 controls myosin isoform switching, cardiac hypertrophy, and fibrosis; and miR-23a promotes cardiac hypertrophy by inhibiting ubiquitin proteolysis, which itself inhibits hypertrophy. Hypoxia results in the repression of miR-320 and miR-199, which promote and block apoptosis, respectively. (Modified from Small EM, Olson EN. Pervasive roles of microRNAs in cardiovascular biology. Nature 2011;469:336.)

Long noncoding RNAs are mechanistically more complex than microRNAs and likely modulate the genome at multiple different levels. For example, lncRNAs may interact with RNAs, proteins, and DNA and can either activate or silence the interaction with other molecules through conformational switching. Recent studies have shown that the profile of myocardial lncRNAs is altered in human HF, and that several lncRNAs are responsible for regulating cardiac structure and function following hemodynamic overload.[51]

Alterations in Left Ventricular Structure

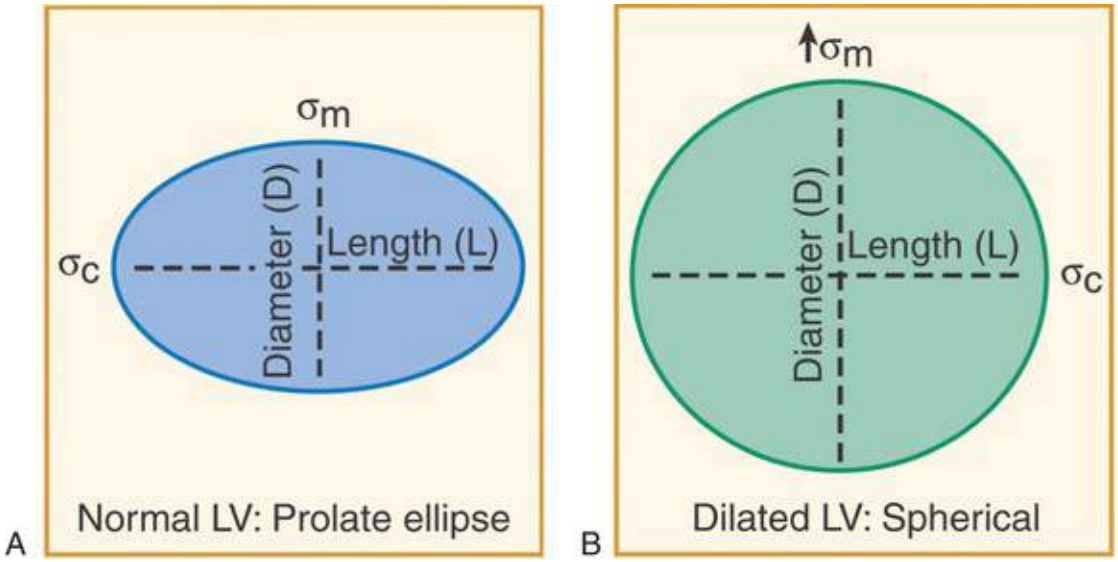
The alterations in the biology of the failing myocyte, as well as in the failing myocardium, are largely responsible for the progressive LV dilation and dysfunction that occur during cardiac remodeling. Many

of the structural changes that accompany LV remodeling may contribute to worsening HF (**eTable 23.2**). Indeed, one of the first observations regarding the abnormal geometry of remodeled ventricle was the consistent finding that the remodeled heart was not only larger but also more spherical in shape. An important point in this context is that a change in LV shape from a prolate ellipse to a more spherical shape results in an increase in meridional wall stress of the left ventricle, thereby creating a de novo energetic burden for the failing heart (**eFig. 23.9**). Since the load on the ventricle at end-diastole contributes importantly to the afterload on the ventricle at the onset of systole, LV dilation itself will increase mechanical energy expenditure of the ventricle, which exacerbates the underlying problems with energy utilization in the failing ventricle (**eFig. 23.10**).

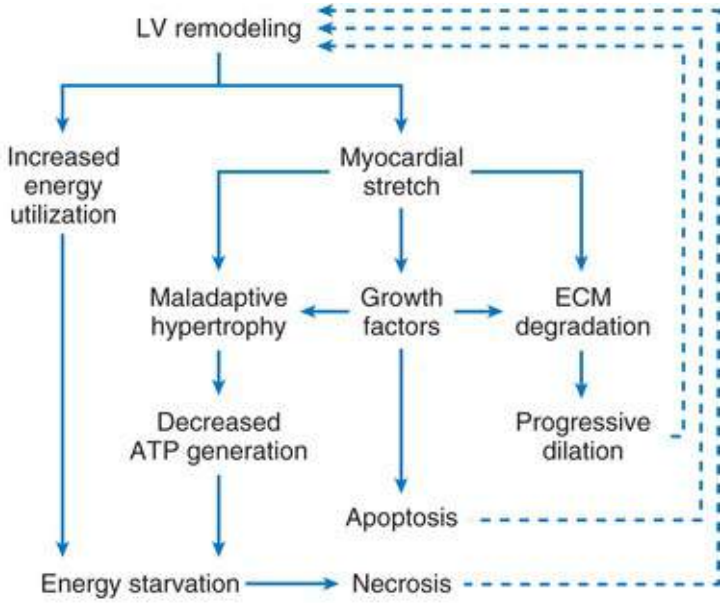
ETABLE 23.2

Mechanical Disadvantages Created by Left Ventricular Remodeling

Increased wall stress (afterload)
Afterload mismatch
Episodic subendocardial hypoperfusion
Increased oxygen utilization
Functional mitral regurgitation
Worsening hemodynamic overloading
A stretch-induced activation of maladaptive signal transduction pathways
Stretch-induced activation of maladaptive gene programs



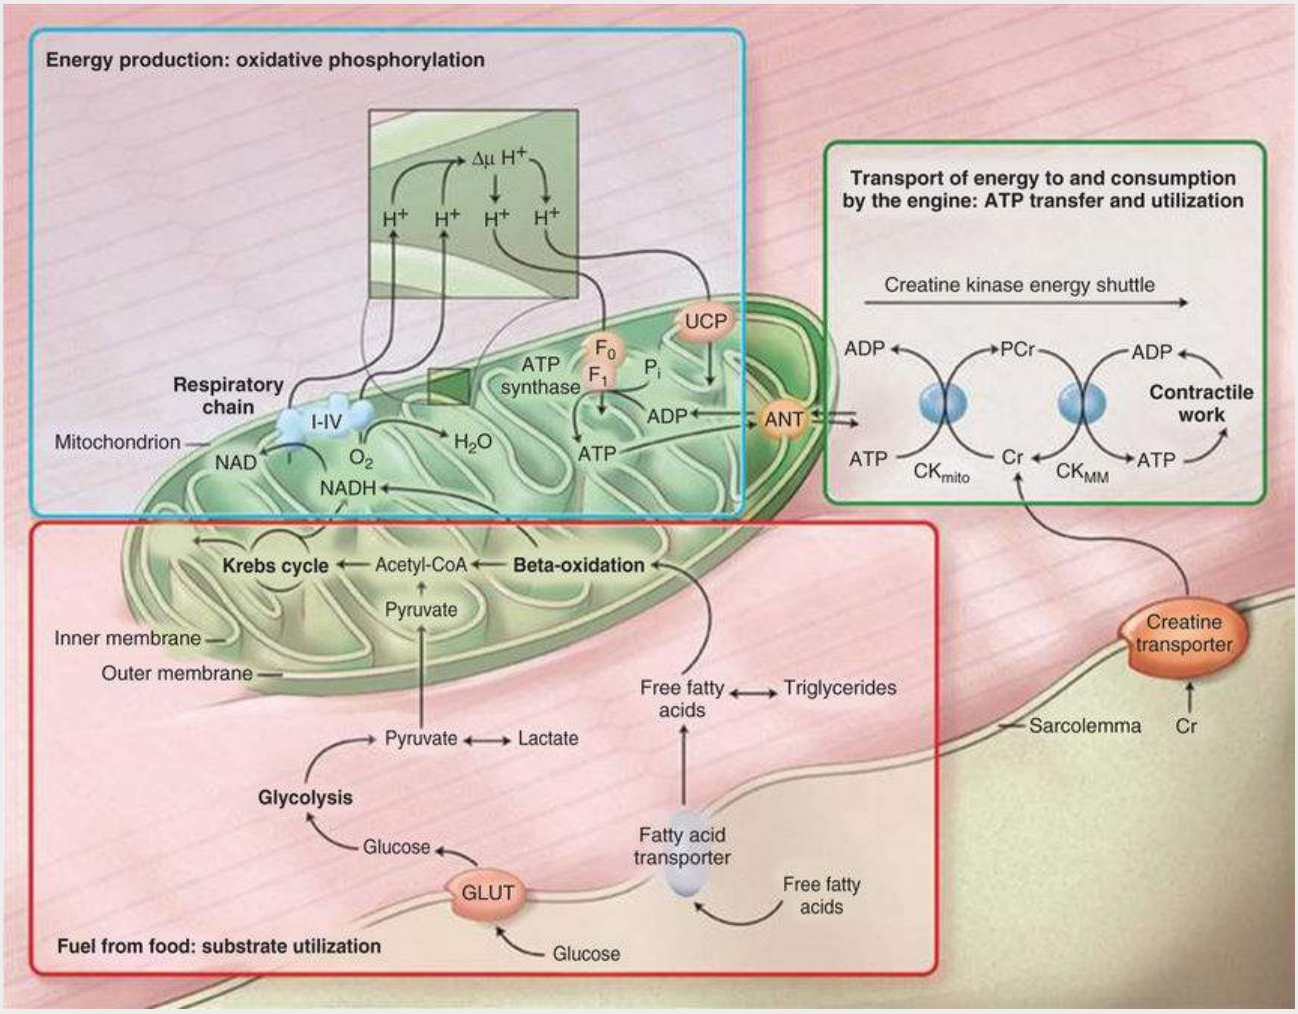
EFIGURE 23.9 Effect of changes in LV shape on LV wall stress. During LV remodeling, ventricle undergoes a change in LV shape from a prolate ellipse **(A)** to a more spherical shape heart **(B).** As shown in **B,** increase in short-axis dimension of ventricle as the heart becomes more spherical in shape leads to an increase in meridional wall stress of the ventricle, thereby creating a de novo mechanical burden for the heart. σ_c, Circumferential wall stress; σ_m, meridional wall stress. (From Mann DL. Left ventricular size and shape: determinants of mechanical signal transduction pathways. Heart Fail Rev 2005;10:95.)



EFIGURE 23.10 Self-amplifying nature of LV remodeling. LV remodeling results in increased afterload on the heart, which increases energy utilization and further stimulates cardiac growth through stretch-mediated activation of growth factors. The former contributes directly to a state of energy starvation, whereas the latter contributes to further cardiac remodeling, including increased myocyte hypertrophy and further matrix remodeling. The sustained activation of growth stimuli also promotes apoptosis and myocardial fibrosis, which contribute to LV dysfunction and LV remodeling. (Modified from Katz AM. Heart Failure. Philadelphia: Lippincott Williams & Wilkins; 2000.)

Cardiac Energetics and Mitochondrial Biology.

Energy transfer in the cardiac myocyte occurs in three stages: uptake and metabolism, energy production through oxidative phosphorylation, and energy transfer by means of the creatine kinase (CK) shuttle (**eFig. 23.11**). Each stage of this process can lead to contractile dysfunction of the heart. Studies in patients with end-stage cardiomyopathy have shown that myocardial ATP concentration, the total adenine nucleotide pool (ATP, ADP, and AMP), CK activity (required for synthesis of ATP), creatine phosphate (CrP) concentration, and CrP/ATP ratio are all decreased in HF. In addition, decreased levels of creatine phosphokinase have been reported, which would slow phosphocreatine shuttle, further exacerbating energy utilization in the failing heart.[52] Thus, in the failing heart, key components of the cardiac energetic system are downregulated. It is unclear at present, however, whether these energetic changes are biomarkers or drivers of LV dysfunction.



EFIGURE 23.11 Energy transfer in the cardiac myocyte occurs in three stages. Each stage may be the site of metabolic derangements causing or accompanying contractile dysfunction of the heart. The first stage is substrate uptake and metabolism (outlined in *red*). In this stage, substrates are broken down by β-oxidation and glycolysis to form acetyl-coenzyme A (acetyl-CoA), from which the Krebs cycle produces NADH and CO_2. The second stage is energy production through oxidative phosphorylation (outlined in *blue*). Respiratory chain complexes in the mitochondria transfer electrons from NADH to oxygen. This creates a proton electrochemical gradient ($\Delta\mu\ H^+$) across the inner mitochondrial membrane, in addition to water and NAD. This gradient drives ATP synthase. Uncoupling proteins (UCPs) use this electrochemical gradient to create heat instead of ATP. The third stage is energy transfer via the creatine kinase shuttle (outlined in *green*). ATP is transferred to and consumed by myofibrillar ATPase and other reactions. *ANT,* Adenine nucleotide translocase; CK_{mito}, mitochondrial creatine kinase isoenzyme; CK_{MM}, myofibrillar creatine kinase isoenzyme; *Cr,* free creatine; *GLUT,* glucose transporter; *PCr,* phosphocreatine; P_i, inorganic phosphate. (Modified from Neubauer S. The failing heart—an engine out of fuel. N Engl J Med 2007;356:11407.)

Although several mechanisms have been proposed to explain the fall in ATP content in HF, one mechanism that has received considerable attention relates to changes in substrate utilization in HF. Under normal conditions, the adult heart derives most of its energy through oxidation of fatty acids in mitochondria. The genes involved in this key energy metabolic pathway are transcriptionally regulated by members of the nuclear receptor superfamily, specifically the fatty acid–activated peroxisome proliferator–activated receptors (PPARs) and the nuclear receptor coactivator, PPAR-gamma coactivator-1α (PGC-1α). In experimental HF models, an initial decrease is seen in the oxidation of fatty acids secondary to downregulation of fatty acid–metabolizing genes, with a resultant shift toward glycolytic metabolism.[53] These observations have given rise to the suggestion that metabolic modulation may be beneficial in HF. Additional content on this topic is presented in the online supplement for this chapter (Metabolic Modulation). In addition to metabolic modulation, there are ongoing randomized phase II clinical trials in patients with HF with a preserved and with a reduced ejection fraction, using a

mitochondrial-targeting protein (elamipretide [MTP-13]) that enhances mitochondrial ATP synthesis.

In addition to loss of substrate, ATP generation may be impaired in the failing heart secondary to abnormalities in mitochondrial dynamics.[54] Studies in yeast have demonstrated that maintaining normal mitochondrial morphology and function depends on the dynamic balance of mitochondrial *fusion* and *fission* (division), collectively called "mitochondrial dynamics." The balance between mitochondrial fusion and fission determines the number, morphology, and activity of mitochondria in the heart. Fusion and fission modulate multiple mitochondrial functions, ranging from energy and ROS production to Ca^{2+} homeostasis and cell death. Although studies in HF are limited, data suggest that mitochondrial fusion may be reduced, which would be predicted to lead to reduced O_2 consumption and alterations in mitochondrial metabolism. Moreover, abnormalities in mitochondrial dynamics may contribute to the cell death through apoptotic and autophagic cell-signaling pathways.[55] Of note, abnormally small and fragmented mitochondria have been observed in end-stage DCM, myocardial hibernation, and congenital heart disease, suggesting that mitochondrial fusion/fission becomes dysregulated in cardiac disease. However, the contribution of abnormalities in mitochondrial fission/fusion in HF as a cause versus a consequence of myocardial injury remains unknown.

LV wall thinning also occurs as the ventricle begins to dilate and remodel. The increase in wall thinning along with the increase in afterload created by LV dilation leads to a functional "afterload mismatch" that may further contribute to a decrease in forward cardiac output. Increased LV wall stress also can lead to sustained expression of stretch-activated genes (angiotensin II, ET, TNF) and stretch activation of hypertrophic signaling pathways. Moreover, the high end-diastolic wall stress might be expected to lead to episodic hypoperfusion of the subendocardium with resultant worsening of LV function, as well as increased oxidative stress, with the resultant activation of gene families that are sensitive to free radical generation (e.g., TNF, IL-1β). Another important mechanical problem from progressive LV dilation is that the papillary muscles are pulled apart, resulting in incompetence of the mitral valve and development of "functional mitral regurgitation." In addition to the loss of forward blood flow, mitral regurgitation results in further hemodynamic volume overloading of the ventricle. Together, the mechanical burdens engendered by LV remodeling might lead to increased LV dilation, decreased forward cardiac output, and increased hemodynamic overloading (**see eFig. 23.10**), any of which is sufficient to contribute to worsening LV function independent of the patient's neurohormonal status.

Reversibility of Left Ventricular Remodeling

Clinical studies have shown that medical and device therapies that reduce HF morbidity and mortality also lead to decreased LV volume and mass and restore a more normal elliptical shape to the ventricle. These salutary changes represent the summation of a series of integrated biologic changes in cardiac myocyte size and function (**eTable 23.3**), as well as modifications in LV structure and organization that are accompanied by shifts of the LV end-diastolic pressure-volume relationship toward normal. For want of better terminology, these changes are collectively called "reverse LV remodeling." Interestingly, in recognized subsets of patients, the heart is undergoes reverse LV remodeling either spontaneously or after medical or device therapies. Importantly, the subsequent clinical course of these patients is associated with fewer future HF events.[56] This phenomenon has often been referred to as "myocardial recovery." Despite the frequent interchangeable use of the terms *myocardial recovery* and *reverse LV remodeling* to describe the reversal of various aspects of the HF phenotype with medical and device therapy, the literature suggests that important differences exist between these two phenomena and that they are not

synonymous. The term *reverse remodeling*, as currently used, describes the biologic process involving the reversal of the cellular, myocardial, and anatomic abnormalities seen in the remodeled ventricle. As shown in **Fig. 23.14**, patients whose hearts have undergone reverse remodeling may experience one of two potential outcomes: freedom from future HF events or recurrence of HF events. Based on the disparate clinical outcomes of reverse remodeling, it has been suggested that the term *myocardial recovery* should be used to describe the normalization of the molecular, cellular, myocardial, and LV geometric changes that are associated with freedom from future HF events. The term *myocardial remission* should be used to refer to the normalization of these changes that are associated with cardiac remodeling but that are insufficient to prevent the recurrence of HF in the face of normal or perturbed hemodynamic loading conditions.[56] Although the biologic differences between myocardial recovery and myocardial remission are not known, it has been suggested that myocardial remission represents reversal of the HF phenotype superimposed on hearts that have sustained irreversible damage, whereas myocardial recovery represents reversal of the HF phenotype superimposed on hearts that have not sustained irreversible damage.

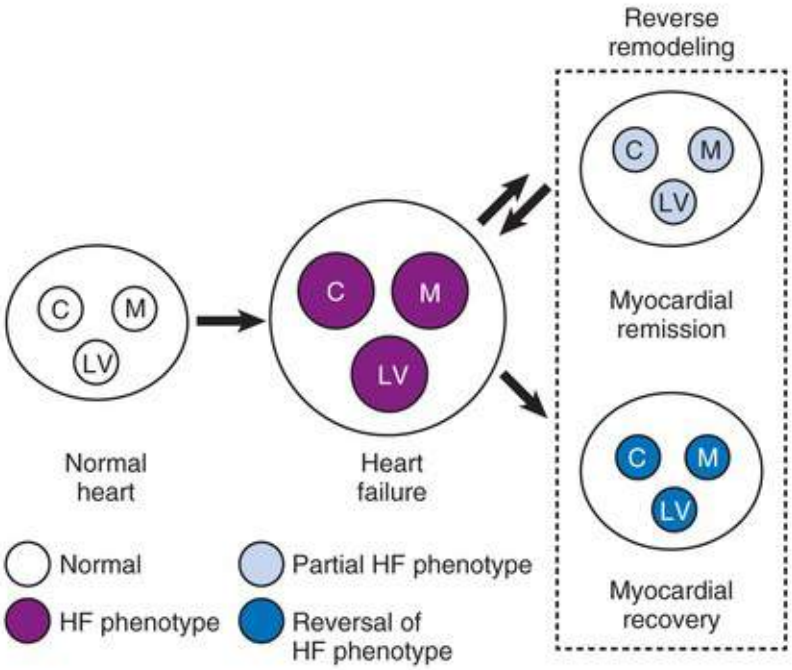


FIGURE 23.14 Reverse left ventricular remodeling and myocardial recovery in heart failure. Cardiac remodeling occurs secondary to abnormalities that arise in the biology of the cardiac myocyte (*C*), the myocardium (cardiocytes and extracellular matrix [*M*]), as well as left ventricular [*LV*] geometry, which have collectively been referred to as the "heart failure phenotype." During reverse remodeling, there is a reversal of the abnormalities in the cardiac myocyte, as well as the extracellular matrix, leading to normalization of LV geometry. Reverse remodeling can lead to two clinical outcomes: (1) myocardial recovery, characterized by freedom from future cardiac events; or (2) myocardial remission, characterized by recurrence of HF events. (Modified from Mann DL, Barger PM, Burkhoff D. Myocardial recovery: myth, magic or molecular target? J Am Coll Cardiol 2012;60:2465.)

Future Perspectives

The clinical syndrome of heart failure can be considered in terms of several different clinical model systems, including cardiorenal, hemodynamic, and neurohormonal. Each of the models has strengths and weaknesses in explaining the mechanisms responsible for HF, as well as in developing effective new therapies for HF. Nonetheless, current models for explicating the mechanisms for HF are inadequate and do not adequately describe disease progression in HF. Moreover, they do not provide an adequate scaffold for understanding newer device therapies that appear to work through neurohormonally independent mechanisms. This emphasizes the importance of cardiac remodeling as a mechanism of disease progression in HF. Future therapeutic advances are likely to require a more comprehensive understanding and analysis of the pathobiology of HF, particularly cell-cell interactions during LV remodeling, as well as the complex interactions that govern the process of reverse LV remodeling. In this regard, the emerging field of systems biology, which uses network theory to describe how the interrelationships between genes, proteins, and metabolites determine functional changes at the level of the cell, tissue, and organ, may allow investigators to accelerate the pace of novel target identification, as well as improve the likelihood of success in clinical trials.

Vasoconstricting Peptides in Heart Failure

Endothelin

The three endothelin (ET) peptides—ET-1, ET-2, and ET-3—all are potent vasoconstrictors. Although released primarily by endothelial cells, ET also can be synthesized and released by a variety of other cell types, such as cardiac myocytes. ET-1 is the predominant isoform of the ET peptide family and is ubiquitously expressed. ET-1 is synthesized as a protein precursor termed *preproET-1*. Preproendothelin-1 is processed by multiple proteases in a process that involves the proteolytic release of proendothelin-1 (“big endothelin”), followed by C-terminal trimming by a carboxypeptidase and further processing by endothelin-converting enzyme (ECE) to generate the biologically active 21–amino acid ET-1 peptide. However, studies in ECE-knockout mice have confirmed the presence of significant levels of mature ET-1, suggesting that there may be alternative ECE-independent (e.g., chymase, non-ECE metalloproteinases) pathways for generation of ET-1. At least two subtypes of ET receptors, designated A and B, have been identified in human myocardium. Endothelin ET(A) receptors mediate vasoconstriction, cell proliferation, pathologic hypertrophy, fibrosis, and increased contractility, whereas ET(B) receptors are involved in the clearance of ET-1 and the release of NO and prostacyclin. The release of ET from endothelial cells in vitro can be enhanced by several vasoactive agents (e.g., NE, angiotensin II, thrombin) and cytokines (e.g., TGF-β, TNF, IL-1). Several reports have documented an increase in circulating levels of ET-1 in patients with heart failure (HF) and have shown that ET levels correlate with patient outcomes. Furthermore, plasma ET concentrations correlate directly with pulmonary artery pressure and pulmonary

vascular resistance. Based on the biologic properties of ET, ET receptor antagonists were developed for the treatment of patients with HF. Although early experimental studies showed that ET(A) receptor antagonists inhibited myocardial hypertrophy in rats with pressure overload–induced hypertrophy caused by aortic banding and prevented cardiac remodeling in rats with myocardial infarction, and although early clinical studies confirmed the ability of these new agents to improve hemodynamics, the effect of chronic ET receptor antagonism has not been beneficial in clinical HF trials, and use of such agents has led to worsening outcomes in some settings.[1]

Neuropeptide Y

Neuropeptide Y (NPY) is a vasoconstricting peptide that is released together with NE from sympathetic nerve endings. NPY is abundant in cerebral cortex, hippocampus, thalamus, brainstem, and hypothalamus, where it is colocalized with agouti-related protein (AgRP), and positively modulates food intake. NPY is released from sympathetic nerves in the heart and influences coronary artery constriction and myocardial contraction. In addition, NPY potentiates the vasoconstrictor effects of other extracellular messengers, including alpha-adrenergic agonists and angiotensin II, and also inhibits acetylcholine release from parasympathetic nerve endings in the heart. Six NPY (NPY[1-6]) receptor subtypes have been identified thus far, of which NPY(1), NPY(2), and NPY(5) appear to be responsible for mediating functional responses in the heart.[1] Recent studies have suggested that NYP exerts important mitogenic and hypertrophic effects in endothelial and vascular smooth muscle cells, as well as cardiac myocytes. Although the role of NPY in HF is not known, circulating concentrations of NPY-like immunoreactivity are significantly increased in moderate to severe forms of HF and correlate with circulating levels of NE.[1]

Urotensin Ⅱ

Mammalian urotensin II is the most potent endogenous cardiostimulatory peptide identified thus far, with an 8- to 110-fold greater potency than that of ET-1. The effects of urotensin II are mediated by binding to the urotensin receptor. Urotensin II mediates vascular tone and increased contractile force in human atrium and ventricle. Analogous to ET-1, urotensin II provokes trophic and/or mitogenic actions in vascular smooth muscle cells, cardiac myocytes, and cardiac fibroblasts. However, unlike ET-1, which uniformly constricts most blood vessels, the vasoactive effects of urotensin II are both species- and vascular bed–dependent. Urotensin receptor (GPR14) expression is increased in cardiac myocytes, endothelial cells, and fibroblasts in the rat heart after coronary artery ligation. Urotensin II treatment increased collagen mRNA and protein levels in cardiac fibroblasts and augmented cardiac hypertrophy in cultured neonatal cardiomyocytes after transfection with recombinant urotensin II receptor.[2] Plasma levels of urotension II have been found to be elevated in some but not all studies in HF patients. Of interest, with iontophoresis of urotensin II into the skin, urotensin II mediated a dose-dependent vasodilator response in normal persons but a dose-dependent vasoconstrictor response in HF patients, suggesting that urotensin II may contribute to the increased peripheral vascular tone that occurs in HF.[2]

Matrix Metalloproteinases and Tissue Inhibitors of Metalloproteinases

The matrix metalloproteinases (MMPs) represent a family of zinc-dependent proteases that play an important role in normal tissue remodeling, as well as in pathologic processes such as inflammation, tumor invasion, and metastasis. The MMPs are secreted as inactive zymogens that must be activated by cleavage of the N-terminal sequence of the propeptide domain, which allows the Zn^{2+} binding site of the catalytic domain to become exposed. The exception is membrane-type 1 MMP (MT-MMP1), which is cell surface–bound and is processed before cell surface localization by a furin-dependent mechanism. The MMPs can be classified into subgroups based on substrate specificity or structure, or both (**eTable 23.4**). This classification includes the collagenases (e.g. MMP-1 and MMP-13), the stromelysins (e.g., MMP-3), the gelatinases (e.g, MMP-9 and MMP-2), and the membrane-type MMPs (MT-MMPs). Once the activated, the MMPs are capable of degrading all the ECM components. Myocardial MMP abundance and activation have been assessed in end-stage human HF.[1] Although the majority of MMP species are increased in HF, the abundance of MMP-1 is significantly reduced in HF patients.[2] Furthermore, different levels of MMP-2 abundance and activity have been observed in congestive heart failure (CHF) myocardium of ischemic or nonischemic origin. Loss of tissue inhibitor of matrix metalloproteinases (TIMP)–mediated inhibitory control has been suggested as a reason for enhanced MMP activity in patients with dilated cardiomyopathy, in whom a reduction in relative myocardial levels of TIMP-1 and TIMP-3 and/or alterations in MMP/TIMP binding have been reported. This disparity between MMP and TIMP levels favors a persistent MMP activation, enhanced ECM proteolysis, and progressive LV dilation.[2] The role of MMP inhibition in the postinfarction setting was examined in humans in the PREMIER (Prevention of Myocardial Infarction Early Remodeling) trial, in which 253 patients with ST-segment elevation MI and an EF between 15% and 40% were randomized in 1 : 1 ratio to placebo or an MMP inhibitor (PG-116800) with high affinity for MMP-1, -3, -8, -9, -13, and -14. In this small study, MMP inhibition failed to reduce LV remodeling or improve clinical outcomes after MI. The failure to show a benefit may have been related to inadequate dosing of the MMP inhibitor.[3]

ETABLE 23.4

Classes of Matrix Metalloproteinases (MMPs) Identified in Human Myocardium

NAME	NUMBER	SUBSTRATE/FUNCTION	ABUNDANCE/ACTIVITY IN HEART FAILURE
Collagenase			
Interstitial collagenases	MMP-1	Collagens I, II, III, VII and basement membrane components	Decreased
Collagenase 3	MMP-13	Collagens I, II, III	Increased
Neutrophil collagenase	MMP-8	Collagens I, II, III and basement membrane components	
Gelatinase			
Gelatinase A	MMP-2	Gelatins, collagens, I, IV, V, VII and basement membrane components	Increased/Unchanged
Gelatinase B	MMP-9	Gelatins, collagens, IV, V, XIV and basement membrane components	Increased
Stromelysin			
Stromelysin 1	MMP-3	Fibronectin, laminin, collagens III, IV, IX and MMP activation	Increased
Membrane-Type MMP			
MT1-MMP	MMP-14	Collagens I, II, III, fibronectin, laminin-1, activates pro-MMP-2 and pro-MMP-13	Increased

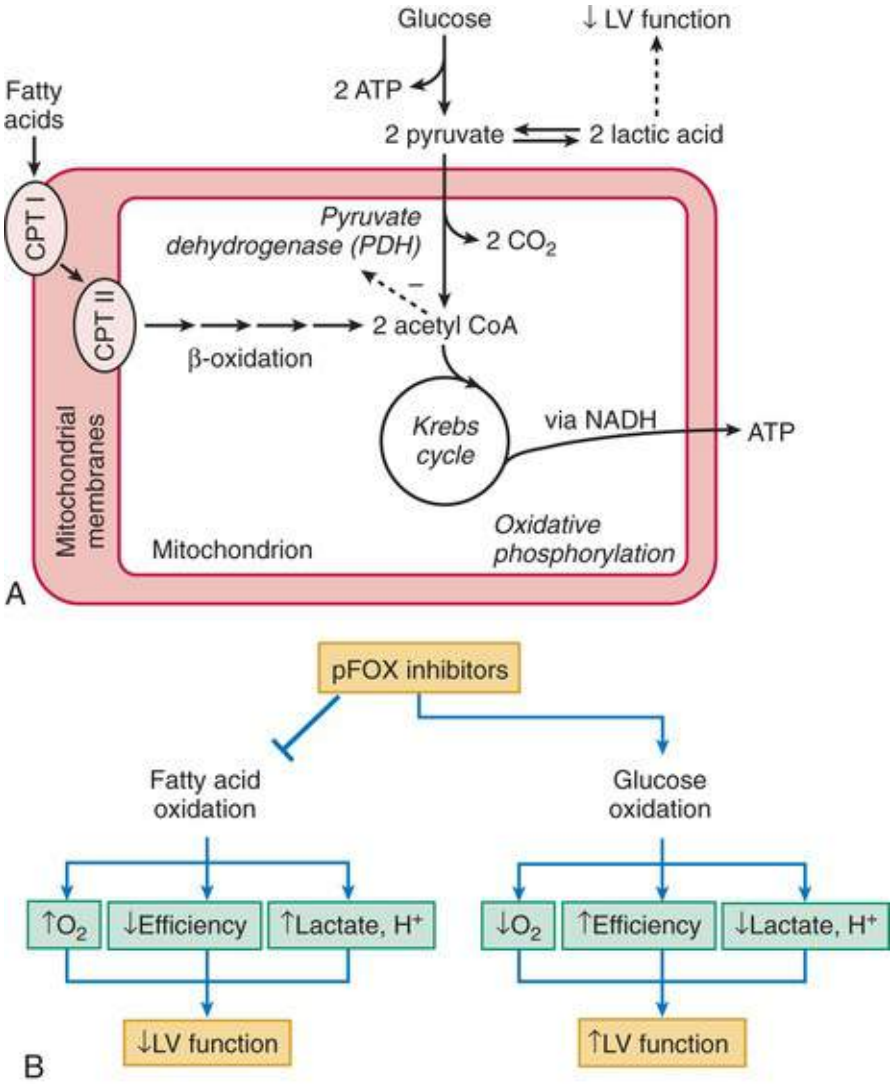
Metabolic Modulation

Optimization of myocardial energy utilization represents another unique approach for the treatment of HF. A number of derangements in myocardial metabolism may partly explain the decrease in high-energy phosphates and phosphocreatine that have been reported in the failing heart. In the normal heart, free fatty acids (FFAs) are the preferred fuel for the heart, producing approximately four times the ATP per mole of substrate utilized compared with glucose. However, FFA oxidation is less efficient than glucose oxidation, requiring 10% to 12% more O_2 consumption to produce equivalent amounts of ATP. Under conditions where O_2 is the limiting substrate, as occurs in the failing heart, glycolysis becomes the more efficient pathway, requiring less O_2 compared with FFA oxidation. Fatty acid oxidation is physiologically regulated at several levels, including the concentration of circulating FFA substrate, at the level of entry into the mitochondrion, and by the activity of several of the mitochondrial matrix enzymes that comprise the beta-oxidation pathway.[1] On the other hand, the rate of glucose oxidation is regulated primarily, although not exclusively, by the rate of FFA oxidation, which inhibits the pyruvate dehydrogenase complex (PDH), the activity of which is rate limiting for glucose oxidation (**eFig. 23.12**). Inhibition of PDH can lead to increased glucose utilization through conversion of pyruvate to lactate, resulting in progressive tissue acidosis, and impaired myocyte contractility (**eFig. 23.12A**). From a theoretical perspective, shifting energy utilization from FFAs to glucose would optimize metabolic efficiency, reverse abnormalities in the cellular milieu, and improve cardiac function (**eFig. 23.12B**). Although the results of the studies on substrate utilization in HF have often yielded conflicting results, the aggregate data support the concept that rates of FFA oxidation are normal or slightly increased in pathologic hypertrophy of early HF, whereas FFA oxidation is decreased during the latter stages of HF, accompanied by an absolute or relative increase in glucose utilization during late stages of HF.[2]



EFIGURE 23.12 Metabolism of free fatty acids and glucose. **A,** Metabolic pathway for glucose metabolism and fatty acid oxidation. **B,** Effects of switching metabolism from fatty acid beta-oxidation to glucose oxidation (under conditions in which oxygen supply is rate limiting) using partial inhibitors of fatty acid oxidation (*pFOX*). (From Dimmeler S, Mann DL, Zeiher AM. Emerging therapies and strategies in the treatment of heart failure. In Bonow RO, Mann DL, Zipes DP, Libby P, editors. Braunwald's Heart Disease: A Textbook of Cardiovascular Medicine. 9th ed. Philadelphia: Saunders; 2012, pp 627-43.)

The prototype partial inhibitors of fatty acid oxidation (pFOX), etomoxir, oxfenicine, and perhexiline, act by inhibiting carnitine palmityltransferase I (CPT I), the gatekeeper of FFA entry to the mitochondrion (**eFig. 23.12A**). These agents shift energy utilization from FFAs to glucose by decreasing oxidation of FFAs. However, since there is no apparent feedback from CPT I activity to sarcolemmal FFA import, CPT I inhibitors can lead to accumulation of unmetabolized lipids in cardiac myocytes, which may lead to lipotoxicity-induced cardiac myocyte cell death. *Etomoxir* is an oxirane carboxylic acid derivative that indirectly promotes increased glucose oxidation through inhibition of CPT I. In an open-label, uncontrolled trial conducted in 10 patients with NYHA Class II-III HF, treatment with etomoxir for 3 months was associated with a significant improvement in left ventricular ejection fraction (LVEF), cardiac output at peak exercise, and clinical status.[3] Subsequent phase II studies with etomoxir were halted because the compound did not have the expected efficacy in the treatment of HF (MediGene 2002 Annual Report, March 26, 2003). Although *oxfenicine* was shown to be beneficial in the canine rapid-pacing model of HF, in other animal models oxfenicine therapy resulted in a dose-related increase in cardiac mass, as well as an increase in liver and kidney weights. *Perhexiline* is currently in use clinically as an antianginal agent. Although there were early reports of hepatotoxicity with this agent, hepatotoxicity occurred in patients with a genetic variant of a cytochrome P-450 enzyme (slow hydroxylation), which

resulted in drug accumulation, as well as accumulation of phospholipids in the liver and nerves. The risk of toxic effects is virtually eliminated by maintaining plasma concentrations between 150 and 600 ng/mL, at which levels the drug still remains effective.[3] Perhexiline has shown promise as adjunctive therapy for HF in a small, short-term, randomized double-blind clinical trial in patients with ischemic and nonischemic cardiomyopathy. In this study, 8 weeks of treatment with perhexiline resulted in an increase in the combined primary endpoint of peak oxygen uptake and LVEF, and an improvement in quality of life (Minnesota Living with Questionnaire). Importantly, maximum O_2 uptake was increased significantly in both the ischemic and the nonischemic group, suggesting that the benefit of perhexiline was not entirely anti-ischemic.[4] Although there remains some optimism that CPT I inhibitors can be used as adjunctive therapy in HF, other pFOX inhibitors may have less side effects.

The pFOX inhibitors trimetazidine and ranolazine were also originally developed as antianginal agents. *Trimetazidine* is a piperazine compound that has been widely used outside the United States as an antianginal agent. Trimetazidine has no discernible vasodilator properties at rest or during dynamic exercise and has a very favorable side effect profile. The exact mechanism of action of trimetazidine is not known, but it appears to work, at least in part, through inhibition of long-chain 3-ketoacyl coenzyme A thiolase, a crucial enzyme in the terminal steps of mitochondrial beta-oxidation. Clinical trials have shown improvements in ejection performance, reverse cardiac remodeling, and NYHA functional class with trimetazidine.[3] Trimetazidine has been evaluated in a number of small clinical trials in patients with both ischemic and nonischemic cardiomyopathy.[1,3] Two months of treatment with trimetazidine resulted in significant improvement in LVEF at rest and enhanced LV wall motion during a dobutamine stress test compared with placebo in NYHA Class II and III HF patients.[1] In two recent small clinical studies, trimetazidine was shown to improve systolic LV function in patients with diabetes and ischemic cardiomyopathy compared with placebo.[1,5] In contrast, another study, which assessed the effects of trimetazidine in patients with HF who were diabetic, demonstrated no significant effect on exercise capacity and only minor effects on LV systolic function.[3] In a study that specifically enrolled elderly patients with CAD and LVEF less than 50%, the group that received 6 months of trimetazidine on top of standard therapy showed a significantly greater improvement in LVEF (7%), as well as smaller LV end-diastolic and end-systolic dimensions. In addition, the trimetazidine group had improved NYHA functional class and quality-of-life scores (Minnesota Living with Questionnaire). These findings have been confirmed in recent larger trials with longer-term follow-up (18 to 24 months), which have also shown improvements in LVEF, reduction in LV volumes, and improvement in NYHA functional class in patients with ischemic cardiomyopathy (LVEF <50%).[3] Given the antianginal effects of trimetazidine, it is not surprising that this agent led to improvements in LV function and NYHA functional class in patients with ischemic cardiomyopathy. However, a recent study with trimetazidine also included patients with nonischemic cardiomyopathy and showed similar increases in LVEF, reductions in LV end-systolic volume, and similar trends for improved quality of life and exercise capacity in both the ischemic and the nonischemic group.[6] Thus it appears that trimetazidine has both functional and physiologic benefits regardless of the HF etiology.

Ranolazine (Ranexa) is a novel anti-ischemic drug that prolongs the QT interval and is the first FDA-approved pFOX inhibitor for the treatment of angina. The principal mechanism of action for this drug as an antianginal remains controversial, although recent studies suggest that the antianginal effects of ranolazine may be related to decreased sodium entry into cells by inhibiting the rapid component of the delayed rectifier K^+ current [I_{kr}]. Ranolazine also increases the activity of pyruvate decarboxylase, a key regulator of glucose metabolism, most likely due to loss of inhibition of the end products of the beta-oxidation (NADH, acetyl-CoA). Although no clinical trials have yet been reported using ranolazine in

patients with dilated cardiomyopathy, there are studies with ranolazine in patients with a preserved ejection fraction (**see Chapter 26**).

Glucagon-Like Peptide 1

Sustained activation of the sympathetic nervous system (**Chapter 22**) in HF leads to increased lipolysis, with a subsequent rise in levels of circulating fatty acids with a resultant insulin resistance. Although the exact role of insulin resistance in HF is not known, studies with the incretin hormone glucagon-like peptide-1 (GLP-1), which increases postprandial insulin secretion and improves insulin sensitivity, have demonstrated improvements in contractility in both experimental and human HF. In a study of 12 patients with NYHA functional class III/IV HF, a continuous infusion of GLP-1 for 12 weeks improved LVEF (21% to 27%) and functional capacity, even in non-diabetic patients.[7] Similarly, in a study of 10 patients with acute myocardial infarction and LV systolic dysfunction (LVEF <40%), a 72-hour continuous infusion of GLP-1 was associated with a significant improvement in LVEF, as well as global and regional wall motion.[8] In contrast to these early encouraging findings, there was no improvement in cardiac index, LV ejection fraction or brain natriuretic peptides levels in a small study of 20 non-diabetic patients with NYHA class II-III HF, following a 48-hour infusion of GLP-1. Moreover, there was a small but potentially concerning rise in heart rate and diastolic blood pressure in this study.[9] Exenatide, a GLP-1 agonist, increased both heart rate and cardiac index in male NYHA Functional Class III/IV patients (n = 20) with type 2 diabetes, along with a decrease in pulmonary capillary wedge pressure in a crossover study with intravenous infusions for 2 consecutive days with either exenatide (0.12 pmol/kg/min) or placebo for 6 hours, followed by a washout period for 18 hours. There were no observed adverse effects in this short-term study.[10] A recent randomized placebo-controlled phase II study with the GLP-1 agonist liraglutide, in 300 patients with a reduced ejection fraction, showed that compared with placebo, liraglutide had no significant (P = 0.31) effect on the primary endpoint, which was a global rank score of time to death, time to rehospitalization for HF, and time-averaged proportional change in N-terminal pro-B-type natriuretic peptide level from baseline to 180 days.[11] Moreover, a prespecified subgroup analyses in patients with diabetes revealed no significant between-group differences. In the more recent LEADER trial in patients with type 2 diabetes and increased cardiovascular risk, liraglutide exhibited a significant reduction in time to first major cardiovascular event.[12]

Micronutrient Supplementation

The heart requires a continuous supply of energy-providing substrates and amino acids in order to maintain normal structure and function. In HF, alterations in substrate metabolism, the tricarboxylic acid cycle, or oxidative phosphorylation may contribute to contractile dysfunction. For example, deficiencies in coenzyme Q10 (CoQ10), L-carnitine, amino acids, thiamine, and other B vitamins have been documented in the failing heart, raising the interesting possibility that micronutrient supplementation might improve the abnormal energetic milieu of the failing heart. Although a number of clinical supplementation trials of key micronutrients involved in cardiac metabolism, including CoQ10, L-carnitine, thiamine, and taurine, have yielded promising results in patients with HF, none has yielded conclusive results. Because of the absence of definitive clinical trial data in this area, the ACC/AHA practice guidelines (**see Chapter 25**) do not recommend the use of nutritional supplements as a treatment for HF in patients with current or prior HF symptoms.

Diagnosis and Management of Acute Heart Failure

G. Michael Felker, John R. Teerlink

Acute heart failure (AHF) is among the most common causes for hospitalization in patients older than 65 years in the developed world. In the United States alone, 4 million patients are hospitalized each year with a primary or secondary diagnosis of heart failure (HF), and AHF contributes to more than 7 million hospital days annually.[1] AHF has a similar burden in Europe and is increasingly recognized as a as a global public health problem.[2] The prevalence of HF is projected to continue to increase over time because of a convergence of several epidemiologic trends: (1) the aging of the population, given the age-related incidence of HF; (2) the reduction in hypertension-related mortality and the greatly improved survival after myocardial infarction (MI), resulting in more patients living with chronic left ventricular (LV) dysfunction (**see Chapter 21**); and (3) the availability of effective therapy for prevention of sudden death (**see Chapters 27 and 42**). Previously considered part of the natural history of chronic HF, AHF is increasingly recognized as a distinct disorder with unique epidemiology, pathophysiology, treatments, and outcomes.

Epidemiology

Nomenclature and Definition

A variety of overlapping terms have been used to characterize AHF in the literature, including “acute heart failure syndrome” (AHFS), “acute decompensated heart failure” (ADHF), “acute decompensation of chronic heart failure” (ADCHF), and “hospitalization for heart failure” (HHF). Although none of these is universally accepted, we use the terminology “acute heart failure” in this chapter. Broadly speaking, AHF can be defined as the new onset or recurrence of symptoms and signs of HF requiring urgent or emergent therapy and resulting in unscheduled care or hospitalization. Although the word “acute” in the nomenclature suggests a sudden onset of symptoms, many patients may have a more subacute course, with gradual worsening of symptoms that ultimately reach a level of severity sufficient to seek unscheduled medical care.

Scope of the Problem

AHF represents a major burden in the developed world. In the United States, HF is the primary diagnosis for more than 1 million hospitalized patients annually, and a secondary diagnosis for an additional 3 million hospitalizations.[1] Similar numbers of hospitalizations are reported in Europe.[2] The direct and indirect costs associated with HF approach 40 billion U.S. dollars per year in the United States, and the majority of these expenditures are related to the costs of hospitalizations.[3,4] As noted, the overall prevalence of chronic heart failure continues to grow. However, recent data suggest that the age-adjusted rate of hospitalization for HF has begun to decrease. In a study using U.S. Medicare claims data from 1998 to 2008, age-related incidence of hospitalization for HF declined for all race and gender groups.[5] Other data suggest that while HF as a primary diagnosis may have decreased, the incidence of HF as a

secondary diagnosis has remained stable[6] (**eFig. 24.1**). Similar data have been published in several countries in Europe.[7] To what extent these changes are related to more effective treatments of chronic HF, or alternatively, changes in care to create alternative care pathways for avoiding hospitalization, is unknown. Changes in medical care (especially in the United States) have led to increased efforts to manage milder forms of HF decompensation without hospitalization, utilizing outpatient diuretic clinics and observation units, although available data suggest that even these milder forms of decompensation are still associated with adverse prognosis.[8,9] Despite these potentially encouraging trends, it appears likely that HF hospitalization will be a major clinical and economic problem for health care systems for the foreseeable future. A major development in the understanding of the epidemiology, clinical characteristics, and outcomes of patients with AHF has been the development of large, relatively unselected registries of AHF, which have provided a "real world" perspective on the epidemiology and outcomes of this clinical syndrome worldwide (**Table 24.1**).

EFIGURE 24.1 Rates of hospitalizations as the primary and secondary hospitalization for heart failure (HF) in the United States. (From Blecker S et al. Heart failure–associated hospitalizations in the United States. J Am Coll Cardiol 2013;61:1259-67.)

Preserved Versus Reduced Ejection Fraction

As with chronic HF, recent decades have seen increasing recognition of the epidemiologic importance of HF with normal or near-normal systolic function, “heart failure with preserved ejection fraction” (HFpEF). On the basis of available registry data, 40% to 50% of patients hospitalized have HFpEF. Important epidemiologic differences exist between “heart failure with reduced ejection fraction” (HFrEF) and HFpEF (**see Chapter 21**). The in-hospital mortality of patients with HFpEF appears to be lower compared with that of patients with HFrEF, but postdischarge rehospitalization rates are similarly high for both groups. Patients with AHF and HFpEF are more likely to be rehospitalized for and to die from noncardiovascular causes than patients with AHF and reduced EF, reflecting their more advanced age and greater burden of comorbidity. More recently, the concept of “midrange ejection fraction” (generally considered as EF of 40% to 49%) has been proposed as an additional refinement of the standard HFrEF versus HFpEF dichotomy, but specific data on AHF outcomes in this group are lacking.[10]

Age, Race, and Gender

There are significant differences in the epidemiology of AHF based on age, race, and gender. AHF disproportionally affects elderly people, with a mean age of 75 years in large registries. AHF affects men and women almost equally, but there are important differences by gender. In the ADHERE Registry, women admitted for AHF were older than men (74 versus 70 years) and more frequently had preserved systolic function (51% versus 28%).[11] Differences in ethnic groups have been studied most extensively in the United States and have focused primarily on differences between African American and white

patients. In the Organized Program to Initiate Lifesaving Treatment in Hospitalized Patients with Heart Failure (OPTIMIZE-HF) Registry, African American patients admitted with AHF were younger (64 versus 75 years) and more likely to have LV systolic dysfunction (57% versus 51%) with a lower mean EF (35% versus 40%), hypertensive etiology for HF (39% versus 19%), renal dysfunction, and diabetes compared with the non–African American group.[12] Lower estimated mortality rates have been reported for African American than for non–African American patients, but when adjustments are made for these differences in comorbidities and age, mortality rates are similar.

Comorbidities

Concomitant diseases are common in patients admitted with AHF, reflecting the elderly population. These comorbidities not only represent diseases that are risk factors for the development of HF, but also can complicate diagnosis and management. Hypertension is the most prevalent of the concurrent conditions, present in approximately two thirds of AHF patients (**see Chapters 46 and 47**), whereas coronary artery disease (CAD) is present in about half and dyslipidemia in more than one third[13,14] (**Chapter 61**). Other conditions resulting from the vascular injury produced by these diseases, such as cerebrovascular accident (stroke), peripheral vascular disease, and chronic renal insufficiency, are also common in patients with AHF. Diabetes mellitus is present in more than 40% of U.S. patients with AHF, most likely related to increasing incidence of obesity, and ranges from 27% to 38% in Europe. Chronic obstructive pulmonary disease (COPD) is also present in approximately 25% to 30%, which confounds the presenting symptoms of dyspnea and is associated with lower utilization of evidence-based therapy. Atrial fibrillation (AF) appears to be more common in Europe (up to 42%, versus 31% in U.S. patients with AHF) and can both precipitate AHF and complicate its management.

Global Differences in AHF

Although most data continue to emerge from North America and Europe, AHF is increasingly recognized as a global issue, and important differences between regions of the world have emerged in terms of epidemiology, therapy, and outcomes.[15] Although there are various country- or region-specific registries (**see Table 24.1**), to date most available data highlighting these differences has come from large global outcome trials. Although these studies can provide important insight into regional differences, they do suffer from inherent limitations and may not be truly representative of the general population because of selection bias. The growth of less selected registries in other areas of the world will provide new insights into global burden of disease.

Pathophysiology

AHF is not a single disease but a heterogeneous clinical syndrome. As such, pathophysiology of AHF is complex and highly variable, with many overlapping pathogenic mechanisms that may be operative to a greater or a lesser degree. This fundamental heterogeneity complicates the attempt to create a simple and unified conceptual model. One potentially useful framework for understanding the pathophysiology of AHF is to consider it as the result of the interaction of underlying substrate, initiating mechanisms or triggers, and amplifying mechanisms, all of which contribute to a common set of clinical signs and symptoms (primarily related to congestion, end-organ dysfunction, or both) that define AHF (**Fig. 24.1**). In this context, *substrate* refers to underlying cardiac structure and function. The underlying substrate may be

one of normal ventricular function, for example, patients without a prior history of HF who develop AHF because of sudden changes in ventricular function from an acute insult such as MI or acute myocarditis (**see Chapter 79**). Alternatively, some patients may have no prior history of HF but abnormal substrate (e.g., stage B patients with asymptomatic LV dysfunction) with a first presentation of HF (de novo heart failure). Also, most patients with AHF have a substrate of chronic compensated HF, who then decompensate and present with AHF.

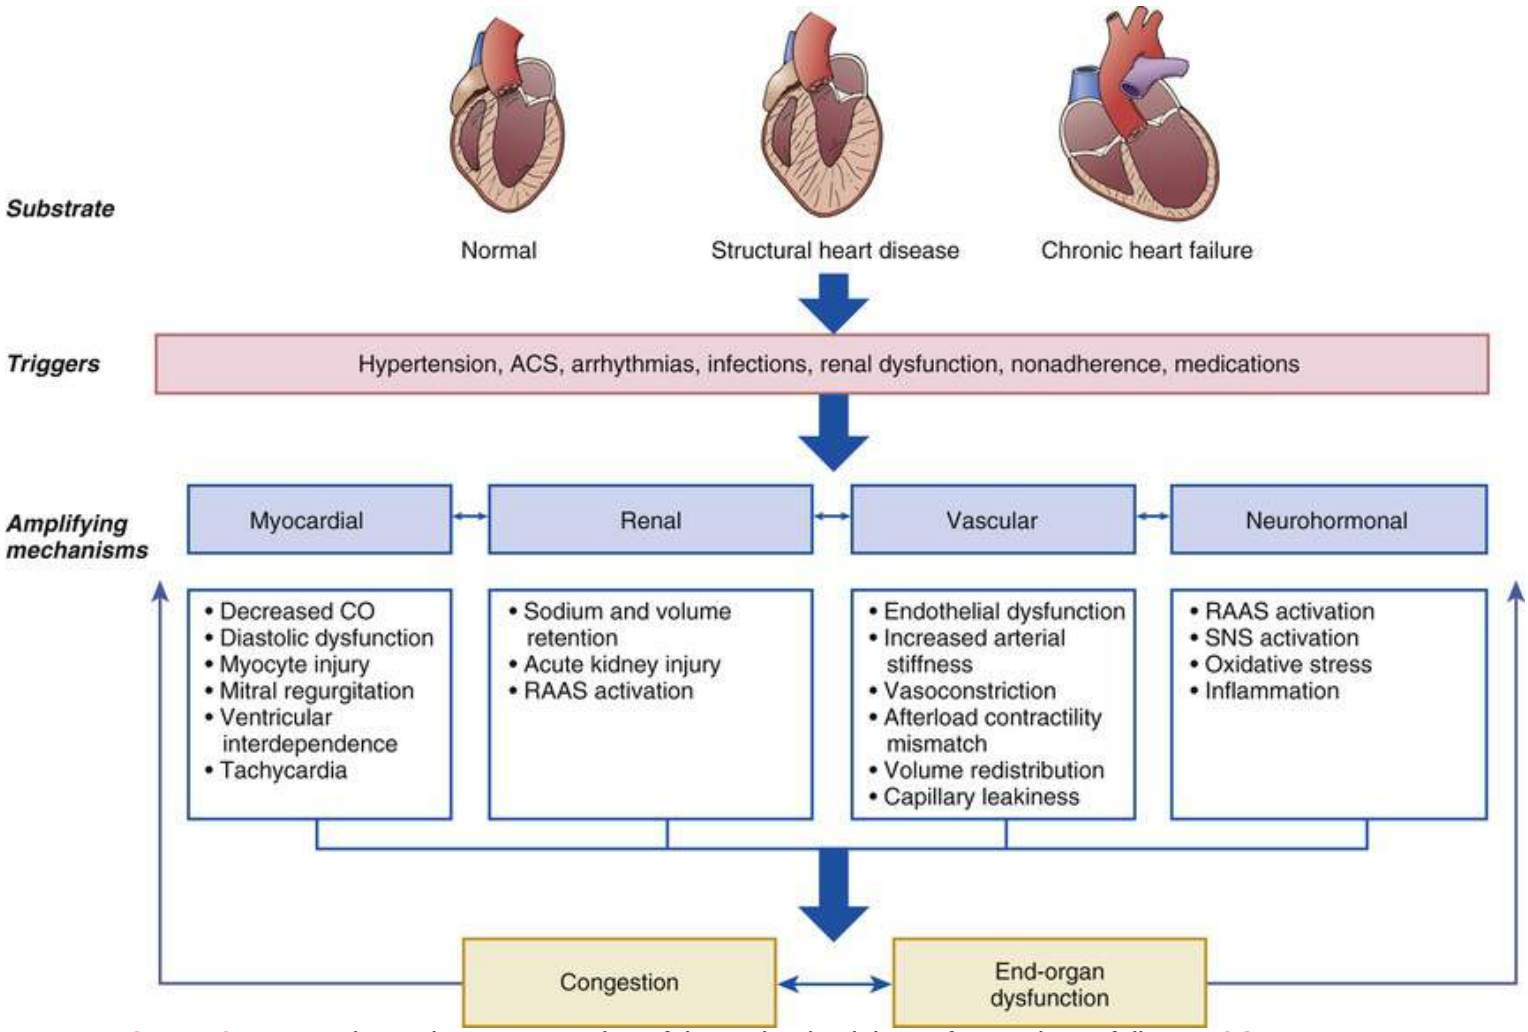

FIGURE 24.1 A schematic representation of the pathophysiology of acute heart failure. ACS, Acute coronary syndrome; CO, cardiac output; RAAS, renin-angiotensin-aldosterone system; SNS, sympathetic nervous system.

Initiating mechanisms vary according to, and interact with, the underlying substrate and may be cardiac or extracardiac. For patients with normal substrate (normal myocardium), a substantial insult to cardiac performance (e.g., acute myocarditis) is required to lead to the clinical presentation of AHF. For patients with abnormal substrate at baseline (asymptomatic LV dysfunction), smaller perturbations (e.g., poorly controlled hypertension, AF, or ischemia) may precipitate an AHF episode. For patients with a substrate of compensated or stable chronic HF, medical or dietary nonadherence, agents such as nonsteroidal anti-inflammatory drugs (NSAIDs) or thiazolidinediones, and infectious processes are all common triggers for decompensation.

Regardless of the substrate or initiating factors, a variety of “amplifying mechanisms” perpetuate and contribute to the episode of decompensation. These include neurohormonal and inflammatory activation, ongoing myocardial injury with progressive myocardial dysfunction, worsening renal function, and

interactions with the peripheral vasculature, all of which may contribute to the propagation and worsening of the AHF episode.

Congestion

Systemic or pulmonary congestion, often caused by a high ventricular diastolic pressure, dominates the clinical presentation of most patients hospitalized for AHF. In this sense, congestion can be seen as a final common pathway producing clinical symptoms leading to hospitalization. A general view of AHF pathophysiology is that gradual increases in intravascular volume lead to symptoms of congestion and clinical presentation, and normalization of volume status with diuretic therapy results in restoration of homeostasis. Whereas this mechanism may be operative in some patients, this model is a vast oversimplification. Although some data suggest that increases in body weight often precede decompensation and hospitalization for HF, careful studies using implantable hemodynamic monitors suggest that increases in invasively measured LV filling pressures can occur without substantial changes in body weight.[16] These observations have led to increasing interest in the concept of *volume redistribution* and the dynamic role of the vasculature as a contributing mechanism to decompensation in HF (see later, Vascular Mechanisms).

One potentially important concept is the distinction between "clinical congestion" and "hemodynamic congestion." Although patients present with signs and symptoms of systemic congestion such as dyspnea, rales, elevated jugular venous pressure, and edema, this state is often preceded by *hemodynamic congestion*, defined as high ventricular diastolic pressures without overt clinical signs. Similarly, clinical congestion may resolve with treatment but hemodynamic congestion may persist, leading to a high risk of rehospitalization. It has been postulated that hemodynamic congestion may contribute to the progression of HF because it may result in increased wall stress as well as in renin-angiotensin-aldosterone system (RAAS) and sympathetic nervous system (SNS) activation. This may trigger a variety of molecular responses in the myocardium, including myocyte loss and increased fibrosis. The natriuretic peptides (**see Chapter 23**), which are the intrinsic counterregulatory hormone in HF, may have abnormal processing that leads to diminished biologic activity in patients with advanced HF.[17] In addition, elevated diastolic filling pressures may decrease coronary perfusion pressure, resulting in subendocardial ischemia that may further exacerbate cardiac dysfunction. Increased LV filling pressures can also lead to acute changes in ventricular architecture (more spherical shape), contributing to worsening mitral regurgitation.

These mechanisms also play an important role in *pathologic remodeling of the ventricle*, a chronic process that may be accelerated by each episode of decompensation. Consistent with this paradigm is the well-established clinical observation that each hospitalization for AHF heralds a substantial worsening of the long-term prognosis, an effect that appears additive with recurrent hospitalizations.[18] Data from studies with implantable hemodynamic monitors have confirmed that chronically elevated filling pressures (i.e., hemodynamic congestion) are associated with increased risk of future events.[19] With the recognition of congestion as the most common aspect of AHF presentation, there has been a formal attempt to better assess and quantitate congestion in HF.[20]

Myocardial Function

Although a variety of extracardiac factors play important roles in AHF, impairments of cardiac function (systolic, diastolic, or both) remain central to our understanding of this disorder (**see Chapter 22**). Changes in systolic function and decreased arterial filling can initiate a cascade of effects that are

adaptive in the short term but maladaptive when elevated chronically, including stimulation of the SNS and RAAS. Activation of these neurohormonal axes leads to vasoconstriction, sodium and water retention, volume redistribution from other vascular beds, increases in diastolic filling pressures, and clinical symptoms. In patients with underlying ischemic heart disease, initial defects in systolic function may initiate a vicious cycle of decreasing coronary perfusion, increased myocardial wall stress, and progressively worsening cardiac performance. Increased LV filling pressures and changes in LV geometry can worsen functional mitral regurgitation, further decreasing cardiac output.

Although decreases in systolic function can clearly play a role in the pathophysiology of AHF, epidemiology data previously summarized show that approximately half of patients with AHF have relatively preserved systolic function. Importantly, abnormalities in diastolic function are present in HF patients regardless of EF. The impairment of the diastolic phase may be related to passive stiffness, abnormal active relaxation of the left ventricle, or both. Hypertension, tachycardia, and myocardial ischemia (even in the absence of CAD) can further impair diastolic filling. All these mechanisms contribute to higher LV end-diastolic pressures, which are reflected back to the pulmonary capillary circulation. Diastolic dysfunction alone may be insufficient to lead to AHF, but it serves as the substrate on which other precipitating factors (e.g., AF, CAD, hypertension) lead to decompensation. One underappreciated aspect of myocardial function in AHF relates to the interdependence of the left and right ventricles. Because of the constraints of the pericardial space, distention of either ventricle from increased filling pressures can result in direct impingement of diastolic filling of the other ventricle. This may be particularly operative in clinical scenarios leading to abrupt failure of the right ventricle (e.g., pulmonary embolism or right ventricular infarction), resulting in diminished filling of the left ventricle and arterial hypotension.

The availability of increasingly sensitive assays for circulating cardiac *troponins* has substantially advanced our understanding of the role of myocardial injury in the pathophysiology of HF. Data from both registries and clinical trial populations indicate that circulating cardiac troponins are elevated in a large proportion of patients with AHF, even in the absence of clinically overt myocardial ischemia.[21,22] In a representative analysis of data from the RELAX-AHF study using a highly sensitive assay, 90% of patients enrolled had a troponin T level above the 99th percentile upper reference limit (URL) at baseline, and troponin elevation was associated with postdischarge outcomes to 180 days[23] (**Fig. 24.2**).

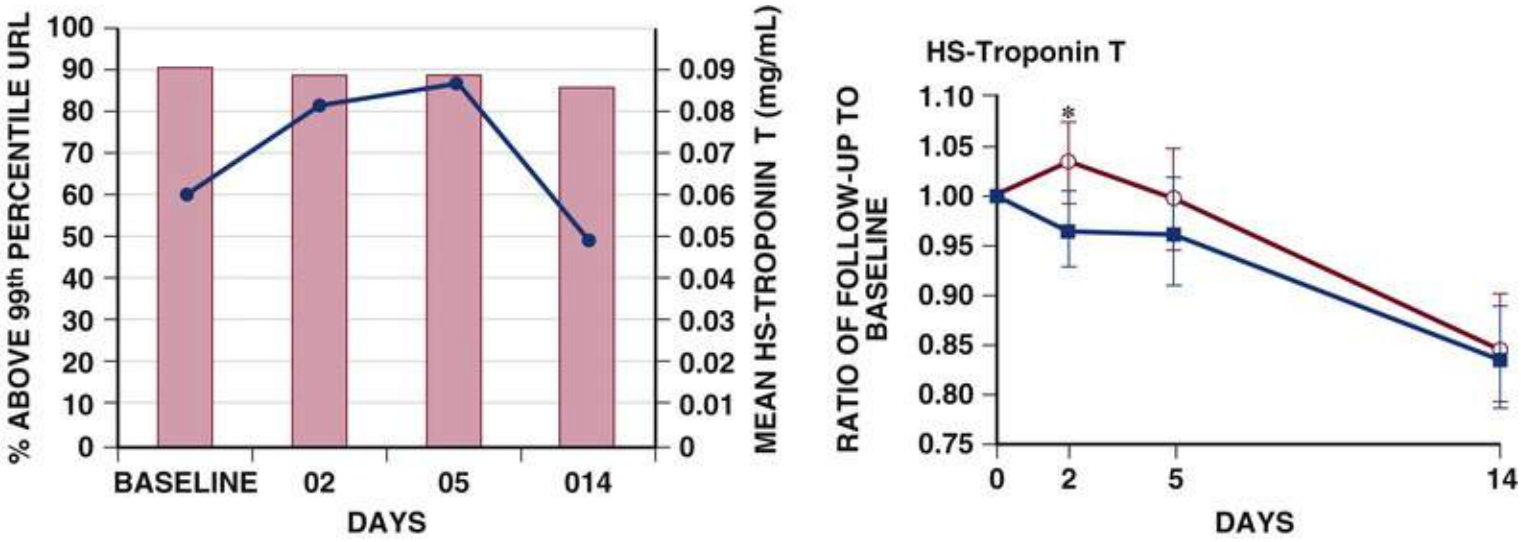

FIGURE 24.2 Incidence of elevated (above the 99th percentile upper reference limit [URL]) high-sensitivity (HS) troponin T in the RELAX-AHF study and effect of serelaxin therapy on troponin levels. (From Felker GM et al. Serial high sensitivity cardiac troponin T measurement in acute heart failure: insights from the RELAX-AHF study. Eur J Heart Fail 2015;17:1262-70; and Metra M et al. Effect of serelaxin on cardiac, renal, and hepatic biomarkers in the Relaxin in Acute Heart Failure (RELAX-AHF) Development Program: correlation with outcomes. J Am Coll Cardiol 2013;61:196-206.)

The precise mechanisms mediating myocardial injury in AHF are poorly defined, but increased myocardial wall stress, decreased coronary perfusion pressure, increased myocardial oxygen (O_2) demand, endothelial dysfunction, activation of the neurohormonal and inflammatory pathways, platelet activation, and altered calcium handling may all contribute to myocyte injury, even in the absence of epicardial CAD.[21] Specific therapeutic interventions that may increase myocardial O_2 demand (e.g., positive inotropic agents) or decrease coronary artery perfusion pressure (e.g., some vasodilators) may exacerbate myocardial injury and further contribute to the cycle of decompensation. Whether avoidance of myocardial injury is a specific target for therapy in AHF remains a subject of active investigation. Data from the RELAX-AHF study of serelaxin suggest that avoidance of myocardial injury (as demonstrated by less troponin elevation) may be an important mechanism of action underlying the observed treatment benefit[24] (**Fig. 24.2**).

Renal Mechanisms

The kidney plays two fundamental roles relative to the pathophysiology of HF: it modulates loading conditions of the heart by controlling intravascular volume and is responsible for neurohormonal outputs (i.e., the RAAS system). Abnormalities of renal function are extremely common in patients with AHF and may be underestimated by creatinine alone—64% of patients in the ADHERE Registry had a glomerular filtration rate (GFR) less than 60 mL/min/1.73 m^2.[25] Baseline measures of renal function are well-established risk factors for poor outcomes in AHF (see later, Risk Stratification). Our understanding of the implications of changes in measures of renal function during HF decompensation and therapy has continued to evolve[26] (**see Chapter 98**).

The term *cardiorenal syndrome* has been increasingly used to describe pathologic interactions between the cardiac and renal axes in the setting of HF. Although specific definitions and nomenclature have varied, in the context of AHF the cardiorenal syndrome describes the clinical situation of worsening measures of renal function in the setting of persistent congestion. This clinical scenario has been associated with poor outcomes in a variety of observational studies. Multiple studies have investigated the pathophysiology and risk factors for this phenomenon, which is related to an intricate interplay of

patient characteristics (age), comorbidities (baseline renal function as assessed by GFR, diabetes mellitus, hypertension), neurohormonal activation (especially of RAAS and SNS), and hemodynamic factors (central venous congestion, and less frequently arterial underfilling with renal hypoperfusion), as well as other factors such as activation of inflammatory cascades and oxidative stress.[27] Although often assumed to be related to low cardiac output and renal blood flow, careful hemodynamic studies have repeatedly confirmed that the strongest predictor of worsening renal function (WRF) in HF patients relates to elevated central venous pressure**,** which is reflected back to the renal veins and leads directly to changes in GFR.[28] Importantly, recent data have emphasized the importance of evaluating changes in renal function in the context of the overall clinical picture. WRF in the setting of ongoing clinical improvement is generally reflective of successful decongestion and does not portend a poor prognosis[29] (**Fig. 24.3**). Although there has been substantial interest in the utility of newer biomarkers, such as neutrophil gelatinase-associated lipocalin (NGAL), to identify episodes of frank kidney injury before changes in markers of renal function, the clinical utility of these markers remains uncertain. A detailed classification system for understanding the interplay between cardiac performance and renal function provides a framework for understanding the complex pathophysiology underlying the cardiorenal syndrome.[27]

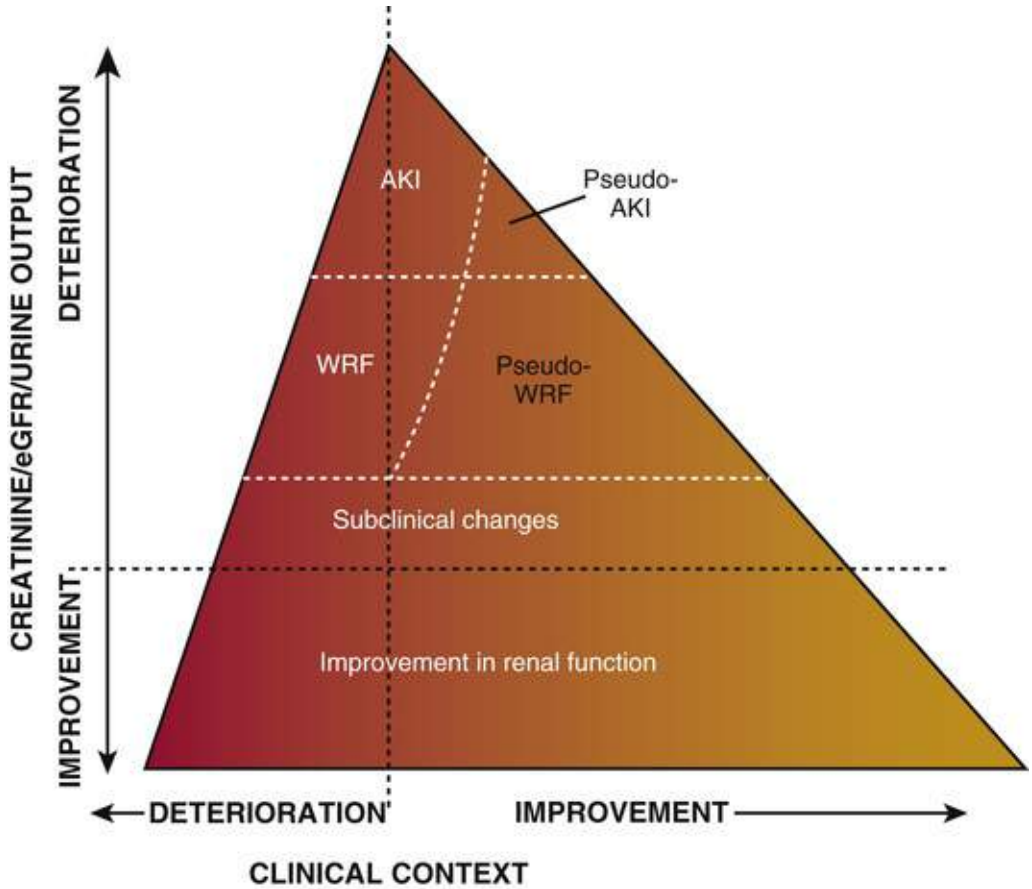

FIGURE 24.3 Schematic of changes in renal function within different clinical contexts in acute heart failure. *AKI,* Acute kidney injury; *eGFR,* estimated glomerular filtration rate; *WRF,* worsening renal failure.
(From Damman K, Testani JM. The kidney in heart failure: an update. Eur Heart J 2015;36:1437-44.)

Vascular Mechanisms

Although abnormalities in cardiac function are central to the pathogenesis of AHF, there is increasing appreciation for the importance of the peripheral vasculature in this disorder. Abnormalities of

endothelial function related to nitric oxide (NO)–dependent regulation of vascular tone are well described in HF.[30] Arterial stiffness, which is related to but distinct from blood pressure, increases cardiac loading conditions and is associated with incident HF and worse outcomes. Peripheral vasoconstriction in the setting of AHF redistributes blood centrally, increasing pulmonary venous congestion and edema. As noted, elevated central venous pressure reduces renal function, resulting in greater fluid retention that further elevates venous pressures. Peripheral arterial vasoconstriction increases afterload, LV filling pressures, and postcapillary pulmonary venous pressures, resulting in worsening of pulmonary edema and dyspnea. This increased afterload causes greater ventricular wall stress and increased myocardial ischemia and cardiac arrhythmias. Abnormal vascular compliance also predisposes these patients to marked blood pressure lability with relatively minor changes in intravascular volume, causing precipitous increases in afterload and ultimately in LV filling pressures resulting in pulmonary congestion. The effects of this vascular abnormality are amplified by LV diastolic dysfunction.

The clinical observation that vasodilator treatment can improve dyspnea in many acutely hypertensive patients without significant diuresis has led to the concept that afterload-contractility mismatch can lead to increased diastolic filling pressures in the setting of minimal total body volume changes. Similarly, the recognition of the large capacitance of the venous (in particular the splanchnic circulation) system has led to increased interest in volume shifts from the "venous reservoir" into the effective circulatory volume as a potentially important and underrecognized mechanism in AHF.[31] These shifts can be mediated by SNS activation, and this has been proposed as a potential explanation for the apparent disconnect between changes in filling pressures and changes in body weight during chronic hemodynamic monitoring. Whether fluid shifts involving this venous reservoir can be modulated by specific therapies is a subject of active investigation.

Neurohormonal and Inflammatory Mechanisms

Although elevations of circulating neurohormones are well documented in patients with AHF, the precise role of neurohormonal activation in the pathophysiology of AHF remains to be fully delineated. Increased plasma concentrations of norepinephrine, plasma renin activity, aldosterone, and endothelin (ET)-1 have all been reported in patients with AHF—all these axes are associated with vasoconstriction and volume retention, which could contribute to myocardial ischemia and congestion, thus exacerbating cardiac decompensation. Inflammatory activation and oxidative stress may also play a role. Proinflammatory cytokines such as tumor necrosis factor-alpha (TNF-α) and interleukin (IL)-6 are elevated in patients with AHF and have direct negative inotropic effects on the myocardium as well as increasing capillary permeability and inducing endothelial dysfunction.[32,33] In addition to direct effects, this activation stimulates the release of other factors, such as the potent procoagulant tissue factor and ET-1, which can lead to further myocardial suppression, disruption of the pulmonary alveolar-capillary barrier, and increased platelet aggregation and coagulation (potentially worsening ischemia). (**See also Chapter 23**.)

Evaluation of the Patient With Acute Heart Failure

The initial evaluation of the patient with acute HF focuses on the following critical aspects: (1) establishing a definitive diagnosis of AHF as rapidly and efficiently as possible; (2) emergent treatment for potentially life-threatening conditions (e.g., shock, respiratory failure); (3) identifying and addressing any relevant clinical triggers or other conditions requiring specific treatment (e.g., ACS, acute pulmonary

embolism); (4) risk stratification in order to triage patient to appropriate level of care (e.g., intensive care unit, telemetry unit, observation unit); and (5) defining the clinical profile of the patient (based on blood pressure, volume status, and renal function) in order to rapidly implement the most appropriate therapy. **Fig. 24.4** presents a proposed flow diagram for the initial evaluation of patients with suspected AHF from the most recent HF guidelines from the European Society of Cardiology (ESC).[10]

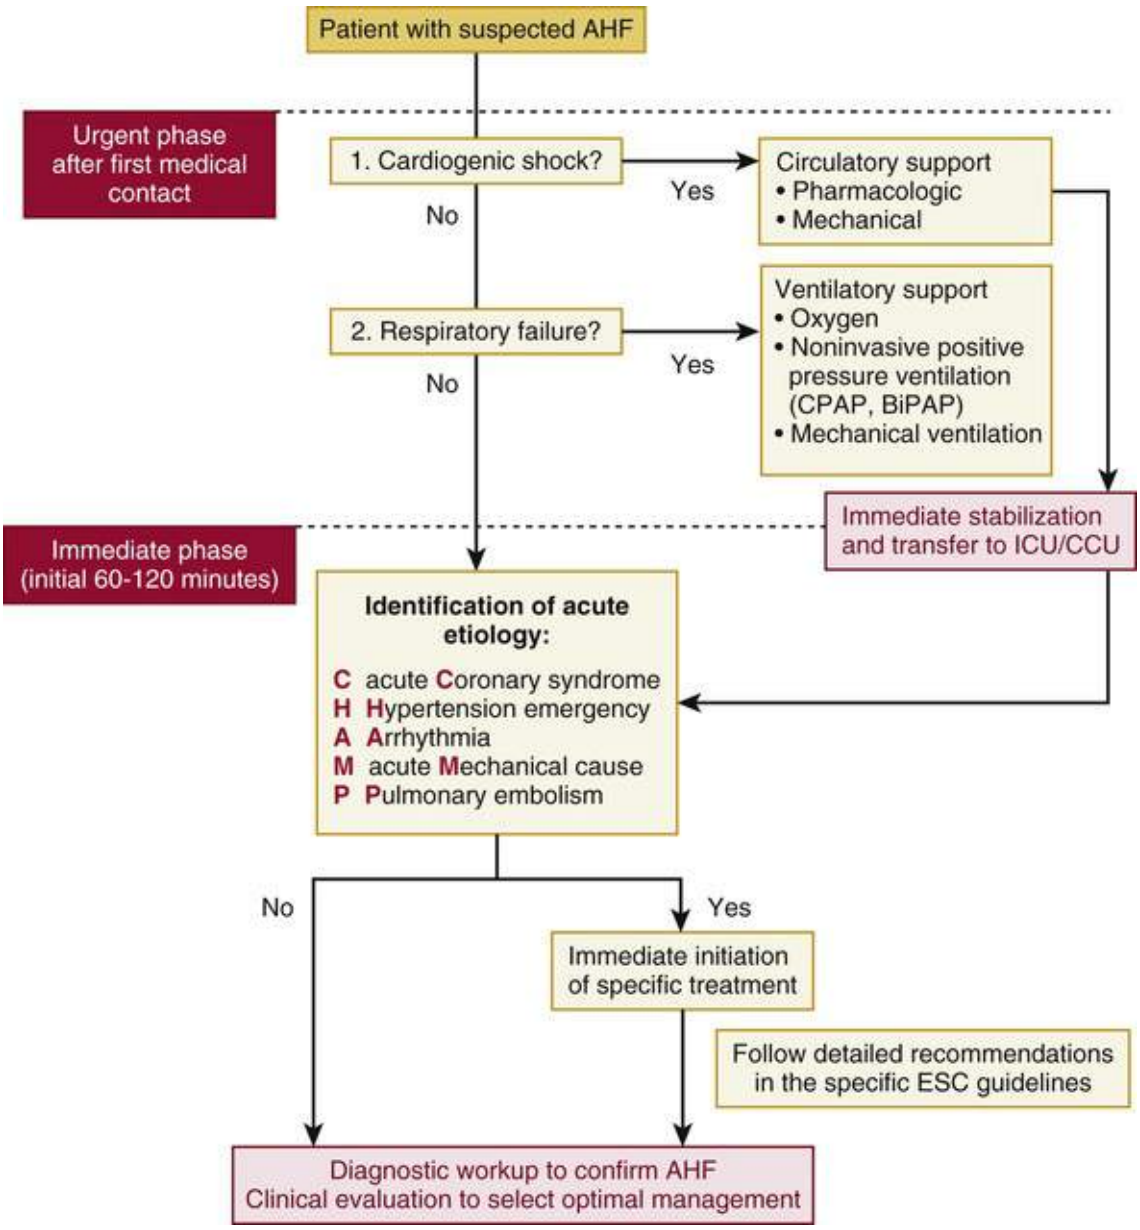

FIGURE 24.4 Algorithm for initial stabilization and management of patients with acute heart failure (AHF). (From Ponikowski P et al. 2016 ESC guidelines for the diagnosis and treatment of acute and chronic heart failure. The Task Force for the Diagnosis and Treatment of Acute and Chronic Heart Failure of the European Society of Cardiology (ESC). Developed with the special contribution of the Heart Failure Association (HFA) of the ESC. Eur Heart J 2016;37:2129-200.)

Classification

The inherent heterogeneity of AHF makes the development of a comprehensive classification scheme difficult, and no single classification system has garnered universal acceptance. One potentially useful distinction is based on the presence or absence of a prior history of HF. New-onset or de novo HF makes up about 20% of hospitalizations for AHF.[14] These patients may have no prior history of cardiovascular

(CV) disease or risk factors (e.g., acute myocarditis), but more frequently, they have a background of risk factors for HF (stage A heart failure according to the ACC/AHA guidelines) or preexisting structural heart disease (stage B heart failure according to the ACC/AHA guidelines) (**see Chapters 21 and 25**). Many of these patients with de novo HF develop AHF in the setting of acute coronary syndrome (ACS). The vast majority of AHF patients, however, have a history of preexisting chronic HF. These patients usually have a less dramatic clinical presentation, since the chronic nature of the disorder has allowed for recruitment of compensatory mechanisms and remodeling (e.g., increased pulmonary lymphatic capacity). Additionally, these patients are typically already being treated with neurohormonal antagonists and loop diuretics, such that neurohormonal activation may be less profound but diuretic resistance more common. A simplified classification scheme defines three general groups of AHF patients (**Table 24.2**):

TABLE 24.2

Simplified Classification and Common Clinical Characteristics of Patients with Acute Heart Failure

CLINICAL CLASSIFICATION	SYMPTOM ONSET	TRIGGERS	SIGNS AND SYMPTOMS	CLINICAL ASSESSMENT	COURSE
Decompensated heart failure	Usually gradual	Noncompliance, ischemia, infections	Peripheral edema, orthopnea, dyspnea on exertion	SBP: variable CXR: often clear despite elevated filling pressures	Variable, high rehospitalization rate
Acute hypertensive heart failure	Usually sudden	Hypertension, atrial arrhythmias, ACS	Dyspnea (often severe), tachypnea, tachycardia, rales common	SBP: high (>180/100 mm Hg) CXR with pulmonary edema Hypoxemia common	High acuity, but patient often responds quickly to therapy with vasodilators, noninvasive ventilation. Postdischarge mortality is low.
Cardiogenic shock	Variable	Progression of advanced HF or major myocardial insult (e.g., large AMI, acute myocarditis)	End-organ hypo-perfusion; Oliguria, confusion, cool extremities	SBP: low or low normal LV function usually severely depressed RV dysfunction common Laboratory evidence of end-organ dysfunction (renal, hepatic)	High inpatient mortality Poor prognosis unless readily reversible cause or mechanical support, transplantation

ACS, Acute coronary syndrome; *AMI,* acute myocardial infarction; *CXR,* chest x-ray film; *LV,* left ventricular; *RV,* right ventricular; *SBP,* systolic blood pressure.

1. *Decompensated heart failure.* This group is composed of patients with worsening signs and symptoms of congestion on a background of chronic HF. The time course of worsening may be acute, subacute, or indolent, with gradually worsening symptoms over days to weeks. They may have either preserved or reduced EF, but cardiac output is generally preserved and blood pressure is within the normal range. Overall, this group represents the largest portion of patients hospitalized for AHF.
2. *Acute hypertensive heart failure.* Hypertension is increasingly recognized as a common feature of the AHF presentation, with 50% of patients presenting with systolic blood pressure (SBP) greater than 140 mm Hg and 25% with greater than 160 mm Hg.[34] In this group, hypertension may be triggered by a high sympathetic tone related to dyspnea and accompanying anxiety (*reactive hypertension*), or acute hypertension with accompanying changes in afterload may be a trigger for decompensation. Both these mechanisms may be operative in a given patient, and cause-and-effect relationships may be difficult to discern. Epidemiologically, patients in whom acute hypertensive HF are more likely to have preserved systolic function, more likely to be women,

and more likely to have sudden onset of symptoms. Frank pulmonary edema with evident rales and florid congestion on chest x-ray film is much more common in this group of patients than in those with more gradual onset of symptoms, likely related to difference in LV compliance, acuity of pressure changes, and pulmonary lymphatic capacity. Although often strikingly ill at the initial presentation with hypoxemia and the possible need for noninvasive ventilation or even intubation, this group tends to respond well to therapy and have lower in-hospital mortality.[14]

3. *Cardiogenic shock*. This group presents with signs and symptoms of organ hypoperfusion despite adequate preload. SBP is often (although not always) decreased, and evidence of frank or impending end-organ dysfunction (renal, hepatic, CNS) is common. This type of AHF is relatively uncommon (4% of AHFS presentations in EHFS II) in broad community registries but more common in tertiary care settings.

While this classification system does not fully capture some less common clinical scenarios (e.g., isolated right HF or high output HF), it usefully encompasses the vast majority of AHF patients likely to be seen in routine clinical practice. The management of several specific clinical scenarios in AHF patients is discussed in more detail later.

Symptoms

The most common reasons for patients to seek medical care for AHF are symptoms related to congestion (**Table 24.3**). Dyspnea is the most common symptom and is present in more than 90% of patients presenting with AHF. The duration and time course of symptom onset can vary greatly, from very acute onset over minutes to slow worsening of chronic symptoms until patients present to medical attention. The sensation of dyspnea is a complex phenomenon influenced by multiple physiologic, psychological, and social factors and can vary dramatically between patients.[35] Dyspnea is typically present at rest or with minimal exertion by the time the patient presents with AHF. Patients may also present with symptoms related to systemic venous congestion, including peripheral edema, weight gain, early satiety, and increasing abdominal girth. Importantly, atypical symptoms can predominate, especially in elderly patients, where fatigue, depression, altered mental status, and sleep disruptions may be the primary complaints.

TABLE 24.3

Common Presenting Symptoms and Signs of Decompensated Heart Failure

SYMPTOMS	SIGNS
Predominantly Related to Volume Overload	
Dyspnea (exertional, paroxysmal nocturnal dyspnea, orthopnea, or at rest), cough, wheezing	Rales, pleural effusion
Foot and leg discomfort	Peripheral edema (legs, sacral)
Abdominal discomfort/bloating; early satiety or anorexia	Ascites/increased abdominal girth; right upper quadrant pain or discomfort; hepatomegaly/splenomegaly; scleral icterus
	Increased weight
	Elevated jugular venous pressure, abdominojugular reflux
	Increasing S_3, accentuated P_2
Predominantly Related to Hypoperfusion	
Fatigue	Cool extremities
Altered mental status, daytime drowsiness, confusion, or difficulty concentrating	Pallor, dusky skin discoloration, hypotension
Dizziness, presyncope, or syncope	Pulse pressure (narrow) Proportional pulse pressure (low)
Other Signs/Symptoms of Acute Heart Failure	
Depression	Orthostatic hypotension (hypovolemia)
Sleep disturbances	S_4
Palpitations	Systolic/diastolic cardiac murmurs

Physical Examination

Despite advances in diagnostics technology, biomarkers, and imaging, heart failure remains a clinical diagnosis and the physical examination continues to play a fundamental role (**see Chapters 10 and 21**). A useful framework in the bedside evaluation of patients with AHF is that developed by Stevenson and colleagues, which focuses on the adequacy of perfusion ("cold" versus "warm") and congestion at rest ("wet" versus "dry"; **see Fig. 21.3**).[36] While this framework does not encompass all the heterogeneity of AHF, it does focus the evaluation on two critical aspects that will significantly influence both prognosis and choice of treatments.

Measuring the blood pressure is a critical part in the evaluation of patients with AHF; hypotension is one of the strongest predictors of poor outcomes and helps to define the clinical profile of the patient and appropriate therapeutic interventions. SBP is typically normal or elevated in patients with AHF, with almost 50% presenting with SBP greater than 140 mm Hg. The combination of underlying hypertension and the marked increase in sympathetic stimulation that accompanies AHF can result in elevations of SBP consistent with hypertensive urgencies or emergencies (12% of patients had SBP >180 mm Hg on admission). Patients with very low SBP are uncommon, with only 2% of patients in ADHERE presenting with an SBP less than 90 mm Hg. Although blood pressure is generally related to cardiac output and the state of organ perfusion, it is important to recognize that hypotension and hypoperfusion are not synonymous. Patients with systemic hypoperfusion may present with normal blood pressure, and likewise, patients with advanced forms of HF may have chronically low blood pressure not associated with acute hypoperfusion. *Pulse pressure* (the difference between systolic and diastolic blood pressure) is a useful measure that is an indirect marker of cardiac output. A low pulse pressure is a marker of a low cardiac output and confers an increased risk in patients admitted with AHF. A high pulse pressure may alert the physician to a high-output state, including the possibility of unrecognized thyrotoxicosis, aortic regurgitation, or anemia.

The *jugular venous pressure* (JVP) is literally a barometer of systemic venous hypertension and is the single most useful physical examination finding in the assessment of patients with AHF. The accurate assessment of the JVP is highly dependent on examiner skill. The JVP reflects the right atrial pressure,

which typically (although not always) is an indirect measure of LV filling pressures. JVP may not reflect LV filling pressures in isolated right ventricular (RV) failure (e.g., from pulmonary hypertension or RV infarct), and significant tricuspid regurgitation can complicate the assessment of the JVP since the large "CV wave" of tricuspid regurgitation can lead to its overestimation.

Rales or inspiratory crackles are the most common physical examination finding and have been noted in 66% to 87% of patients admitted for AHF. However, rales are often not heard in patients with a background of chronic HF and pulmonary venous hypertension, because of increased lymphatic drainage, reinforcing the important clinical pearl that the absence of rales does not necessarily imply normal LV filling pressures. Cool extremities with palpable peripheral pulses suggest decreased peripheral perfusion consistent with a marginal cardiac index, marked vasoconstriction, or both. Of note, the temperature should be assessed at the lower leg as opposed to the foot, and this assessment is relative to the temperature of the examiner's hands.

Peripheral edema is present in up to 65% of patients admitted with AHF and is less common in patients presenting with predominantly low-output HF or cardiogenic shock. As with rales, the presence of edema has a reasonable positive predictive value (PPV) for AHF but a low sensitivity, so its absence does not exclude that diagnosis. Edema caused by AHF is usually dependent, symmetric, and pitting. It is estimated that a minimum of 4 liters of extracellular fluid is accumulated to produce clinically detectable edema.

Other Diagnostic Testing

Biomarkers

The natriuretic peptides are a family of important counterregulatory hormones in HF with vasodilatory and other effects (**see Chapter 23**). In the context of AHF, both brain (B-type) natriuretic peptide (BNP) and N-terminal pro-BNP (NT-proBNP) have been shown to play an important role in the differential diagnosis of patients presenting in the emergency department (ED) with dyspnea and are now strongly recommended by clinical practice guidelines.[37] For diagnostic natriuretic peptide (NP) testing in the setting of AHF, a critical point is that negative predictive value (NPV; i.e., the ability to rule out HF a as a cause of dyspnea) is generally greater than the PPV (i.e, the ability to definitively identify a diagnosis of HF as the cause of dyspnea). As with all biomarker testing, false positives (e.g., due to MI or pulmonary embolism) and false negatives (primarily due to obesity, which results in lower NP levels for a given degree of HF) may occur. Although NP levels tend to be lower in patients with HFpEF than those with reduced systolic function, NP testing cannot reliably distinguish HFpEF from systolic HF in an individual patient.

As noted previously, measurement of cardiac troponin is frequently elevated in patients presenting with AHF, and elevated levels are associated with worse in-hospital and postdischarge outcomes. The development of progressively more sensitive troponin assays has dramatically increased the proportion of patients presenting with AHF with elevations of circulating troponin. Assessment of cardiac troponin in patients with AHF is now recommended by current clinical practice guidelines and serves both to establish prognosis and to help gauge the likelihood of concurrent ACS.

Other Laboratory Testing

Assessment of renal function is a critical component in the management of patients with AHF. Estimated glomerular filtration rate (eGFR) should be calculated because serum creatinine may underestimate the

degree of renal dysfunction, especially in elderly patients. Blood urea nitrogen (BUN) is more directly related to the severity of AHF than creatinine and is typically elevated on admission in a large number of patients with AHF. In addition to reflecting intrinsic renal function, serum BUN is approximately proportional to neurohormonal activation in AHF. A wide variety of other biomarkers, including ST2, galectin 3, and GDF15, have been evaluated in patients with AHF, but none is currently recommended for routine use in patients with AHF. In patients in whom the diagnosis of AHF is uncertain, testing to establish alternative causes (e.g., D-dimer to evaluate for pulmonary embolism or procalcitonin to evaluate for evidence of infection) may be very useful.

Chest Radiograph, Electrocardiogram, and Echocardiogram

Chest radiography is usually performed at presentation in patients with dyspnea and is a fundamental test in the evaluation of patients with suspected AHF. In the ADHERE Registry, 90% of patients underwent chest radiography during hospitalization and there was evidence of congestion in more than 80% of these patients. In patients with a background of chronic HF and/or slow onset of symptoms, evidence of congestion on chest x-ray film may be subtle, and frank pulmonary edema is often absent despite substantially elevated filling pressures.

The electrocardiogram (ECG) is another standard diagnostic test that is appropriate in all patients presenting with AHF (**see Chapter 12**). Careful attention for ECG changes suggestive of ischemia is important, since troponin elevation is common in AHF regardless of etiology, and thus many not be a reliable marker of ACS. Arrhythmias are also a common trigger for AHF, and AF is present in 20% to 30%.

Utilization of echocardiography is very high in patients with AHF—more than 80% of patients in EHFS II had an echocardiogram performed during the index hospitalization[14] (**see Chapter 14**). An echocardiogram is generally the single most useful test in evaluating the etiology of the patient with AHF. Echocardiography can assess global systolic and diastolic function, regional wall motion abnormalities, valvular function, hemodynamics including estimates of filling pressures and cardiac output, and pericardial disease. The tissue Doppler ratio of peak early diastolic transmitral blood flow velocity (E) to the peak early-diastolic mitral annular tissue velocity (Ea) (E:Ea ratio) has been shown to be additive to BNP measures in diagnosing AHF patients presenting with dyspnea. An E:Ea ratio greater than 15 predicts a pulmonary capillary wedge pressure (PCWP) greater than 15 mm Hg and has been demonstrated to be accurate in the ED and intensive care settings.

Clinical Triggers

Whereas the preceding section focused on intrinsic mechanisms involved in the pathophysiology of AHF, a variety of specific identifiable clinical triggers may be identified as well. In the OPTIMIZE-HF registry, 61% of enrolled participants had an identifiable clinical precipitant, with pulmonary processes (15%), myocardial ischemia (15%), and arrhythmias (14%) being the most common[38] (**Fig. 24.5**). More than one precipitant was identified in a substantial minority of the study population. Of the identified triggers, worsening renal function was associated with the highest in-hospital mortality (8%), whereas nonadherence to diet or medication or uncontrolled hypertension had a much better prognosis (<2% in-hospital mortality for each).

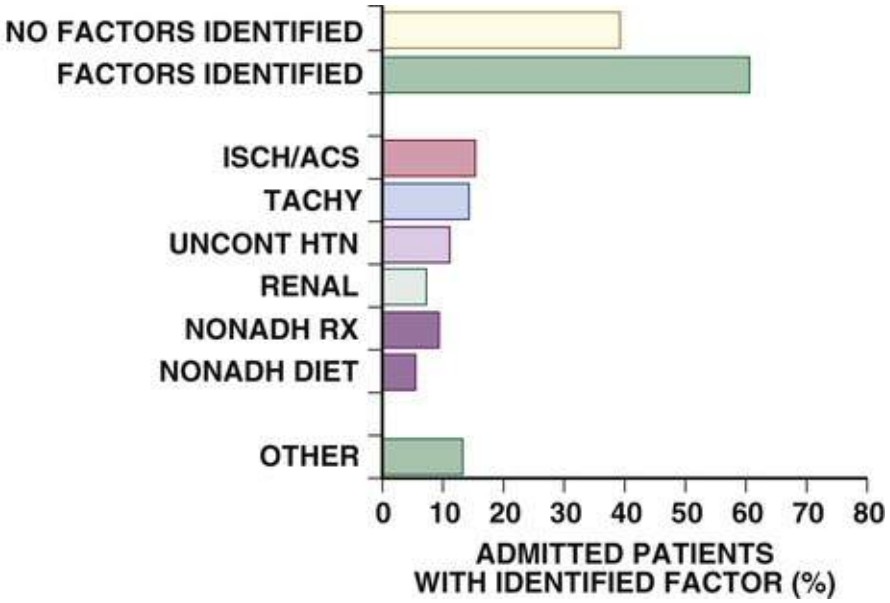

FIGURE 24.5 Identified triggers for acute heart failure hospitalization in the OPTIMIZE-HF Registry. ISCH/ACS, Myocardial ischemia/acute coronary syndrome; TACHY, tachycardia/tachyarrhythmia; UNCONT HTN, uncontrolled hypertension; NONADH Rx, nonadherence to medications; NONADH DIET, nonadherence to diet. (From Fonarow GC et al. Factors identified as precipitating hospital admissions for heart failure and clinical outcomes: findings from OPTIMIZE-HF. Arch Intern Med 2008;168:847-54.)

Risk Stratification

Risk stratification can serve as important clinical tools by helping to identify those patients at both ends of the spectrum of risk; patients who are at very high risk may be observed more closely or treated more intensively, whereas patients at low risk may avoid hospitalization altogether or need less rigorous follow-up and monitoring. A variety of predictive models have been developed in AHF, which can generally be divided into two groups: those focused on in-hospital mortality and those focused on postdischarge events (death or rehospitalization).

Predictive Models of in-Hospital Mortality

Data from the ADHERE Registry have been used to develop a classification and regression tree (CART) analysis to identify the best predictors of in-hospital mortality and to develop a risk stratification model.[39] Of the 39 variables evaluated, the CART method identified elevated BUN, lower SBP, and higher serum creatinine at admission to be the best predictors of in-hospital mortality. These three variables allowed for discrimination of groups with very low (2%) or extremely high (22%) in-hospital mortality.

Predictive Models of Postdischarge Events

As noted, there is a substantial risk of mortality or rehospitalization in the first 60 to 90 days after discharge in AHF patients. Some variables may predict mortality but not rehospitalization, and vice versa. In general, models for prediction of mortality have performed better than models focused on the composite of death or rehospitalization, potentially because rehospitalization risk is influenced by a variety of social factors not easily captured in multivariable models. There has been intense focus on preventing rehospitalization in AHF, and as such, models for predicting rehospitalization have been of substantial interest. A few readily available markers have generally been associated with prognosis across multiple studies, as summarized next.

Blood Pressure.
SBP has been found to be an important predictor of outcomes in a variety of studies, with higher blood pressure consistently associated with lower risk. In a detailed analysis of SBP in patients from the OPTIMIZE-HF study, there was a relatively monotonic relationship between blood pressure and mortality across the spectrum of blood pressure, with no evidence of increased risk even at very high levels of blood pressure (>180 mm Hg).[34]

Blood Urea Nitrogen.
Renal function (estimated by BUN, creatinine, and GFR) is an important predictor of prognosis in patients with AHF.[39] Of note, BUN has consistently been shown to be a stronger predictor of outcome than creatinine. BUN appears to integrate a variety of important prognostic aspects, including intrinsic renal function and neurohormonal activation (due to impaired urea clearance).[40,41]

B-Type (Brain) Natriuretic Peptide and N-Terminal Pro-BNP.
BNP and NT-proBNP have been demonstrated to be powerful predictors of risk in HF. In the setting of AHF, natriuretic peptide levels at initial presentation are important predictors of both short-term and long-term outcomes. In the PRIDE study of patients presenting to the ED with unexplained dyspnea, a single NT-proBNP value at initial presentation was an independent predictor of mortality to 1 year.[42] In the ADHERE Registry, admission BNP level was a significant predictor of in-hospital mortality regardless of EF. Data from the OPTIMIZE Registry comparing admission BNP, discharge BNP, and change in BNP over the course of hospitalization identified discharge BNP as the having the greatest power for predicting postdischarge events.[43]

Management of the Patient With Acute Heart Failure

Phases of Management

A central aspect of AHF is the need for urgent care beyond that which may be given in the outpatient setting. The management of AHF patients may be considered in the context of four phases of treatment with distinct goals. To achieve these goals, a seamless integration of the various phases of management with a high level of coordination between the in-hospital and postdischarge caregivers is necessary. Different treatment strategies and a detailed description of various therapies are presented later.

Phase I: Urgent/Emergent Care

The initial goals in the management of a patient presenting with AHF are to expeditiously establish the diagnosis (as previously discussed), treat life-threatening abnormalities, initiate therapies to rapidly provide symptom relief, and identify the etiology and precipitating triggers for the episode of AHF.

Initial therapies may follow the algorithm in **Fig. 24.6**. Insofar as dyspnea is the most common complaint in AHF patients, the initial management of uncomplicated AHF usually targets this symptom.[44] In patients with severe hypoxemia (oxygen saturation [Sa_{O_2}] <90%), O_2 administration is recommended. Although Sa_{O_2} on presentation is inversely related to short-term mortality, inhaled oxygen (Fi_{O_2} ≥0.4) may cause adverse hemodynamic effects (e.g., hyperoxia-induced vasoconstriction) in patients with systolic dysfunction[45] and therefore is not routinely recommended for patients without hypoxemia.[46] In patients with COPD, high Fi_{O_2} concentrations should not be used, to avoid the risk of respiratory depression and

worsening hypercarbia.

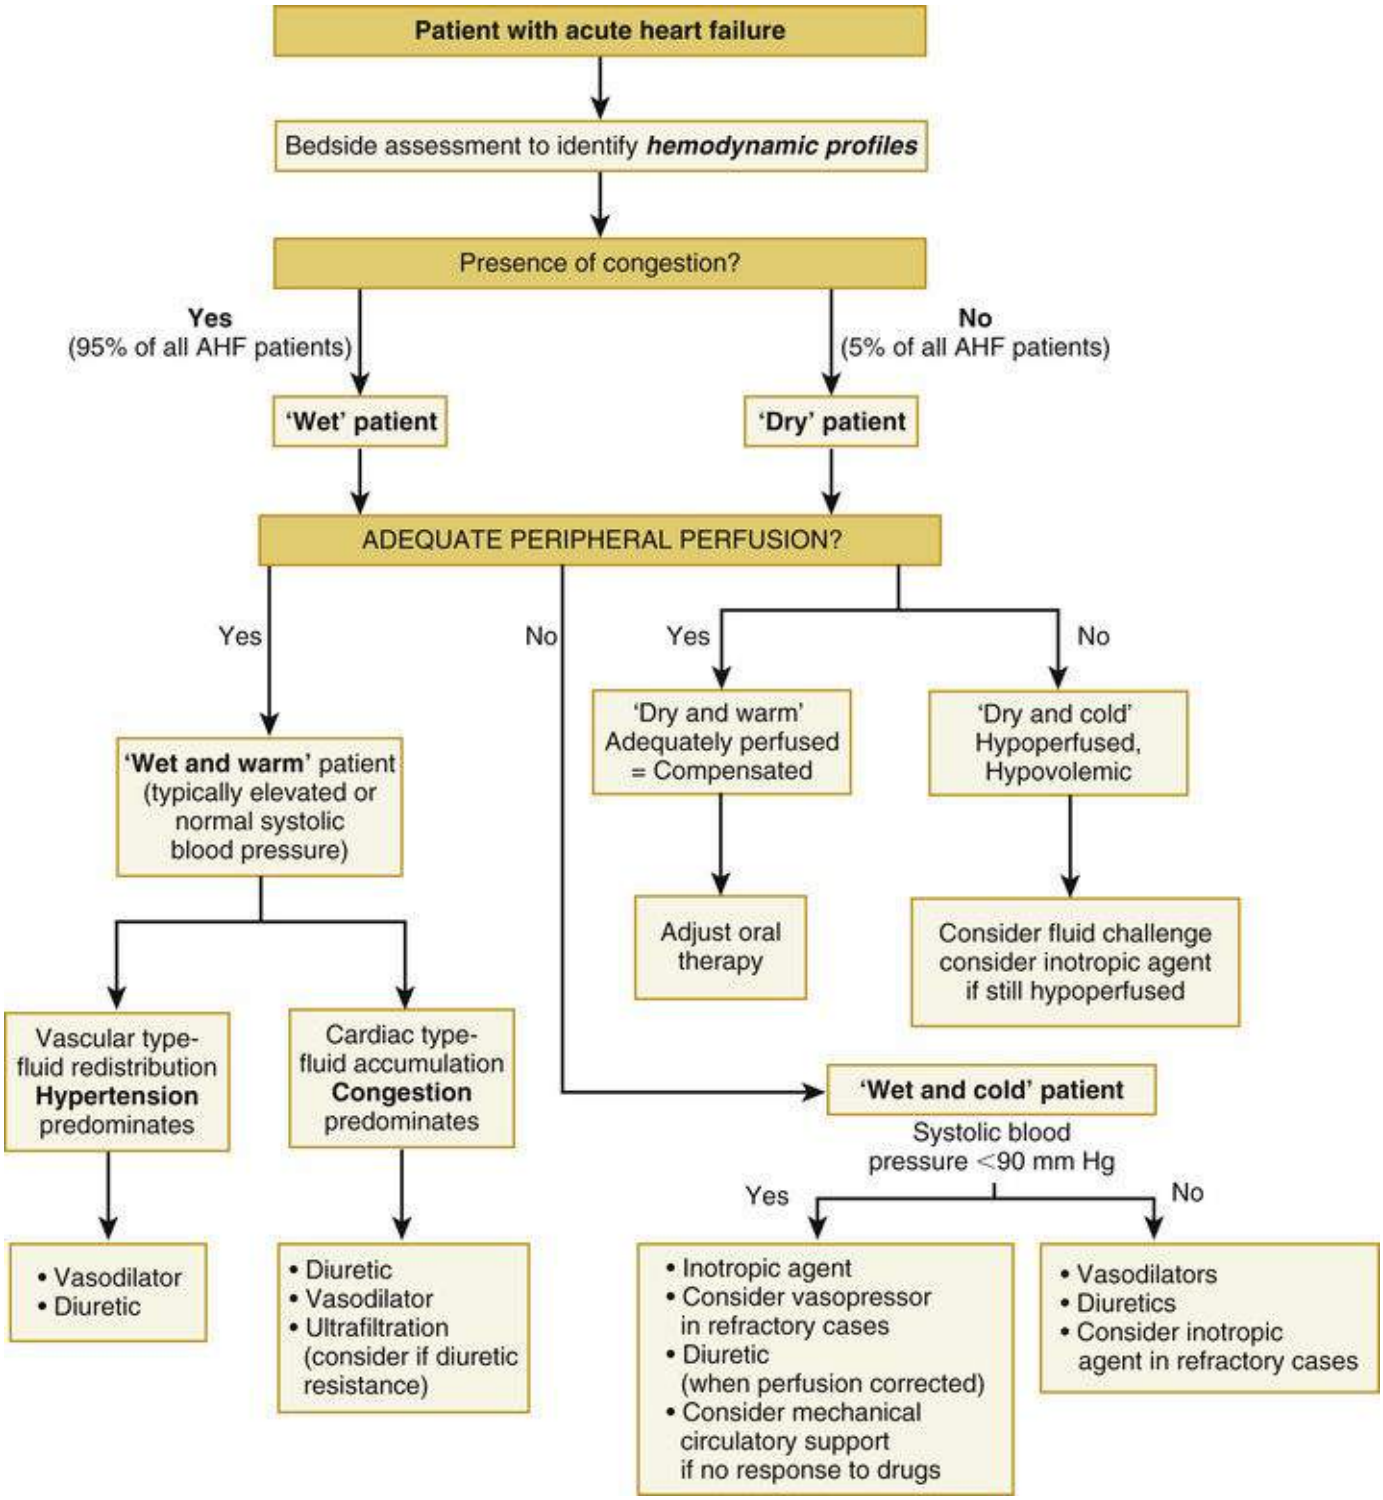

FIGURE 24.6 Algorithm for management of patients admitted with AHF based on degree of congestion and perfusion. (From Ponikowski P et al. 2016 ESC guidelines for the diagnosis and treatment of acute and chronic heart failure. The Task Force for the Diagnosis and Treatment of Acute and Chronic Heart Failure of the European Society of Cardiology (ESC). Developed with the special contribution of the Heart Failure Association (HFA) of the ESC. Eur Heart J 2016;37:2129-200.)

Early clinical studies and meta-analyses suggest that in patients with cardiogenic pulmonary edema, treatment with continuous positive airway pressure (CPAP) or noninvasive intermittent positive-pressure ventilation (NIPPV) improves symptoms and physiologic variables and reduces the need for invasive ventilation and mortality.[47] The Three Interventions in Cardiogenic Pulmonary Oedema (3CPO) trial

enrolled 1069 patients with pulmonary edema who were randomized to standard O_2 therapy, CPAP, or NIPPV.[48] Noninvasive ventilation (NIV) with CPAP or NIPPV was associated with greater improvement in patient-reported dyspnea, heart rate, acidosis, and hypercapnia after 1 hour of therapy, although it was not associated with a 7-day mortality benefit or a decreased need for intubation compared with standard O_2 therapy. CPAP is typically initiated with a positive end-expiratory pressure (PEEP) of 5 to 7.5 cm H_2O and titrated to 10 cm H_2O as needed for dyspnea relief and improvement in Sa_{O_2}. Contraindications to the use of NIV include immediate need for endotracheal intubation (inability to protect the airways, life threatening hypoxia) and lack of patient cooperation (altered sensorium, unconsciousness, anxiety, inability to tolerate mask). Caution should be used in patients with cardiogenic shock, RV failure, and severe COPD. Potential side effects and complications include anxiety, claustrophobia, dry mucous membranes, worsening RV failure, hypercapnia, pneumothorax, and aspiration. Mechanical ventilation with endotracheal intubation is required in about 4% to 5% of all patients.[14,49] Morphine may be useful in patients with severe anxiety or distress but should be used cautiously or avoided, especially in the presence of hypotension, bradycardia, advanced atrioventricular (AV) block, or carbon dioxide (CO_2) retention. Morphine use has been associated with increased likelihood of mechanical ventilation, intensive care unit (ICU) admission, prolonged hospital stay, and mortality in some retrospective analyses.

Intravenous (IV) loop diuretics are the most frequently administered pharmacologic therapy for AHF; more than 75% of patients in the ED receive IV diuretics, with a mean time to first IV administration of 2.2 hours in ADHERE.[49] Although some patients with volume redistribution rather than hypervolemia may derive benefit from vasodilators alone, symptomatic patients with objective evidence of congestion consistent with pulmonary or systemic venous hypertension or edema should generally receive urgent diuretic therapy for relief of symptoms related to congestion. Initial therapy is typically a bolus injection with a dose between 1 and 2.5 times the patient's oral loop diuretic dose for those receiving chronic diuretic therapy (see later, Diuretics). In the absence of hypotension, vasodilators play an important role in the initial therapy of patients with pulmonary edema and poor oxygenation. A treatment strategy of early initiation of IV nitrate therapy in patients with severe cardiogenic pulmonary edema has been shown to reduce the need for mechanical ventilation and the frequency of MI.[50]

After the emergent care of the patient, evaluation for triage is performed, and a critical decision concerns whether to admit the patient to the hospital. Although low-risk patients may be discharged with careful follow-up, the vast majority who present to the ED with AHF are hospitalized.[51] Although fewer than 5% of HF patients are initially treated in an ED observation unit, these specialized care centers may be effective in decreasing hospitalizations, ICU and critical care unit (CCU) admissions, and related health care costs while maintaining the quality of patient care.[52] In general, hospitalization is recommended for patients with evidence of severe decompensated HF, including hypotension, WRF, or altered mentation; dyspnea at rest associated with either tachypnea or, less often, significant hypoxemia (Sa_{O_2} <90%); hemodynamically significant arrhythmia (usually AF either with rapid ventricular response or new onset); and ACS. Hospitalization should be considered in patients with worsened congestion, even in the absence of dyspnea and often reflected by significant weight gain (≥5 kg), other signs or symptoms of pulmonary or systemic congestion, newly diagnosed HF, complications of HF therapy (e.g., electrolyte disturbances, frequent ICD firings), or other comorbidities.[53]

Specific Clinical Presentations

Atrial Fibrillation with Rapid Ventricular Response (see Chapter 38).

AF with rapid ventricular response is the most common tachyarrhythmia requiring treatment in patients with AHF. It may be difficult to determine with certainty whether the AF was a trigger for AHF or whether progressive HF decompensation led to AF. Although the ventricular response frequently decreases in parallel with the relief of dyspnea, and consequent decreased sympathetic drive, additional therapy may be required. Immediate cardioversion is generally not indicated, except in the unstable patient, because while the patient remains significantly decompensated, cardioversion is associated with a high rate of recurrent AF. In patients with systolic dysfunction, IV digoxin (in the absence of an accessory pathway), cautious use of beta-adrenergic blocker therapy or amiodarone may be used. Diltiazem and other agents that suppress ventricular function should be avoided in patients with significant systolic dysfunction but may be effective in patients with preserved function.

Right Ventricular Heart Failure.

The most common cause of RV HF in AHF is left-sided failure. Isolated RV HF is relatively rare and is generally caused by acute RV infarction, acute pulmonary embolism, or severe pulmonary hypertension. Isolated RV HF caused by an acute RV infarction is best treated with early reperfusion, whereas hemodynamically significant pulmonary embolism may be treated with thrombolytics. Hemodynamic stabilization by optimizing central venous pressure (CVP) with carefully monitored fluid loading (target CVP, approximately 10 to 12 mm Hg), and increasing RV systolic function with IV inotropic support under invasive hemodynamic guidance may also be necessary.[54] Selective pulmonary artery vasodilation by inhaled (NO, prostacyclin analogues) or IV (prostacyclin analogues, sildenafil) agents may improve RV function through decreased afterload. If the patient is mechanically ventilated, normoxia and hypocarbia should be goals using moderate tidal volumes (approximately 8 mL/kg) and as low a PEEP as possible (<12 cm H_2O) to maintain moderate plateau pressures.

Acute Coronary Syndromes (see Chapters 58 and 59).

ACS may be the underlying trigger in patients presenting with AHF, but as previously noted, the diagnosis is confounded by the high prevalence of elevated troponins in AHF itself. These patients may present with chest discomfort, electrocardiographic changes consistent with ischemia, and elevated serum troponin. Aggressive therapy for ACS should be rapidly instituted. In the absence of cardiogenic shock, inodilators should be avoided in patients with ACS and with significant asymptomatic CAD because experimental data have shown that inodilators can cause necrosis of ischemic and hibernating myocardium.

Cardiogenic Shock (see Chapter 59).

Cardiogenic shock is characterized by marked hypotension (SBP <80 mm Hg) lasting more than 30 minutes, associated with severe reduction of cardiac index (usually <1.8 L/min/m^2) despite adequate LV filling pressure (PCWP >18 mm Hg), resulting in organ hypoperfusion. Cardiogenic shock is an unusual presentation of AHF, occurring in less than 4% of the patients in EHFS II,[14] most of whom had MI. Mechanical complications of AMI such a mitral regurgitation, cardiac rupture with ventricular septal defect or tamponade, and isolated RV infarct may also be causes in this setting. IV inotropes or even vasoconstrictors may be required in these patients, with mechanical circulatory support, such as intra-aortic balloon pump (IABP) or left ventricular assist device (LVAD), for critical refractory cases, as a bridge to heart transplant or other mechanical intervention. A variety of newer approaches to provide hemodynamic support are now available, which may permit temporary stabilization until decisions about the appropriateness of other therapies (e.g., durable mechanical support or transplantation) can be made (**see Chapter 29**).

Phase II: Hospital Care

The goals for the management of a patient with AHF during the hospitalization phase are to complete the diagnostic and acute therapeutic processes that were initiated at the initial presentation; to optimize the patient's hemodynamic profile, volume status, and clinical symptoms; and to initiate or optimize chronic HF therapy. Ideally, these goals would be met in a manner to minimize intensive care and total hospital length of stay (LOS). Monitoring of daily weights, fluid intake and output, and vital signs, including orthostatic blood pressure, as well as a daily assessment of symptoms and signs are crucial. Laboratory monitoring should include daily analysis of electrolytes and renal function. Diagnostic evaluations should include an echocardiogram, if not recently performed. Evaluation for myocardial ischemia may be needed if there is suspicion of ischemia as a trigger of decompensation. Dietary sodium restriction (2 g daily) and fluid restriction (2 L daily) may be useful to help treat congestion, although the utility of sodium and fluid restriction in this setting has increasingly been called into question.[55] The increased risk of venous thromboembolism in HF is exacerbated by the decreased mobility of hospitalized patients with AHF, and venous thromboembolism prophylaxis is indicated in all patients unless there is a clear contraindication.

Most outpatient medications should generally be continued during inpatient therapy at existing doses, and it should be recognized that AHF hospitalization represents an opportunity to review and optimize chronic HF therapy. Although changes in renal function may necessitate dose adjustment or temporary discontinuation of RAAS inhibitors, including angiotensin-converting enzyme (ACE) inhibitors, angiotensin receptor blockers (ARBs), angiotensin receptor neprilysin inhibitors (ARNIs), and/or mineralocorticoid receptor antagonists, in general this should be avoided where possible. Patients admitted receiving beta blockers have a lower occurrence of ventricular arrhythmias, a shorter LOS, and reduced 6-month mortality than those not receiving them. Patients who had beta blockers withdrawn had significantly lower outpatient use of beta blockers and higher in-hospital mortality, short-term mortality, and combined short-term rehospitalization and mortality, even after adjustments for potential confounders.[56] Therefore, patients should continue beta-blocker therapy during the admission for AHF, unless significant hypotension or cardiogenic shock are present. Identification of other untreated targets (e.g., revascularization, consideration of CRT in appropriate candidates) should be performed during the hospitalization. The hospitalization phase of AHF management is also an opportunity to provide education and behavioral therapies to patients. Patients should receive specific and clear education about HF, including indications for specific drugs, outpatient monitoring of fluid status through daily weights, self-adjustment of diuretics, exercise programs, and nutritional counseling, as well as possible consultation with physical and occupational therapy. Comorbidities should be aggressively addressed because these often complicate HF management. The hospitalization is also a possible opportunity to enroll the patient in appropriate HF disease management programs.

The Cardiorenal Syndrome in Hospitalized Patients

The cardiorenal syndrome represents one of the greatest therapeutic challenges in the field of AHF (**see Chapter 98**). Although there is no consensus definition to date, in the context of AHF, cardiorenal syndrome is often described as the clinical state where the volume overload of HF is resistant or refractory to treatment due to progressive renal insufficiency. A commonly used practical definition is an increase in serum creatinine of more than 0.3 mg/dL (or 25% decreases in GFR) despite evidence of persistent clinical or hemodynamic congestion. Using this definition, the cardiorenal syndrome occurs in approximately 25% to 35% of the patients admitted with AHF, associated with longer LOS and higher postdischarge mortality.[26] This definition of the cardiorenal syndrome emphasizes the importance of

persistent congestion, because multiple studies have suggested that changes in renal function during successful decongestion therapy are usually transient and may not be associated with adverse outcomes.[29,57]

Although the diagnosis of the cardiorenal syndrome may be straightforward, the clinical management is a major challenge. Since absolute serum creatinine concentrations can be misleading, eGFR should be calculated in patients with AHF. As noted, arterial underfilling from overdiuresis or low cardiac output does not appear to be the most frequent primary cause of WRF, although hypotension can be an important factor.[58] Progressive deterioration of renal function (BUN >80 mg/dL and creatinine >3.0 mg/dL) or hyperkalemia may necessitate discontinuation of RAAS inhibitors, although use of other vasodilators should be considered, either IV (nitroglycerin or nitroprusside) or oral (isosorbide dinitrate and hydralazine). Increasing doses of diuretics are typically required, although diuretic resistance may be profound. The degree of diuretic resistance, sometimes quantified as diuretic efficiency, is known to be associated with increased LOS and adverse prognosis.[59] Although ultrafiltration is often considered in this scenario, clinical trial data have not supported the efficacy or safety of this approach.[60] Overall, the appropriate management of patients with cardiorenal syndrome remains a major unmet clinical challenge in AHF.

In-Hospital Worsening Heart Failure

Traditional assessments of the inpatient course of patients with AHF have generally lacked granularity and focused primarily on in-hospital mortality. However, there has been increasing emphasis from both a clinical and a research perspective on difference in the clinical “trajectory” of patients during inpatient AHF treatment. It is apparent that different patients may have markedly different clinical courses during inpatient therapy for AHF, from relatively uncomplicated courses marked by steady improvement in HF status, to those characterized by progressive deterioration in clinical status[8] (**Fig. 24.7**). Fundamentally, the concept of in-hospital worsening heart failure (WHF) encompasses clinical worsening (as manifest by worsening signs and/or symptoms of HF) that necessitates a significant intensification of therapy. Both terminology and specific definitions of WHF have varied between studies, leading to widely varying estimates of prevalence from 5% to 42% In general, the development of WHF during inpatient AHF therapy is associated with both longer LOS (by about 5 days in a recent pooled analysis), as well as adverse postdischarge outcomes (50% to 100% increase in 30- or 60-day mortality or HF rehospitalization).[61] As expected, different severity of WHF implies different risk, with WHF treated with increased diuretics alone associated with less increase in baseline risk than WHF requiring IV inotropes or mechanical circulatory or respiratory support. Although the definition of WHF continues to evolve, researchers and regulators have shown substantial interest in the concept of WHF as a clinical trial endpoint in AHF studies. WHF is a primary endpoint in two phase 3 AHF studies (TRUE-HF[62] and RELAX-AHF-2[63]; see later).

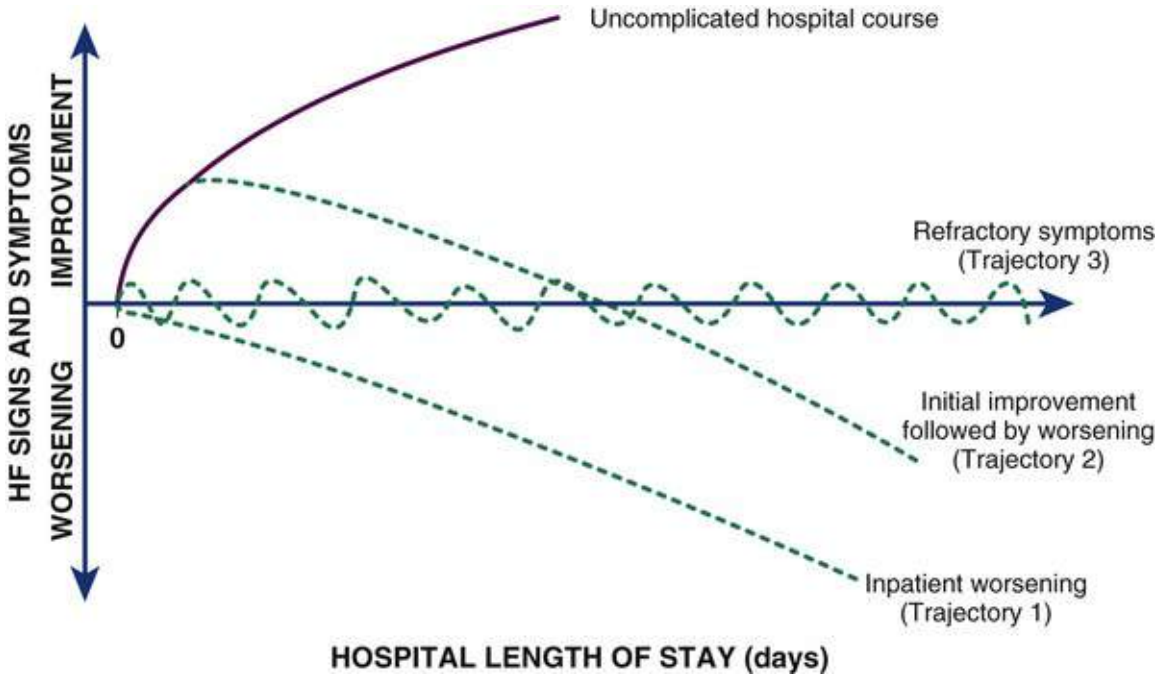

FIGURE 24.7 Various clinical trajectories of patients with acute heart failure during inpatient management. (From Butler J et al. In-hospital worsening heart failure. Eur J Heart Fail 2015;17:1104-13.)

Phase III: Predischarge Planning

The predischarge phase focuses on the goals of evaluating readiness for discharge, optimizing chronic oral therapy, minimizing the side effects of treatments, and ultimately preventing early readmission and improving symptoms and survival. Although there may be considerable pressures to discharge patients rapidly, particularly in the United States, careful optimization of medical regimen before discharge may reduce the risk of subsequent readmissions and improve long-term outcomes.[64] Despite that most patients present with congestion, many are discharged without significant weight loss, and available data demonstrate that persistent clinical congestion at discharge is associated with a high risk for rehospitalization.[65] Similarly, elevations of discharge BNP level have been associated with risk for rehospitalization after discharge.[43] Evaluation of functional capacity with simple maneuvers such as climbing one flight of stairs or walking down the corridor may be a simple and valuable tool to use before discharge.

Pharmacologic therapies known to improve long-term outcomes in chronic HF, such as beta blockers, ACE inhibitors or ARBs, and mineralocorticoid receptor antagonists, should be initiated as soon as reasonable during the hospitalization and before discharge in hemodynamically-stable, appropriate patients. The recent approval of two new therapies for chronic HF with reduced EF (sacubitril/valsartan and ivabradine) has created uncertainty about how to deal with these agents in the setting of AHF. In patients already treated chronically with these agents before this episode of AHF, they should generally be continued during hospitalization (similar to beta blockers and other RAAS inhibitors). To date, there are no data to support the new initiation of either of these agents in hospitalized AHF patients, although several studies are ongoing. Predischarge initiation of a beta blocker increases the proportion of patients receiving appropriate therapy at 60 days and may also reduce 60- to 90-day mortality. Clinical practice guidelines provide general criteria for considerations of hospital discharge, although substantial clinical judgment is still required[66] (**Table 24.4**).

TABLE 24.4

Considerations Before Discharge After Acute Heart Failure Hospitalization

Recommended for All Heart Failure (HF) Patients
Exacerbating factors addressed
Near-optimal volume status observed
Transition from intravenous to oral diuretic successfully completed
Patient and family education completed, including clear discharge instructions
LVEF documented
Smoking cessation counseling initiated
Near-optimal pharmacologic therapy achieved, including ACE inhibitor and beta blocker (for patients with reduced LVEF), or intolerance documented
Follow-up clinic visit scheduled, usually for 7 to 10 days
Should Be Considered for Patients with Advanced HF or Recurrent Admissions for HF
Oral medication regimen stable for 24 hours
No intravenous vasodilator or inotropic agent for 24 hours
Ambulation before discharge to assess functional capacity after therapy
Plans for postdischarge management (scale present in home; visiting nurse or telephone follow-up generally no longer than 3 days after discharge)
Referral for disease management, if available

ACE, Angiotensin-converting enzyme; *LVEF,* left ventricular ejection fraction.

Modified from Lindenfeld J et al. HFSA 2010 Comprehensive Heart Failure Practice Guideline. J Card Fail 2010;e1-194.

Phase IV: Postdischarge Management

Early recurrence of signs and symptoms of HF suggestive of worsening volume overload and/or neurohormonal activation are likely to contribute to the high rates of readmission that are observed in AHF.[67] Prompt interventions may therefore allow intervention to prevent the progression of volume overload and new admissions. At least some rehospitalizations for HF appear to be preventable.[68] A series of studies have also investigated the benefits of postdischarge support, especially patient-centered discharge instructions, transition coaches, follow-up telephone calls, and early physician follow-up, although results of these studies have been mixed in terms of impact on outcomes.[69,70] A follow-up appointment is optimally scheduled within 7 to 10 days after discharge, but closer follow-up (<1 week) should be considered for patients with high-risk features.

Treatment Strategies

Targeting Congestion

Treatment strategies for AHF have been largely empiric and limited by an incomplete understanding of its epidemiology and pathophysiology, as well as the relatively blunt nature of the available therapeutic tools (**see Fig. 24.6**). The current general approach focuses on the successful treatment of clinical and hemodynamic congestion, while limiting untoward effects on myocardial or end-organ function, identifying addressable triggers, and optimizing proven long-term therapies. This approach incorporates information from three main aspects of the patient's clinical presentation: blood pressure, volume status, and renal function.

Blood Pressure

Blood pressure (BP) reflects the interaction between vascular tone and myocardial pump function and is one of the most important prognostic indicators in AHF (see above). Most patients present with elevated BP and consequently will benefit from and safely tolerate vasodilator therapy. Vasodilators may decrease preload by reversing venous vasoconstriction and the related central volume redistribution from the peripheral and splanchnic venous systems, and reduce afterload by decreasing arterial vasoconstriction with a resultant improvement in cardiac and renal function. Vasodilators are the primary therapy for AHF

with pulmonary edema, and for nonhypotensive patients with low cardiac output (poor peripheral or central perfusion with SBP >85 to 100 mm Hg). A systematic review of clinical studies supported the ability of vasodilators to improve short-term symptoms and appear safe to administer, but revealed no data suggesting an impact on mortality.[71] However, in an international registry of 4953 patients admitted for AHF (ALARM-HF; 75% admitted to ICU/CCU care settings), analysis of a propensity-based matched cohort of 1007 matched pairs demonstrated improved in-hospital survival in patients treated with vasodilators and diuretics compared to patients treated only with diuretics of 7.8% compared to 11.0% in-hospital mortality, respectively ($P = 0.016$).[72] Interestingly, this difference in survival was particularly evident in patients with SBP less than 120 mm Hg (**Fig. 24.8**). The selection of agent depends on the clinical situation, local practice, and availability (see later, Specific Therapies).

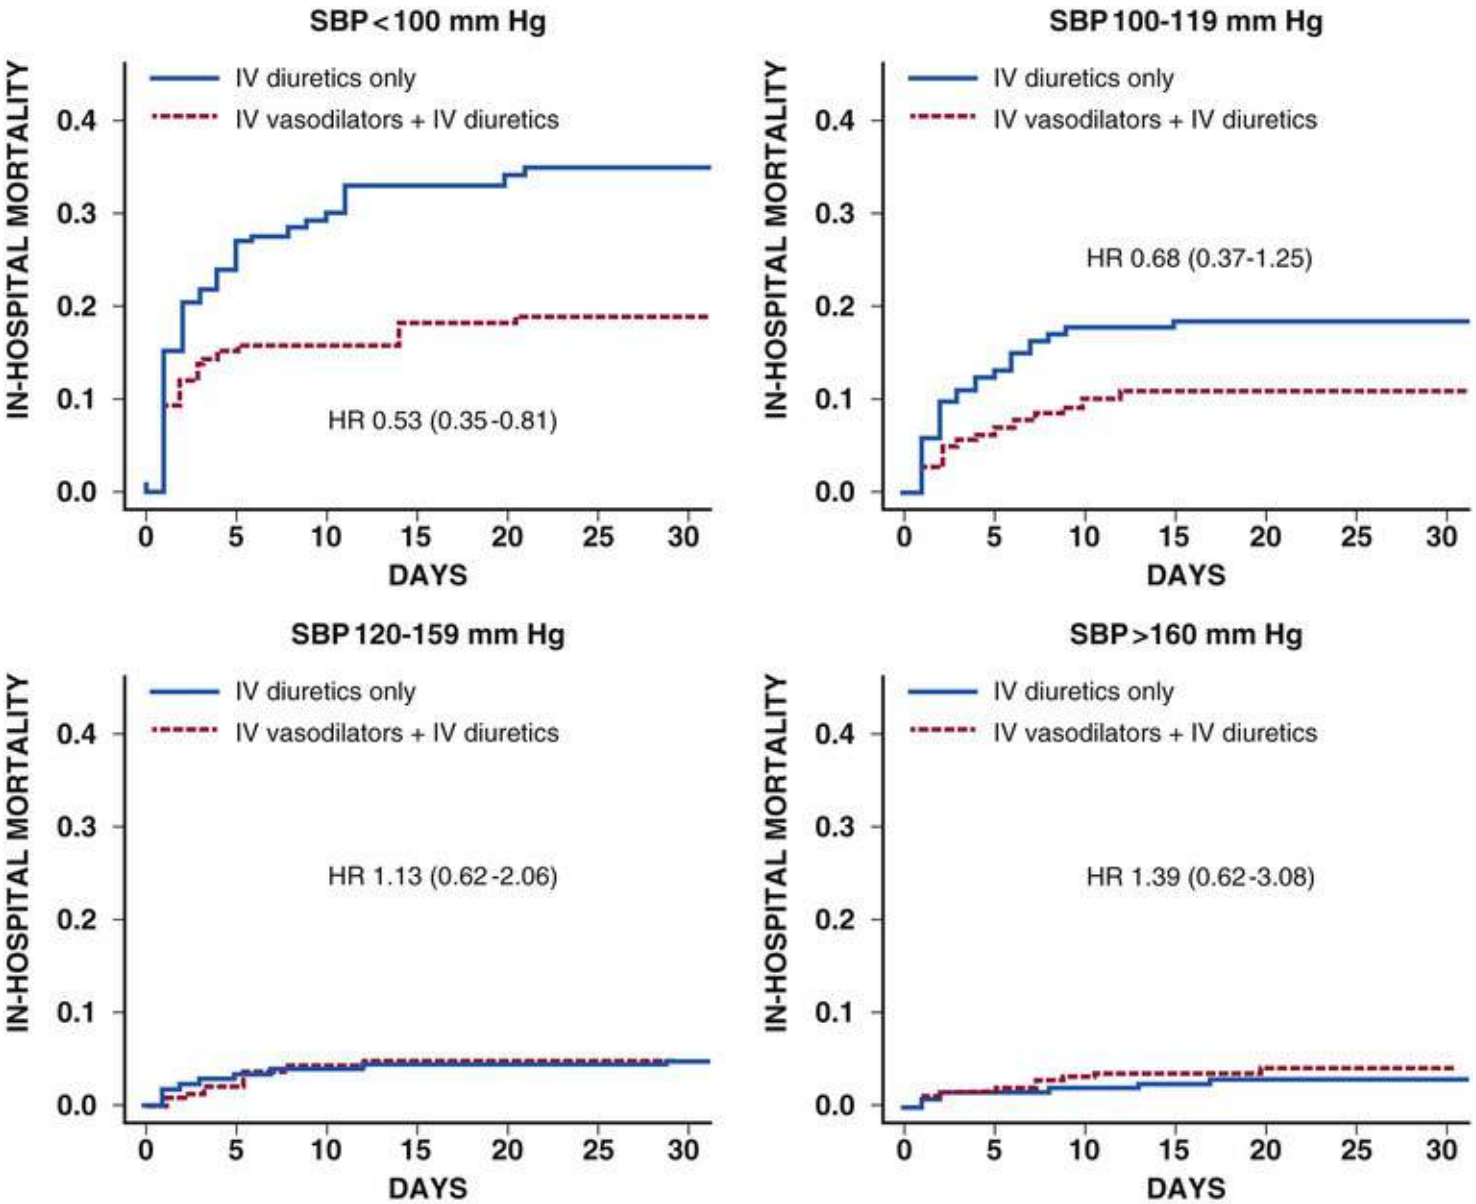

FIGURE 24.8 Effects of IV vasodilators on in-hospital mortality of patients with various levels of systolic blood pressure (SBP). SBP ranged from <100 to ≥160 mm Hg. The number of patients is 318, 334, 668, and 694 for SBP <100, 100-119, 120-159, and ≥160 mm Hg, respectively. HR, Hazard ratio. Values in parentheses are 95% confidence interval. (From Mebazaa A et al. Short-term survival by treatment among patients hospitalized with acute heart failure: the global ALARM-HF registry using propensity scoring methods. Intensive Care Med 2011;37:290-301.)

Hypotension (SBP <85 to 90 mm Hg) or signs of peripheral hypoperfusion are poor prognostic signs in

patients with AHF. Treating the potentially reversible, underlying etiologies, such as ACS, pulmonary embolus, and (rarely) hypovolemia, is essential. Hypovolemic hypotension, usually related to overdiuresis, is unusual in patients presenting with symptomatic AHF, and unappreciated volume overload may be present, especially in obese patients in whom neck veins and ascites are difficult to assess. If there is clear evidence of hypovolemia, carefully monitored "fluid challenges" may be attempted, although rapid IV fluid boluses can precipitate congestive symptoms. Asymptomatic hypotension, as an isolated finding in the absence of congestion and poor peripheral or central perfusion, does not require emergent treatment. Inotropic therapy may be indicated for persistent symptomatic hypotension or evidence of hypoperfusion in the setting of advanced systolic dysfunction. An analysis of 954 propensity-matched pairs of patients from the ALARM-HF Registry suggested that IV catecholamine use was associated with 1.5-fold increase in in-hospital mortality for dopamine or dobutamine use and a more than 2.5-fold increase for norepinephrine (NE) or epinephrine use.[72] Specific inotropic agents vary by country and local clinical practice (see specific agents later). In most patients, invasive pulmonary artery catheter monitoring is not necessary, since the measures of urine output, BP, and end-organ function may be clinically evaluated. The use of vasoconstrictors, such as high-dose dopamine, phenylephrine, epinephrine, or NE, should generally be avoided unless absolutely necessary for refractory symptomatic hypotension or hypoperfusion. Rarely, overdosage of afterload-reducing agents can precipitate admissions for AHF with a clinical presentation similar to cardiogenic shock or "pseudosepsis," in which case careful administration of vasoconstrictors may be indicated.

Volume Status

Most patients with AHF have evidence of volume overload, and for patients in whom this is the dominant presenting feature, such as those with significant peripheral edema or ascites, IV diuretics remain the foundation of AHF therapy. Patients with clinically evident congestion typically have 4 to 5 liters of excess volume and amounts greater than 10 liters are not uncommon. The choice of diuretic regimen is influenced by the amount and rapidity of the desired fluid removal and the renal function (see next section). Diuresis addresses the underlying abnormality and frequently improves symptoms and signs of elevated filling pressures. However, IV vasodilator therapy may provide more rapid relief in highly symptomatic patients with evidence of pulmonary congestion. In fact, many patients with hypertensive AHF may require minimal diuretics. Surprisingly, in a study of 131,430 admissions for HF, 11% of the patients received a median of 1 liter of IV fluids, predominantly normal saline, during the first 2 days of hospitalization. Patients receiving IV fluids had increased rates of subsequent critical care admission, intubation, renal replacement therapy, and hospital death compared with those who received only diuretics.[73] Thus, careful attention to volume status is critical because patients' symptoms of congestion may resolve despite persistent hemodynamic congestion (i.e., elevated filling pressures). Hospital discharge before hemodynamic congestion is fully treated appears to be a common cause of rehospitalization.[74]

Renal Function

Renal function is the third main aspect of a contemporary approach to treatment of the patient with AHF (**see Chapter 98**). Treatment of AHF in the presence of normal renal function is generally uncomplicated. Diuretics may be given in standard doses, although renal function, electrolytes, and volume status must be carefully monitored. However, approximately two thirds of patients present with at least moderate renal insufficiency.[25] This may be from preexisting kidney disease or may be a manifestation of worsening HF.

Abnormal renal function is typically associated with some degree of diuretic resistance, and higher doses of diuretics or other strategies may be needed (see later, Diuretics). The important clinical problem of WRF during AHF therapy, the cardiorenal syndrome, is discussed earlier.

Invasive Hemodynamic Strategy

Invasive hemodynamic management with pulmonary artery catheterization (PAC) may be a useful strategy in the management of some patients with AHF. PAC is an invasive procedure that provides detailed hemodynamic data, including direct assessment of filling pressures and cardiac output, and calculation of pulmonary and systemic vascular resistance. Potential risks of PAC include bleeding, infection, arrhythmias, and rare catastrophic events, such as pulmonary artery (PA) rupture or infarction. The use of PAC in the routine management of AHF has been a subject of controversy. The Evaluation Study of Congestive Heart Failure and Pulmonary Artery Catheterization Effectiveness (ESCAPE) was a randomized controlled trial (RCT) of 433 patients with severe symptomatic HF despite recommended therapies randomized to receive therapy guided by clinical assessment and PAC or by clinical assessment alone.[75] In ESCAPE, use of PAC did not significantly affect the days alive and out of hospital during the first 6 months (133 versus 135 days), mortality (43 versus 38 deaths), or number of days hospitalized (8.7 versus 8.3 days) compared to clinical assessment alone. Based on the results of the ESCAPE trial, use of PAC in AHF management has declined; in EHFS II, only 5% of patients had a PAC during AHF hospitalization. Importantly, the ESCAPE study excluded patients in whom the treating clinician did not have equipoise about the need for invasive hemodynamic measurement. Invasive hemodynamic assessment with PAC may still play an important role in select patients, especially those with shock or other severe hemodynamic compromise, with oliguria or anuria, or with unclear hemodynamics and poor response to therapy. In patients with advanced HF in whom PAC are used to tailor therapy, an LV filling pressure (as approximated by PCWP) of less than 16 mm Hg, right atrial pressure less than 8 mm Hg, and a systemic vascular resistance between 1000 and 1200 dynes-sec/cm^{-5} are useful targets.

Process of Care, Outcomes, and Quality Assessment

The first point of contact at the admitting hospital for most patients (80%) is the emergency department.[76] Many patients with AHF may be effectively managed in and safely discharged from the ED, and specific algorithms for care and criteria for discharge are evolving.[77] Once the patient with AHF is hospitalized, there appear to be substantial geographic differences in process of care and hospital course worldwide. In the U.S. ADHERE Registry, 23% of patients were admitted to an ICU setting, whereas a substantially higher proportion (51%) had an ICU stay in a similar European registry (EHFS II). Median length of stay is also markedly different across geographic regions, with LOS in the United States being approximately 4 days, more than twice that in Europe (median of 9 days in EHFS II), and even higher in Japan (21 days in ATTEND Registry). These differences in LOS do not appear to be fully explained by differences in case mix or severity of illness. The longer LOS outside the United States is generally associated with lower rates of short-term rehospitalization, although a cause-and-effect relationship is not fully established. A focus on reducing LOS in the United States appears to have been accompanied by an increase in postdischarge events, both mortality and (in particular) rehospitalization.[78] In contrast, in U.S. Veterans Affairs hospitals, HF hospitalizations have increased slightly, whereas 30-day mortality has decreased significantly.[79]

In general, the natural history of AHF is characterized by relatively low in-hospital mortality but a high rate of recurrent postdischarge events (**Table 24.5**). Inpatient mortality in AHF ranges between 3% and

7%, with the notable exception of patients in cardiogenic shock, who have greatly increased in-hospital mortality (40% in EHFS II).[14] Although in-hospital mortality is low, hospitalization for AHF portends a substantial worsening of the clinical course in many patients. In the EVEREST study, despite careful attention to evidence-based care in the context of a large clinical trial, 26% of enrolled patients had died in a median follow-up period of 9.9 months. Of all deaths, 41.0% were caused by HF, 26.0% were sudden cardiac death, 2.6% resulted from acute MI, 2.2% from stroke, and 13.2% from noncardiovascular causes.[80]

TABLE 24.5

Outcomes in Patients with Acute Heart Failure from Select Trials and Registries

STUDY	PATIENTS (*n*)	REHOSPITALIZATION	MORTALITY	
			In-Hospital	Postdischarge
Trials				
ASCEND-HF	7141	6% at 30 days		13% at 6 mo

The Rehospitalization Problem

The high rates of rehospitalization after discharge from a HF hospitalization have become a major focus of clinicians, policymakers, and payers. Claims data using the U.S. Medicare sample suggest striking rate of rehospitalization in elderly patients, with a 30-day rehospitalization rate of 27%, although rates are substantially lower in younger non-Medicare cohorts.[81,82] Rates of rehospitalization within 6 months approach 50% in many cohorts, in particular the elderly. Of note, approximately half the rehospitalizations are not HF related, which underscores the total burden of comorbidity in HF patients as well as the challenges in affecting this event rate with HF-focused interventions. In EVEREST, careful adjudication of postdischarge hospitalizations showed that 46% were for HF, 15% for other CV causes, and 39% for non-CV causes.[80] These rehospitalizations represent a major driver of health expenditures, accounting for over $39 billion spent on HF care per year in the United States.[4] Although controversial, reducing rehospitalization rates for HF has been identified as a major focus of quality improvement and

cost containment by payers such as the U.S. Centers for Medicare and Medicaid Services. As a result, a variety of interventions and initiatives related to inpatient management, discharge planning, and transitions of care have been implemented in an attempt to decrease rehospitalization rates for HF, although the nature, implementation, and effectiveness of these practices have varied widely across health systems.[83] Despite these significant efforts, recent evidence suggests only a minor impact on rehospitalizations.[84] There is also uncertainty about what proportion of rehospitalizations are avoidable, although a systematic review suggests that a quarter or more may be preventable.[68] To date, only improved utilization of proven evidence-based therapies (e.g., beta blockers, ACE inhibitors) during acute hospitalization has been shown to improve postdischarge outcomes.[64] Hospital discharge before congestion is adequately treated appears to be a common cause of early readmission.[74] Early postdischarge follow-up has also been associated with lower rehospitalization rates in retrospective registry data.[70] A variety of other interventions centered on telemedicine, disease monitoring, and disease management remain under active investigation.

Specific Therapies

Diuretics

Loop diuretics are the primary pharmacologic treatment for volume overload in patients with AHF and typically result in rapid symptom relief in most patients[85] (**see Chapter 25**). Loop diuretics (furosemide, torsemide, bumetanide, and ethacrynic acid; **Table 24.6**) can lead to excretion of up to 25% of the filtered sodium, and IV administration avoids variable bioavailability and allows for rapid onset of action, typically within 30 to 60 minutes. Preliminary data suggest that genetic variants modulate the response to furosemide in patients with decompensated HF.[86] Based on the results of the DOSE study, initial doses of approximately 2.5 times the outpatient dose should be considered for patients receiving chronic oral diuretic therapy, with underlying renal dysfunction, or with severe volume overload. Given the steep dose-response curve of these agents, titration should be rapid, with doubling of the dose until an effective response is noted. If there is significant volume overload (>5 to 10 L) or diuretic resistance, a continuous IV infusion can be considered.

TABLE 24.6

Therapeutic Approaches for Volume Management in Acute Heart Failure (AHF)

SEVERITY OF VOLUME OVERLOAD	DIURETIC	DOSE (mg)	COMMENTS
Moderate	Furosemide, or	20-40, or up to 2.5 times oral dose	IV administration preferable in symptomatic patients
	Bumetanide, or	0.5-1.0	Titrate dose according to clinical response.
	Torsemide	10-20	Monitor Na^+, K^+, creatinine, BP
Severe	Furosemide, or	40-160, or 2.5 times oral dose 5-40 mg/hr infusion	Intravenously
	Bumetanide, or	1-4/0.5-2 mg/hr infusion (max, 2-4 mg/hr, limit 2-4 hr)	Bumetanide and torsemide have higher oral bioavailability than furosemide, but IV administration preferable in AHF.
	Torsemide	20-100/5-20 mg/hr	
	Ultrafiltration	200-500 mL/hr	Adjust ultrafiltration rate to clinical response; monitor for hypotension; consider hematocrit sensor.
Refractory to loop diuretics	Add HCTZ, *or*	25-50 twice daily	Combination with loop diuretic may be better than very high dose of loop diuretics alone.
	Metolazone, *or*	2.5-10 once daily	Metolazone more potent if creatinine clearance <30 mL/min
	Chlorothiazide, *or*	250-500 mg IV 500-1000 mg PO	
	Spironolactone	25-50 once daily	Spironolactone best choice if patient not in renal failure and normal or low serum K^+, although may not be very potent
In case of alkalosis	Acetazolamide	0.5	Intravenously
Refractory to loop diuretics and thiazides	Add dopamine (renal vasodilation), *or*		
	dobutamine or milrinone (inotropic agent)		
	Ultrafiltration, or hemodialysis if coexisting renal failure		

Despite their ubiquitous use in AHF, loop diuretics have generally not been tested in rigorously controlled clinical trials. Loop diuretics may lead to neurohormonal activation and electrolyte repletion and have been associated in observational studies with both increased WRF risk and decreased survival, although a recent analysis suggested no relationship between diuretic exposure and 30-day all-cause mortality or HF hospitalization.[87] DOSE, a randomized double-blind study, prospectively compared diuretic strategies in AHF.[88] Using a 2 × 2 factorial design, 308 patients were randomized to treatment with IV furosemide using either twice-daily bolus dosing or continuous infusion and to either a low-dose (equivalent to numerical value of oral outpatient dose given IV) or a high-dose (2.5 times the oral dose given IV) strategy. There was no significant difference in either of the co–primary endpoints of global assessment of symptoms and change in creatinine at 72 hours with administration by bolus compared to infusion or with the low- versus high-dose strategy. The high-dose strategy was associated with greater relief of dyspnea and net fluid loss at 72 hours, although more patients in the high-dose group had a transient increase in creatinine greater than 0.3 mg/dL, which resolved by hospital discharge (**eTable 24.1**). The significance of this finding is unclear; although there were no apparent differences in hospital LOS or days alive out of the hospital, the study was not powered for long-term clinical outcomes. Overall, there were no differences in results between the continuous infusion and intermittent bolus strategies in the clinical trial setting of DOSE, suggesting that whichever approach is most likely to reliably produce the desired diuresis in the particular local clinical practice should be used.

From Felker GM et al. Diuretic strategies in patients with acute decompensated heart failure. N Engl J Med 2011;264:797-805.

In the setting of diuretic resistance, administration of a thiazide-like diuretic that blocks the distal tubule can provide significant augmentation of the diuretic effect.[89] IV chlorothiazide (500 to 1000 mg) or oral metolazone (2.5 to 10 mg) given before the loop diuretic are effective agents, although care must be taken to monitor for hypotension, WRF, and electrolyte abnormalities, which may be profound. NSAIDs can greatly reduce the efficacy of diuretics by reducing renal synthesis of vasodilatory prostaglandins and should be avoided. If hypokalemia is a persistent problem with replacement requirements, administration of a potassium-sparing diuretic, such as spironolactone or eplerenone, should be considered and may also provide synergistic diuretic effects, especially at higher doses,[90] as well as long-term beneficial effects on outcomes (**see Chapter 25**).

Vasodilators

In the absence of hypotension, vasodilators can be used as first-line therapy in combination with diuretics in the management of AHF patients to improve congestive symptoms[91] (**Table 24.7**). As noted, in the ALARM-HF Registry using propensity-matching techniques, patients admitted with AHF and treated with diuretics and vasodilators had significantly better in-hospital survival than patients treated with diuretics alone or those treated with inotropes.[72] However, a more recent analysis of 11,078 patients admitted for AHF demonstrated no mortality benefit at 7, 30, or 365 days,[92] consistent with the findings of a systematic review.[71] After extensive review of these and other data, the UK National Institute for Health and Care Excellence found no evidence to support the routine use of vasodilators in patients with AHF.[93] In practice, however, vasodilators appear to provide symptom relief in these patients. Vasodilators can be classified as (1) predominantly venous dilators, with consequent reduction in preload; (2) arterial dilators, leading to a decrease in afterload; and (3) balanced vasodilators, with combined action on both the venous and the arterial system. Currently available vasodilators include the organic nitrates (nitroglycerin [NTG] and isosorbide dinitrate), sodium nitroprusside, and nesiritide. All these drugs act by activating soluble guanylate cyclase (sGC) in the smooth muscle cells, leading to higher intracellular concentrations of cyclic guanosine monophosphate (cGMP) and consequent vessel relaxation (**see Chapter 23**). These should be used with caution in patients who are preload or afterload dependent (e.g., severe diastolic dysfunction, aortic stenosis, CAD), since these drugs may cause severe hypotension. BP should be monitored frequently and the drug discontinued if symptomatic hypotension develops.

Table 24.7

Intravenous Vasoactive Agents for Treatment of Acute Heart Failure

INTRAVENOUS MEDICATION	INITIAL DOSE	EFFECTIVE DOSE RANGE	COMMENTS
Vasodilators			
Nitroglycerin; glyceryl trinitrate	20 µg/min	40-400 µg/min	Hypotension, headache Tolerance with continuous use after 24 hours
Isosorbide dinitrate	1 mg/hr	2-10 mg/hr	Hypotension, headache Tolerance with continuous use within 24 hours
Nitroprusside	0.3 µg/kg/min	0.3-5 µg/kg/min (usually <4 µg/kg/min)	Caution in patients with active myocardial ischemia Hypotension; cyanide side effects (nausea, dysphoria); thiocyanate toxicity; light sensitive
Nesiritide†††	2 µg/kg bolus with 0.010-0.030 µg/kg/min infusion*	0.010-0.030 µg/kg/min†	Uptitration: 1 µg/kg bolus, then increase infusion rate by 0.005 µg/kg/min no more frequently than every 3 hours, up to maximum of 0.03 µg/kg/min Hypotension, headache (less than with organic nitrates)
Inotropes			
Dobutamine	1-2 µg/kg/min	2-20 µg/kg/min	For inotropy and vasodilation; hypotension, tachycardia, arrhythmias; ?mortality
Dopamine	1-2 µg/kg/min	2-4 µg/kg/min	For inotropy and vasodilation; hypotension, tachycardia, arrhythmias; ?mortality
	4-5 µg/kg/min	5-20 µg/kg/min	For inotropy and vasoconstriction; tachycardia, arrhythmias; ?mortality
Milrinone	25-75 µg/kg bolus over 10-20 min* followed by infusion	0.10-0.75 µg/kg/min	For vasodilation and inotropy; hypotension, tachycardia, arrhythmias; renal excretion; ?mortality
Enoximone††	0.25-0.75 mg/kg	1.25-7.5 µg/kg/min	For vasodilation and inotropy; hypotension, tachycardia, arrhythmias; ?mortality
Levosimendan††	12-24 µg/kg bolus over 10 min followed by infusion	0.5-2.0 µg/kg/min	For vasodilation and inotropy; active metabolite present for ~84 hours; hypotension, tachycardia, arrhythmias; ?mortality
Epinephrine		0.05-0.5 µg/kg/min	For vasoconstriction and inotropy; tachycardia, arrhythmias, end-organ hypoperfusion; ?mortality
Norepinephrine		0.2-1.0 µg/kg/min	For vasoconstriction and inotropy; tachycardia, arrhythmias, end-organ hypoperfusion; ?mortality

*Some clinicians do not administer a bolus dose, to decrease the risk of hypotension. Bolus not recommended in patients with hypotension.

†Lower doses have also been effective in some small studies.

††Not approved for use in all countries.

Nitrates

Organic nitrates are one of the oldest therapies for AHF. These agents are potent venodilators, producing rapid decreases in pulmonary venous and ventricular filling pressures and improvement in pulmonary congestion, dyspnea, and myocardial O_2 demand at low doses. At slightly higher doses and in the presence of vasoconstriction, nitrates are also arteriolar vasodilators, reducing afterload and increasing cardiac output. Nitrates are relatively selective for epicardial, compared to intramyocardial, coronary arteries, resulting in increased coronary blood flow and making them useful for patients with concomitant active myocardial ischemia. The starting dose of nitroglycerin is usually 20 µg/min with rapid uptitration occurring every 5 to 15 minutes in either 20-µg/min increments or doubling of the dose. The dose may initially be titrated to the goal of immediate symptom relief, but a BP reduction of at least 10 mm Hg in mean arterial pressure with SBP greater than 100 mm Hg may be preferable. The nitrate dose may need to be reduced if SBP is 90 to 100 mm Hg and will often need to be discontinued with SBP less than 90 mm Hg. IV nitrates use appears to be more common in Europe than in the United States (38% in EHFS-II but only 9% in ADHERE).[14,49] Organic nitrates may also be administered orally, sublingually, or by spray, allowing for convenient emergent treatment before establishing IV access.

There is limited clinical trial experience with organic nitrates. Early administration of high-dose IV nitrates is beneficial in improving arterial oxygenation and potentially preventing some consequences of AHF (MI, need for mechanical ventilation), compared to furosemide alone[50] or noninvasive ventilation,[94]

although these studies were small and not blinded. In a study designed to evaluate nesiritide in patients with dyspnea at rest from decompensated HF, nitroglycerin treatment in 143 patients demonstrated nonsignificant, mild decreases in PCWP and no significant improvement in patient-assessed dyspnea within 3 hours, but the dose was remarkably low (42 µg/min).[95] In a small, single-site substudy [96] in which nitroglycerin was aggressively uptitrated to a mean dose of 155 µg/min by 3 hours, there were significant decreases in PCWP (4 to 6 mm Hg decrease from baseline) from 1 to 12 hours, but no difference at 24 hours. The major limitation of organic nitrates is the tolerance that typically develops within 24 hours. Headache is the most common adverse effect (20% within 24 hours[95]). Symptomatic hypotension (5%) may also be noted, but generally resolves when nitrate therapy is discontinued. Given the risk of severe hypotension with potentially catastrophic consequences, the recent use of phosphodiesterase 5 inhibitors (sildenafil, tadalafil, vardenafil) should be ruled out before administration of nitrates.

Sodium Nitroprusside

Sodium nitroprusside (SNP) induces a balanced reduction in afterload and preload that is exquisitely titratable, because of a very short half-life (seconds to a few minutes), and is particularly effective in the setting of markedly elevated afterload (e.g., hypertensive AHF) and moderate-severe mitral regurgitation. IV administration is usually monitored with an indwelling arterial line, although automated BP cuffs are now used in many centers. Titration of the SNP dose to rapidly improve symptoms and to achieve an SBP of 90 to 100 mm Hg are typical goals, and invasive PACs may assist in meeting other hemodynamic goals. Tapering the dose of SNP before discontinuation is advised to avoid the possibility of “rebound hypertension.” Physician discomfort with the cyanide metabolites and the historical institutional requirements for invasive arterial monitoring has limited the use of this highly effective therapy to fewer than 1% of patients with AHF in Europe and the United States.[14,49]

Nitroprusside, a prodrug that is rapidly metabolized to NO and cyanide, has no inherent arrhythmogenic properties, may improve myocardial O_2 demand by reducing afterload and wall stress, creates no significant electrolyte disturbances, and is rarely toxic. Despite its potency, severe hypotension is unusual and rapidly resolves. However, significant vasodilation of the intramyocardial vasculature has been noted, possibly producing a coronary steal phenomenon; and consequently, nitroprusside is not recommended for patients with active myocardial ischemia. The most common complaints with nitroprusside are related to the cyanide metabolite, including nausea, abdominal discomfort, dissociative feelings, and dysphoria. Cyanide rarely accumulates in patients, but impaired hepatic function and doses greater than 250 µg/min for more than 48 hours increase this risk. The thiocyanate metabolite can accumulate in patients with moderate to severe renal insufficiency when exposed to prolonged infusions of high doses (usually >400 µg/min) over days and is usually not relevant in the treatment of AHF. Cyanide levels may be measured but rarely return in a timely fashion to be useful.

There are no randomized studies of nitroprusside in patients with AHF, although multiple studies demonstrated dramatic reduction in PCWP (15 mm Hg) and marked increases in cardiac output, associated with increases in diuresis and natriuresis and decreased neurohormonal activation. In a contemporary analysis of 175 consecutive patients admitted for AHF, IV SNP was associated with greater hemodynamic improvement and lower rates of inotropic support or WRF during hospitalization and with lower rates of all-cause mortality after discharge than nitroprusside, despite a worse

hemodynamic profile at baseline.[97]

Nesiritide

Nesiritide (recombinant human BNP) is identical to endogenous BNP and causes potent vasodilation in the venous and arterial vasculatures, resulting in significant reductions in venous and ventricular filling pressures and mild increases in cardiac output. As with other vasodilators, nesiritide may reduce diuretic requirements, but in clinical studies, there is limited evidence for a significant direct “natriuretic” effect. Nesiritide may be used for treatment of patients with acutely decompensated congestive heart failure (CHF) who have dyspnea at rest or with minimal activity, but it should not be administered for the indication of replacing diuretics, enhancing diuresis, protecting renal function, or improving survival. An optional bolus of 2 µg/kg followed by a 0.01 µg/kg/min infusion is the recommended starting dose for nesiritide. There is limited clinical trial experience with uptitration of the drug, but for patients who remain symptomatic with evidence of volume overload and sufficient BP, uptitration may be considered. Nesiritide has clear effects on hemodynamics and has limited need for frequent dose adjustments and an absence of tolerance, but its high cost and lack of clear clinical benefit beyond other, less expensive, more readily titratable agents have limited its use.

The Vasodilation in the Management of Acute CHF (VMAC) trial randomized 489 patients with decompensated CHF and dyspnea at rest to placebo, nitroglycerin, or nesiritide.[95] After 3 hours, patients receiving nesiritide had a significantly greater decrease in PCWP compared to both nitroglycerin and placebo, and improvement in dyspnea compared to placebo (no difference from nitroglycerin). A pooled analysis of the RCT data suggested that nesiritide may be associated with an increased risk of WRF as well as increased mortality. To address these issues, the ASCEND-HF trial randomized 7141 patients with AHF to nesiritide or placebo for 24 to 168 hours.[98] At 30 days, there was no difference between the two groups with regard to the composite endpoint of death or rehospitalization for HF. The clinical effects on dyspnea were relatively modest and have generally not been regarded as clinically important compared to placebo (**Fig. 24.9**). Use of nesiritide had no impact on WRF but was associated with an increase in the rate of hypotension. Another small study (ROSE-AHF) enrolled 360 patients admitted for AHF specifically to assess the effect of low-dose nesiritide on congestion and renal function.[99] In this study, nesiritide had no beneficial effect on urine output or cystatin C or on any of the other secondary endpoints reflective of decongestion, renal function, or clinical outcomes, although it was associated with more symptomatic hypotension.

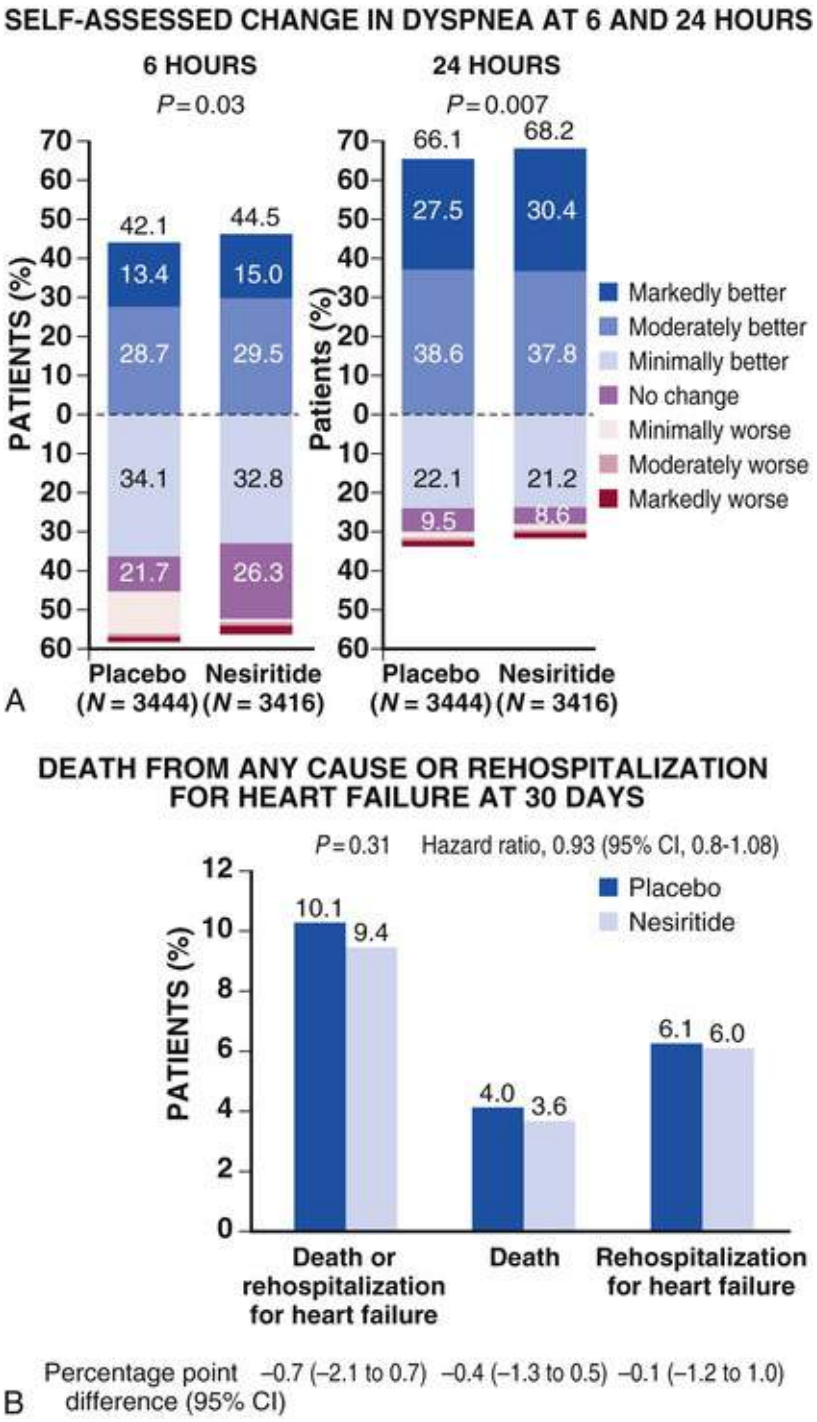

FIGURE 24.9 Changes in dyspnea at 6 and 24 hours **(A)** and the primary clinical endpoints at 30 days **(B).** In **A,** numbers above the bars indicate overall percentage of patients who reported being markedly or moderately better after receiving study treatment (i.e., those represented by percentages above *dashed line*). (From O'Connor CM et al. Effect of nesiritide in patients with acute decompensated heart failure. N Engl J Med 2011;365:32-43.)

Nesiritide exerts its activity via guanylyl cyclase–linked natriuretic peptide receptors (NPR A and B) causing cGMP-mediated vasodilation. Hypotension, at times prolonged (>2 hours)[95] despite the relatively short (18-minute) half-life of the peptide, is more common in patients with volume depletion, and consequently, nesiritide use should be limited to those with congestive signs and symptoms. Headache also occurs, but less often than with nitroglycerin. Other actions of nesiritide include neurohormonal antagonism with reduction in vasopressin, aldosterone, and sympathetic tone and alteration of intrarenal hemodynamics and glomerular filtration. Nesiritide did not improve urine output

or renal function in AHF patients with worsening creatinine.[99]

Inotropes and Inodilators

The inotropic drugs and inodilators (inotropic drugs with vasodilatory properties), increase cardiac output through cAMP-mediated inotropy and reduce PCWP through vasodilation.[100] (**Table 24.7**). However, retrospective data from both registries and trials of AHF patients suggest that even the short-term use (hours to few days) of IV inotropes (except for digoxin) is associated with significant side effects, such as hypotension, atrial or ventricular arrhythmias, and an increase in in-hospital[72] and possibly long-term mortality.[101] Patients with CAD may be at higher risk of adverse events due to reduced coronary perfusion and increased myocardial O_2 requirements with possible myocardial ischemia and injury. Therefore, these agents are reserved for use in select situations of hypoperfusion when other interventions are inappropriate or have failed. The use of these drugs should be limited to patients with reduced EF, who present with low SBP (<90 mm Hg) or low measured cardiac output in the presence of signs of congestion and organ hypoperfusion, such as decreased mentation or reduced urine output.[10,53] Despite these recommendations, inotropes are still frequently used in patients with HFpEF in some regions. Inotropic agents for AHF should be used with close hemodynamic and telemetry monitoring and stopped as soon as adequate organ perfusion is restored. All these agents may increase conduction through the AV node, causing a rapid ventricular response in patients presenting with AF. Additionally, IV inotropes may be employed in cardiogenic shock as a temporary therapy to prevent hemodynamic collapse or as a life-sustaining bridge to more definitive therapy for those patients awaiting mechanical circulatory support, ventricular assist devices (VADs), or cardiac transplantation. In North American and European registries, approximately 15% and 25% of patients were treated with inotropic agents, although given the minimal supportive clinical evidence, there is marked local variability in the use of these drugs.[102]

Dobutamine

Dobutamine is the most commonly used positive inotrope in Europe and the United States, despite evidence that it increases mortality.[103,104] Dobutamine at doses of 1 to 2 µg/kg/min may improve renal perfusion in patients with cardiogenic shock, although higher doses (5 to 10 µg/kg/min) may be necessary for more profound hypoperfusion. Tachyphylaxis may occur with infusions of more than 24 to 48 hours, partially because of receptor desensitization. In general, dobutamine (or dopamine) is the preferred inotrope in patients with significant hypotension and in the setting of significant renal dysfunction, given the renal excretion of milrinone. Concomitant beta-blocker therapy will result in competitive antagonism of the effects of dobutamine, and higher doses of dobutamine (10 to 20 µg/kg/min) may be required to obtain the desired hemodynamic effects. The lowest effective dose of dobutamine should be used in the context of continuous BP and rhythm monitoring. The patient should be gradually weaned off dobutamine and the clinical status reevaluated with each dose adjustment. Temporary adjustments to afterload-reducing agents or diuretics may assist in weaning.

As an agonist of both $beta_1$- and $beta_2$-adrenergic receptors with variable effects on the alpha receptors, dobutamine has multiple actions (**see Chapter 22**). Beta receptor stimulation results in increased inotropy and chronotropy through increases in intracellular cAMP and calcium, as well as by direct

activation of voltage-sensitive calcium channels. At low doses, stimulation of $beta_2$ and alpha receptors causes vasodilation, resulting in decreased aortic impedance and systemic vascular resistance with reduction in afterload and indirect increases in cardiac output. At higher doses, vasoconstriction can ensue with decreased venous capacitance and increased right atrial pressure. Adverse effects of dobutamine include tachycardia, increasing ventricular response to AF, increased atrial and ventricular arrhythmias, myocardial ischemia, and possibly cardiomyocyte necrosis from direct toxic effects and induction of apoptosis.[105]

Hemodynamic and other effects of dobutamine have been studied, but there has been only one placebo-controlled randomized trial in patients with AHF. Although some methodologic concerns exist, the Calcium Sensitizer or Inotrope or None in Low Output Heart Failure (CASINO) study demonstrated significantly increased mortality with dobutamine compared to placebo, consistent with the results of other studies of this class of drugs.[103]

Dopamine

In both the United States and Europe, dopamine is used as often as dobutamine, presumably as a vasoconstrictor and for its putative effects on renal vasodilation. As a precursor to the synthesis of NE, an agonist of both adrenergic and dopaminergic receptors, and an inhibitor of NE uptake, dopamine has complex effects that vary significantly with dose. Initiation of dopamine therapy causes a rapid release of NE that can precipitate tachycardia, as well as atrial and ventricular arrhythmias. In addition, intermediate to high doses can cause significant vasoconstriction, precipitating HF and poor perfusion. Patients should be gradually weaned from these doses down to 3 to 5 µg/kg/min and then discontinued, to avoid potential hypotensive effects of low-dose dopamine.

Low-dose dopamine (≤2 µg/kg/min) has been proposed to cause specific dilation of renal, splanchnic, and cerebral arteries, potentially increasing renal blood flow in a selective manner, as well as promoting natriuresis through direct distal tubular effects. The DAD-HF study of 60 patients admitted for AHF suggested that a combination of low-dose furosemide and low-dose dopamine resulted in comparable urine output and dyspnea relief, but improved renal function profile and potassium homeostasis, compared to high-dose furosemide.[106] However, the DAD-HF II study of 161 patients found no beneficial effect of the addition of low-dose dopamine to furosemide.[107] In the ROSE-AHF study of 360 patients hospitalized with AHF, low-dose dopamine did not increase urine volume during 72 hours, did not improve cystatin C concentrations, but did reduce hypotension and increased tachycardia compared to placebo.[99] Therefore, there appears to be no indication for low-dose dopamine therapy to improve renal function.

Intermediate-dose dopamine (2 to 10 µg/kg/min) results in enhanced NE release, stimulating cardiac receptors with an increase in inotropy and mild stimulation of peripheral vasoconstricting receptors. Since the positive inotropic effect is largely dependent on myocardial catecholamine stores, which are often depleted in patients with advanced HF, dopamine is a poor inotrope in patients with severe systolic dysfunction.

High-dose dopamine (10 to 20 µg/kg/min) causes peripheral and pulmonary artery vasoconstriction, mediated by direct agonist effects on $alpha_1$ receptors. These doses pose a significant risk of precipitating limb and end-organ ischemia and should be used cautiously.

Epinephrine

Epinephrine is a full beta receptor agonist and a potent inotropic agent with balanced vasodilator and vasoconstrictor effects. The direct effect of epinephrine on increasing inotropy independent of myocardial catecholamine stores makes epinephrine a useful agent in the treatment of transplant patients with denervated hearts.

Phosphodiesterase Inhibitors

Cyclic adenosine monophosphate (cAMP) is a ubiquitous signaling molecule that increases inotropy, chronotropy, and lusitropy in cardiomyocytes and causes vasorelaxation in vascular smooth muscle (**see Chapter 22**). Phosphodiesterase (PDE) IIIa is compartmentalized in the cardiac and vascular smooth muscle, where it terminates the signaling activity of cAMP by degrading it to AMP. Many specific inhibitors of PDE IIIa, such as milrinone and enoximone, have been developed to provide organ-specific improvements in hemodynamics through increasing myocardial and vascular smooth muscle cell cAMP concentrations. In theory, subcellular localization may allow stimulation of inotropy without increasing heart rate with low doses of highly specific PDE inhibitor. The independence of the mechanism from adrenergic receptors bypasses receptor downregulation, desensitization, and antagonism by beta blockers. Although studies have shown improved hemodynamic efficacy with PDE inhibitors compared to dobutamine in patients receiving beta-blocker therapy, such limitations of dobutamine's effects are not typically clinically relevant. In addition, this mechanism allows for synergistic effects with beta receptor agonists, such as dobutamine. Such combination therapy may be useful in patients with greatly reduced LV systolic function. PDE inhibitors cause significant peripheral and pulmonary vasodilation, reducing afterload and preload while increasing inotropy. These effects make PDE inhibitors well suited for patients with LV dysfunction and pulmonary hypertension or for post-transplant patients.

Milrinone.

Although the most frequently used PDE inhibitor, only 3% of patients in ADHERE[49] and less than 1% in EHFS II[14] received milrinone. Therapy may be initiated with a 25- to 75-µg/kg bolus over 10 to 20 minutes, although in clinical practice the bolus dose is usually omitted. Infusions are typically started at 0.10 to 0.25 µg/kg/min and may be uptitrated to hemodynamic effect. Given the elimination half-life of 2.5 hours and the pharmacodynamic half-life of more than 6 hours, effects from uptitration are delayed by at least 15 minutes after dosage adjustment. Also because of these pharmacodynamics, patients who have had prolonged administration of milrinone may have delayed deterioration, so they should be observed for at least 48 hours after cessation. Milrinone is renally excreted, necessitating dose adjustment in the presence of renal dysfunction or substitution with dobutamine. Milrinone has many side effects, including hypotension and atrial and ventricular arrhythmias. In OPTIME-CHF (Outcomes of a Prospective Trial of Intravenous Milrinone for Exacerbations of Chronic Heart Failure),[108] 951 patients admitted with exacerbation of systolic HF not requiring IV inotropic support were randomized to milrinone or placebo infusion. There was no difference in the primary endpoint of days hospitalized for cardiovascular causes with 60 days, but significant increases in sustained hypotension and new atrial arrhythmias were noted in the milrinone-treated patients. In addition, a post hoc subgroup analysis demonstrated increased mortality in patients with an ischemic etiology of HF who received milrinone.[101] This study reinforces the caution that must be exercised in selecting PDE inhibitors for the treatment of patients with AHF.

Enoximone.
This PDE IIIa inhibitor is available in Europe. Enoximone dosing is essentially one-tenth that of milrinone, with a bolus dose of 0.25 to 0.75 µg/kg over 10 to 20 minutes, followed by an infusion of 1.25 µg/kg/min. Enoximone is extensively metabolized by the liver into renally cleared active metabolites, so doses should be reduced in the setting of either renal or hepatic insufficiency. Otherwise, the previous comments apply to this PDE inhibitor as well.

Levosimendan

Levosimendan is a novel agent that increases myocardial contractility and produces peripheral vasodilation, through cardiac myofilament calcium sensitization by calcium-dependent (systolic) troponin C binding and activation of vascular smooth muscle potassium channels, respectively. Levosimendan also has some PDE inhibitor activity, which some contend is responsible for its inotropic activity in patients.[109] Levosimendan was administered to almost 4% of patients in EHFS II[14] and is available in more than 40 countries (although not in the United States), where it is used in patients with reduced LV systolic function and hypoperfusion in the absence of severe hypotension. Although it may be given with a bolus of 12 to 24 µg/kg over 10 minutes, many clinicians directly initiate a continuous infusion at 0.05 to 0.10 µg/kg/min, which may be uptitrated to 0.2 µg/kg/min. In clinical trials, levosimendan significantly increased cardiac output, reduced PCWP and afterload, and improved dyspnea. The potent vasodilating effects of levosimendan can cause significant hypotension, the risk of which may be reduced by maintaining filling pressures.[100] Levosimendan has an active, acetylated metabolite with a half-life longer than 80 hours, allowing it to have hemodynamic effects days after discontinuation of the infusion.

Initial clinical studies demonstrated reduced arrhythmias and improved survival with levosimendan compared to placebo and dobutamine. REVIVE-II (Randomized Multicenter Evaluation of Intravenous Levosimendan Efficacy Versus Placebo in the Short Term Treatment of Decompensated Heart Failure), a recent study of 600 patients, demonstrated significant improvement in the clinical status, serial BNP, and hospital LOS with levosimendan treatment compared to standard care, but there were also more episodes of hypotension, AF, and ventricular ectopy, as well as a nonsignificant increase in early mortality at 14 to 90 days.[110] SURVIVE (Survival of Patients with Acute Heart Failure in Need of Intravenous Inotropic Support trial) randomized 1327 patients with systolic dysfunction, evidence of low cardiac output, and dyspnea at rest despite diuretics and vasodilators to either levosimendan or dobutamine. An early reduction in mortality was not sustained through 180 days, but levosimendan was associated with a greater incidence of AF and lower incidence of worsening HF compared to dobutamine.[111]

Vasopressors

These agents should be reserved for patients with marked hypotension in whom central organ hypoperfusion is evident. Vasopressors will redistribute cardiac output centrally at the expense of peripheral perfusion and increased afterload. *Norepinephrine* is a potent agonist of the $beta_1$ and the $alpha_1$ receptors but is a weaker agonist of $beta_2$ receptors, resulting in marked vasoconstriction. In general, NE is the preferred vasopressor for cardiogenic shock.[10] In the SOAP II trial, 1679 patients with shock were randomized to either dopamine or NE with a nonstatistical difference increase in mortality with dopamine associated with a significant increase in arrhythmic events.[112] In a subgroup analysis

including the 280 patients with cardiogenic shock, NE had improved survival compared to dopamine. *Phenylephrine* is a selective alpha$_1$ receptor agonist with potent direct arterial vasoconstrictor effects. This agent may be used in patients with severe hypotension, particularly when the hypotension is related to systemic vasodilation, rather than to a decrease in cardiac output. As noted above, *dopamine* may also be used for its vasoconstrictor properties. All these agents may induce end-organ hypoperfusion and tissue necrosis.

Other Pharmacologic Therapies

Digoxin.

Digoxin rapidly improves hemodynamics without increasing heart rate or decreasing BP and may be considered in patients with a low BP caused by low cardiac output.[113] Digoxin may be used intravenously with an initial bolus of 0.5 mg. It should be given slowly because rapid administration may cause systemic vasoconstriction. The initial bolus should be followed by an oral or IV dose of 0.25 mg at least 12 hours after the initial dose. In patients who continue to have signs and symptoms of HF, digoxin therapy should be continued in addition to other therapies, with a dose resulting in a trough serum concentration less than 1 ng/mL. Ischemia, hypokalemia, or hypomagnesemia may increase the likelihood of developing digitalis intoxication, even at the therapeutic doses. Digoxin should not be used in patients with moderate to severe renal impairment, ongoing ischemia, or advanced AV block.

Arginine Vasopressin Antagonists.

Arginine vasopressin (AVP), also known as antidiuretic hormone, is the main regulator of plasma osmolality. Vasopressin levels are inappropriately high in both acute and chronic HF and are thought to have a major role in the pathophysiology of HF. In particular, vasopressin appears to be the major contributor to the development of the hyponatremia observed in patients with HF. In patients with AHF, volume overload, and persistent hyponatremia at risk for or having active cognitive symptoms, therapy with an AVP antagonist for short-term improvement in serum sodium concentration may be considered. Currently available AVP antagonists are *tolvaptan* (an oral, selective V_2 receptor antagonist) and *conivaptan* (V_{1a}/V_2 receptor antagonist for IV use). Although both agents have been approved for the treatment of clinically significant hypervolemic and euvolemic hyponatremia, they have not been shown to be improve long-term outcomes in HF and are not currently approved for this indication. The Efficacy of Vasopressin Antagonism in Heart Failure Outcome Study with Tolvaptan (EVEREST) was an international trial that evaluated more than 4000 patients admitted with AHF and reduced EF. Tolvaptan added to standard therapy for AHF modestly improved signs and symptoms during hospitalization and modestly reduced body weight without affecting renal function, heart rate, or BP, but postdischarge survival and readmission rate were not affected by chronic postdischarge therapy with tolvaptan.[114,115] Two recent, small, double-blind studies of short-term therapy with tolvaptan compared to placebo in AHF did not show a clinically important benefit of tolvaptan therapy in this setting.[116] In patients with AHF, the addition of conivaptan to standard therapy increased urine output without a significant improvement in signs/symptoms or a decrease in body weight.[117]

Calcium Channel Blockers.

CCBs without significant myocardial depressant effects, such as *nicardipine* and *clevidipine*, may be potentially useful in patients with AHF presenting with severe hypertension refractory to other therapies. In a pilot study of 104 patients with hypertensive AHF who exhibited pulmonary congestion, clevidipine

rapidly provided significant BP control associated with improvement in dyspnea compared to standard of care.[118]

Other Nonpharmacologic Therapies

Ultrafiltration

Peripheral ultrafiltration is an available modality to remove sodium and water in hospitalized patients with HF. The theoretical advantage of ultrafiltration is the removal of isotonic fluid, resulting in greater and more reliable salt removal, potentially without the neurohormonal activation seen with diuretics.[85] Potential limitations of ultrafiltration include the need for large-bore venous access, systemic anticoagulation, and increased complexity of nursing care related to management of the device. Although theoretically attractive, the appropriate use of ultrafiltration in AHF remains uncertain.

The Ultrafiltration Versus Intravenous Diuretics for Patients Hospitalized for Acute Decompensated Heart Failure (UNLOAD) trial randomized 200 patients with AHF to venovenous ultrafiltration or standard of care within 24 hours of initial presentation. Patients receiving ultrafiltration demonstrated a greater reduction in body weight at 48 hours, but no improvements in dyspnea or renal function.[119] Intriguingly, there was a reduction in postdischarge events at 90 days with ultrafiltration, although the number of events was small. Other recent studies have assessed the optimal use of ultrafiltration in HF. In an observational study of 63 patients with persistent congestion refractory to hemodynamically guided intensive medical therapy, slow continuous ultrafiltration resulted in improved hemodynamics, yet was associated with high incidence of subsequent transition to renal replacement therapy and high in-hospital mortality.[120] The Cardiorenal Rescue Study in Acute Decompensated Heart Failure (CARRESS) randomized 188 patients with AHF, WRF, and persistent congestion to a strategy of stepped pharmacologic care (IV diuretics dosed by investigator to maintain urine output of 3 to 5 L/day plus IV vasodilators or inotropes if needed to achieve target urine output) or ultrafiltration (fluid removal rate, 200 mL/hr).[60] Ultrafiltration resulted in similar weight loss (approximately 12 pounds) but resulted in an increase in creatinine levels, compared to standard care, and was associated with more serious adverse events, especially kidney failure, bleeding complications, and IV catheter-related complications. CARRESS enrolled a high-risk population with a composite rate of death or rehospitalization at 60 days greater than 50%. The AVOID-HF study (Aquapheresis Versus Intravenous Diuretics and Hospitalizations for Heart Failure) was designed as an 810-patient trial that was terminated early after 224 patients were enrolled. Although underpowered, there were trends suggesting longer time to first HF event and fewer HF and cardiovascular events in the adjustable ultrafiltration group compared to those randomized to adjustable IV loop diuretics.[121] There was no difference in renal function, but more patients assigned to ultrafiltration experienced adverse events.

Hypertonic Saline.

Administration of hypertonic saline solution (HSS, 3%) along with high-dose furosemide and sodium and fluid restriction may be associated with greater diuretic and clinical response. The SMAC-HF study randomized 1771 patients hospitalized for AHF to a single-blind strategy of HSS (150 mL 3% normal saline [NS]) plus furosemide (250-mg IV bolus twice daily) and sodium restriction to 120 mmol/day versus furosemide (250-mg IV bolus twice daily) and sodium restriction to 80 mmol/day; both groups

received a fluid intake of 1000 mL/day.[122] After discharge, the HSS group continued with 120 mmol Na/day; the second group continued with 80 mmol Na/day. There was a shorter LOS, increased creatinine clearance at discharge, reduced readmission rate, and improved survival for patients in the HSS group. These hypothesis-generating data are intriguing, but they are limited by the unblinded study design and the potential confounding by postdischarge management. Larger, prospective, blinded trials are needed to evaluate this therapeutic approach further before adoption for clinical practice.

Novel Therapies

Most of the large clinical trials of new therapies for AHF have been negative in terms of efficacy and safety (**Table 24.8**). A variety of potential explanations have been proposed, including lack of drug efficacy, patient selection, timing of therapy, and endpoints.[123] Nonetheless, given the diverse pathophysiology of AHF, it may be unrealistic to expect that a single drug would exert beneficial effects in all patients with AHF. There remain areas of significant unmet need in the treatment of AHF, including vasodilators with proven clinical benefits, agents that improve myocardial performance without significant adverse effects, and agents that improve or protect renal function. There are a number of interesting compounds that are undergoing development and clinical evaluation.

Table 24.8

Select Clinical Trials for Patients with Acute Heart Failure

TRIAL	TREATMENT ARMS	POPULATION	RESULTS
VMAC (2002) *n* = 489	Nesiritide (Nes; 0.01-0.03 μg/kg/min with optional 2-μg/kg bolus; from 24 hr up to 7 days) vs. placebo (only during first 3 hr) vs nitroglycerin (NTG; from 24 hr up to 7 days)	Dyspnea at rest ≥2 signs of HF within 72 hours CXR with pulmonary edema	Change in PCWP, at 3 hr (1°): −5.8 mm Hg Nes, −3.8 mm Hg NTG, −2 mm Hg placebo ($P < 0.001$); at 24 hr: −8.2 mm Hg Nes, −6.3 mm Hg NTG ($P < 0.04$) Self-evaluation of dyspnea at 3 hr, Likert (1°): Nes vs. placebo, $P = 0.03$; Nes vs. NTG, $P = 0.56$; at 24 hr: NTG vs. Nes, $P = 0.13$ Self-evaluation of global clinical status, at 3 hr: Nes vs. placebo, $P = 0.07$; Nes vs. NTG, $P = 0.33$; at 24 hr: NTG vs. Nes, $P = 0.08$
OPTIME-HF (2002) *n* = 951	Milrinone (0.5 μg/kg/min, titratable to 0.75) vs. placebo, for 48-72 hr	Presenting within 48 hr Known systolic HF LVEF ≤40%	Days with CV hospitalization or dead in 60 days (1°): milrinone, 12.3 vs. placebo 12.5 ($P = 0.71$) Failure of therapy due to adverse event within 48 hr: milrinone 20.6% vs. placebo 9.2% ($P < 0.001$) Excess sustained hypotension ($P = 0.004$), new atrial fibrillation/flutter ($P < 0.001$), VT/VF ($P = 0.06$)
ESCAPE (2005) *n* = 433	Pulmonary artery catheter (PAC)–guided therapy vs. clinical assessment (CA)–guided therapy	LVEF ≤30% SBP ≤125 mm Hg ≥1 sign *and* ≥1 symptom of HF 3-mo duration of HF symptoms despite ACE inhibitor and diuretics	Days alive out of hospital during 6 mo (1°): PAC, 133 days vs. CA, 135 (HR 1.00; 95% CI 0.82-1.21; $P = 0.99$) Greater number of adverse events in PAC group
VERITAS (2007) *n* = 1435	Tezosentan (Tezo; 5 mg/hr for 30 min, followed by 1 mg/hr for 24-72 hr) vs. placebo	Presenting within 24 hr Persistent dyspnea Respiratory rate ≥24 bpm At least two of: elevated BNP/NT-proBNP, clinical pulmonary edema, CXR with congestion, LV systolic dysfunction	Change in dyspnea AUC, 24 hr (1°): VERITAS-1, Tezo −562 vs. placebo −550 mm/hr ($P = 0.80$); VERITAS-2, Tezo −367 vs. placebo −342 ($P = 0.60$) Death or worsening HF, 7 days: VERITAS-1 and -2, Tezo 26.3% vs. placebo 26.4 ($P = 0.95$)
SURVIVE (2007) *n* = 1327	Levosimendan (Levo; loading 12 μg/kg, followed 0.1-0.2 μg/kg/min; for 24 hr) vs. dobutamine (Dob; 5 μg/kg/min, titratable up to 40 μg/kg/min; for at least 24 hr)	LVEF ≤30% Requiring IV inotropic support At least one of following: dyspnea at rest, oliguria, PCWP ≥18 mm Hg or CI ≤2.2 L/min/m^2	All-cause mortality, 180 days (1°): Levo, 26% vs. Dob 28% (HR 0.91; 95% CI 0.74-1.13; $P = 0.40$) Change in BNP from baseline to 24 hr: Levo, −631 vs Dob, −397, $P < 0.001$ No change in dyspnea at 24 hr, days alive out of hospital at 180 days, all-cause mortality at 31 days, CV mortality at 180 days
EVEREST (2007) *n* = 4133	Tolvaptan (Tol; 30 mg PO qd) vs. placebo, for at least 60 days	Randomized within 48 hr NYHA III-IV symptoms LVEF ≤40% Signs of volume expansion	Composite of changes in global clinical status and body weight, 7 days (1°): $P < 0.001$, for Tol superiority; no difference in clinical status; change in body weight, 1 day: Tol, −1.76 kg vs. placebo, −0.97; $P < 0.001$ All-cause mortality (1°): Tol, 25.9% vs. placebo 26.3% (HR 0.98, 95% CI 0.87-1.11, superiority $P = 0.68$; noninferiority $P < 0.001$ CV death or HF hospitalization (1°): Tol, 42.0% vs. placebo 40.2% (HR 1.04, 95% CI 0.95-1.14, superiority $P = 0.55$

UNLOAD (2007) *n* = 200	Ultrafiltration (UF; fluid removal titrated by investigator up to 500 mL/hr) vs. diuretic (titrated by investigator, at least twice daily oral dose), for 48 hr	Randomized within 24 hr ≥2 signs of congestion	Weight loss, 48 hr (1°): UF, −5.0 kg vs. diuretics, −3.1, *P* = 0.001 Dyspnea score, 48 hr (1°): UF, 6.4 vs. diuretics, 6.1; *P* = 0.35 HF rehospitalization, 90 days: UF, 0.22 vs. diuretics, 046, *P* = 0.022; days rehospitalized: UF, 1.4 days vs. diuretics, 3.8; *P* = 0.022; unscheduled HF visits: UF, 21% of patients vs. diuretics, 44%, *P* = 0.009
3CPO (2008) *n* = 1069	Noninvasive positive-pressure ventilation (NIPPV) vs. continuous positive airway pressure (CPAP) vs. oxygen therapy (O_2)	Clinical diagnosis of cardiogenic pulmonary edema CXR with pulmonary edema Respiratory rate >20 bpm Arterial pH <7.35	All-cause mortality, 7 days (1°): NIPPV + CPAP 9.5% vs. O_2 9.8% (OR 0.97, 95% CI 0.63-1.48; *P* = 0.87) Composite death or intubation, 7 days (1°): NIPPV + CPAP, 11.1% vs. O_2 11.7% (OR 0.94, 95% CI 0.59-1.51; *P* = 0.81) NIPPV + CPAP better than O_2: change in arterial pH, 1 hr (*P* < 0.001); dyspnea score, 1 hr (*P* = 0.008)
DAD-HF (2010) *n*=60	Dopamine 5 μg/kg/min plus low-dose furosemide (5 mg/hr continuous infusion) vs. high-dose furosemide (20 mg/hr continuous infusion	Hospitalized for ADHF with evidence of volume overload and eGFR ≥30 mL/min/1.73 m^2	SCr increase >0.3 mg/dL within 24 hr (1°): 6.7% low-dose dopamine/low-dose furosemide vs. 30% high-dose furosemide, *P* = 0.042 >20% decrease in eGFR within 24 hr (1°): 10% low-dose dopamine/low-dose furosemide vs. 33.3% high-dose furosemide, *P* = 0.057
PROTECT (2010) *n* = 2033	Rolofylline 30 mg vs. placebo for up to 3 days	Randomized within 24 hr, persistent dyspnea at rest or with minimal activity, estimated CrCl 20-80 mL/min, BNP ≥500 pg/mL or NT-proBNP ≥2000 pg/mL, IV loop diuretic therapy	Clinical composite (1°): OR for rolofylline 0.92, 95% CI 0.78-1.09, *P* = 0.35
DOSE (2011) *n* = 308	Low-dose vs. high-dose furosemide Continuous vs. intermittent intravenous bolus 1 : 1:1 : 1 2 × 2 factorial design	Randomized within 24 hr ≥1 sign and ≥1 symptom of HF, history of chronic HF treated with furosemide 80-240 mg/day (or equivalent) for at least 1 mo	Global assessment of symptoms (1°): 4236 ±1440 AUC bolus vs. 4373 ±1404 AUC continuous infusion, *P* = 0.47; 4171 ±1436 AUC low dose vs. 4430 ±1401 AUC high dose, *P* = 0.06 Mean change in SCr (1°): 0.05 mg/dL bolus vs. 0.07 mg/dL continuous infusion, *P* = 0.45; 0.04 mg/dL low dose vs. 0.08 mg/dL high dose, *P* = 0.21
ASCEND-HF (2011) *n* = 7141	Nesiritide (Nes) 0.01 μg/kg/min with optional 2 μg/kg bolus (from 24 hr up to 7 days) vs. placebo)	Hospitalized for ADHF, dyspnea at rest, or with minimal activity, ≥1 sign and ≥1 objective measure of ADHF, randomized within 24 hr of first IV treatment for ADHF	Self-reported dyspnea moderately or markedly better at 6 hr: 42.1% placebo vs. 44.5% Nes, *P* = 0.03*; at 24 hr: 66.1% placebo vs. 68.2% Nes, *P* = 0.007* Death or rehospitalization for HF at 30 days: 10.1% placebo vs. 9.4% Nes (HR 0.93, 95% CI 0.8-1.08, *P* = 0.31)
CARRESS-HF (2012) *n* = 188	Ultrafiltration (UF) vs. stepped pharmacologic care (Pharm)	Develop cardiorenal syndrome before (within 6 wk) or after (within 7 days from admission) hospitalization	Change in creatinine level: UF +0.23 mg/dL vs. Pharm −0.04 ±0.53 mg/dL, *P* = 0.003 Weight loss: 5.5 ±5.1 kg [12.1 ±11.3 lb] in Pharm group vs. 5.7 ±3.9 kg [12.6 ±8.5 lb] in UF group, *P* = 0.58 Serious adverse events: 72% in UF group vs. 57% in Pharm group, *P* = 0.03
RELAX-AHF (2013) *n* = 1161	Serelaxin (Ser) 30 μg/kg/day vs. placebo for 48 hours	Patients with dyspnea at rest or on minimal exertion, congestion on chest x-ray, BNP ≥350 ng/L (or NT-proBNP ≥1400 ng/L), eGFR 30-75 mL/min/1.73 m^2, and SBP >125 mm Hg	Change in dyspnea by VAS AUC to day 5 (1°): 19% improvement by Ser compared to placebo by VAS AUC (448 mm/hr, 95% CI 120-775), *P* = 0.007 Proportion of patients with moderately or markedly improved dyspnea by Likert scale at all 3 early timepoints (6, 12, 24 h; 1°): Ser 27% vs. placebo 26%, *P* = 0.70 Days alive out of hospital up to day 60: Ser 48.3 vs. placebo 47.7, *P* = 0.37 180-day mortality: placebo 65 deaths vs. Ser 42, HR 0.63 (95% CI 0.43-0.93), *P* = 0.02
REVIVE-2 (2013) *n* = 600	Levosimendan (Levo; loading 12 μg/kg, followed by 0.1-0.2 μg/kg/min; for 24 hr) vs. placebo	Dyspneic at rest LVEF ≤35%	Clinical composite endpoint, 5 days (1°): Levo superior, *P* = 0.015 More frequent hypotension and cardiac arrhythmias, during the infusion period; numerically higher risk of death, 90 days (REVIVE-1 and -2: Levo, 49 deaths/350 patients; vs. placebo, 40/350, *P* = 0.29)
ROSE (2013) *n* = 360	Dopamine (2 μg/kg/min; *n* = 122) Nesiritide (0.005 μg/kg/min without bolus; *n* = 119) Pooled placebo group (*n* = 119)	Acute heart failure Renal dysfunction (eGFR 15-60 mL/min/1.73 m^2) Randomized within 24 hr of admission	Compared to placebo: Dopamine: no significant effect on 72-hr cumulative urine volume or on change in cystatin C level; increased tachycardia Nesiritide: no significant effect on 72-hr cumulative urine volume or on change in cystatin C level
DAD-HF II (2014) *n* = 161	8-hour continuous infusions of (a) high-dose furosemide (HDF, *n* = 50, 20 mg/hr), (b) low-dose furosemide and low-dose dopamine (LDFD, *n* = 56, 5 mg/hr and 5 μg kg^{-1} min^{-1}, respectively), or (c) low-dose furosemide (LDF, *n* = 55, furosemide 5 mg/hr)	Dyspnea on minimal exertion or rest dyspnea Oxygen saturation <90% on admission ABGs One or more of (a) signs of congestion, (b) interstitial congestion or pleural effusion on chest x-ray, and (c) elevated serum BNP levels	No significant differences in 60-day and 1-year all-cause mortality and hospitalization for HF, dyspnea relief (Borg index), worsening renal function, and LOS
AVOID-HF (2016) *n* = 224 (810 planned)	Adjustable ultrafiltration (AUF; *n* = 110)) Adjustable IV loop diuretics (ALD; *n* = 114).	Chronic daily oral loop diuretics Fluid overload Received ≤2 IV loop diuretic doses Randomized within 24 hr of admission	Estimated days to first HF event 62 for AUF group vs. 34 for ALD group, *P* = 0.106 At 30 days, fewer HF and CV events for AUF vs. ALD group Renal function changes similar More AUF patients with adverse events
ATOMIC-AHF (2016) *n* = 606	3 sequential cohorts (~200 patients per cohort): Cohort 1: Omecamtiv mecarbil (OM, target plasma concentration 115 ng/mL) vs. placebo Cohort 2: OM (target plasma concentration, 230 ng/mL) vs.	LVEF ≤40% Dyspnea at rest or with minimal exertion Elevated natriuretic peptides Randomized within 24 hr of initial IV diuretic.	Dyspnea relief: no significant difference vs. placebo (3 OM dose groups and pooled placebo: placebo, 41%; OM cohort 1, 42%; cohort 2, 47%; cohort 3, 51%; *P* = 0.33); increased dyspnea relief in cohort 3 at 48 hr (placebo, 37% vs. OM, 51%; *P* = 0.034) and through 5 days (*P* = 0.038) Plasma concentration-related increases in LVEF (*P* < 0.0001) and decreases in end-systolic dimension (*P* < 0.05).

	placebo Cohort 3: OM (target plasma concentration 310 ng/mL) vs. placebo		
BLAST-AHF (2016) *n* = 621	a. Placebo (*n* = 183) b. TRV027 1 mg/hr (*n* = 128) c. TRV027 5 mg/hr (*n* = 182) d. TRV027 25 mg/hr (*n* = 125)	History of HF Elevated natriuretic peptides ≥2 physical HF signs SBP ≥120 and ≤200 mm Hg eGFR (sMDRD) 20-75 mL/min/1.73 m^2 Excluded if use of ARBs 7 days prior, IV inotropes or vasopressors within 2 hours prior, or IV nitrates within 1 hr prior to randomization	1° endpoint (multiple outcomes, analyzed as composite z-score), including (1) time from baseline to death through day 30, (2) time from baseline to HF rehospitalization through day 30, (3) first assessment timepoint after worsening HF through day 5, (4) change in dyspnea VAS AUC representing change from baseline over time from baseline through day 5, and (5) initial LOS (in days) from baseline: no difference in any group
TACTICS (2016) *n* = 257	a. Placebo (*n* = 128) b. Tolvaptan (Tol) (*n* = 129)	Acute HF within 24 hr of presentation Elevated natriuretic peptides + 1 additional sign or symptom of congestion Serum sodium ≤140 mmol/L	Dyspnea relief by Likert scale similar between Tol and placebo at 8 hr (25% moderately or markedly improved for Tol vs. 28% placebo, *P* = 0.59) and at 24 hr (50% Tol vs. 47% placebo, *P* = 0.80); proportion defined as responders at 24 hr (1°) 16% for Tol and 20% for placebo, *P* = 0.32; Tol resulted in greater weight loss and net fluid loss vs. placebo, but Tol patients more likely to experience worsening renal function during treatment
TRUE-AHF (2017) *n* = 2157	a. Placebo (*n* = 1069) b. Ularitide (Ula) (*n* = 1088)	Men or women, age 18-85 Unplanned hospitalization or ED visit for acutely decompensated HF Dyspnea at rest, worsening within past week Evidence of HF on CXR BNP >500 pg/mL or NT-proBNP >2000 pg/mL Persistence of dyspnea at rest despite ≥40 mg of IV furosemide (or equivalent) Systolic BP ≥116 and ≤180 mm Hg Start of study drug infusion within 12 hr after initial clinical assessment	Cardiovascular death (1°): Ula 235 deaths, placebo 225; HR = 1.03 (96% CI 0.85-1.25); *P* = 0.75; hierarchical clinical composite at 48 hr (1°): *P* = 0.82 2°: Intensive care LOS during first 120 hours, hospital length of stay during first 30 days, episodes of in-hospital WHF during first 120 hours, proportion with WHF during first 120 hours, rehospitalization for HF within 30 days of hospital discharge, duration (hr) of IV therapy for HF during index admission, all-cause mortality or CV hospitalization at 6 months: all NS; change in NT-proBNP at 48 hr: 47% decrease with Ula, *P* < 0.001; change in serum creatinine during first 72 hr: increased with Ula, *P* = 0.005 Adverse events: hypotension: placebo 10.1% vs. Ula 22.4%; no difference in renal events
RELAX-AHF-2 (2017) *n* = 6545	a. Placebo (*n* = 3271) b. Serelaxin (Ser) (*n* = 3274)	Patients with dyspnea at rest or on minimal exertion, congestion on CXR, BNP ≥500 ng/L (or NT-proBNP ≥2000 ng/L), eGFR >25-75 mL/min/1.73 m^2, SBP >125 mm Hg	Cardiovascular death (1°): Ser 285 deaths, placebo 290; HR = 0.98 (95% CI:0.83-1.15); *P* = 0.39; WHF through day 5 (1°): Ser 6.9%, placebo 7.7%, HR = 0.89 (95% CI 0.75-1.07); *P* = 0.097

Vasodilating Agents.

A variety of novel molecules with vasodilator properties are in development as therapeutics for AHF.[91]

Serelaxin.

Relaxin was first identified as a major hormone of pregnancy with powerful systemic and renal vascular effects, as well as beneficial effects on cardiac preconditioning and ischemia, inflammation, fibrosis, and apoptosis. Serelaxin (recombinant human relaxin-2) demonstrated encouraging effects in a dose-finding pilot study of 234 patients with AHF.[124] The Phase III RELAX-AHF (Efficacy and Safety of Relaxin for the Treatment of Acute Heart Failure) trial enrolled 1161 patients within 16 hours of presentation who had dyspnea, congestion, mild to moderate renal insufficiency, and SBP greater than 125 mm Hg and randomized them to standard of care with a 48-hour infusion of either serelaxin (30 µg/kg/day) or placebo.[125] The trial demonstrated efficacy of serelaxin in improving dyspnea as quantified by the area under the curve of the change from baseline dyspnea visual analog scale over 5 days, which was associated with improvements in signs of congestion, decreased in-hospital WHF, shorter LOS, and both CV and all-cause mortality at 180 days. There were no significant changes in the dyspnea score, as assessed by the 7-level Likert scale over the first 24 hours, and no endpoint related to HF rehospitalization. Serelaxin treatment was also associated with improved markers of end-organ damage or dysfunction, including cardiac, renal, and hepatic markers.[24] There were no serious adverse events of hypotension or other safety signals in the serelaxin-treated patients. Mechanistic studies have confirmed serelaxin's beneficial effects on hemodynamics[126] and renal function.[127] Based on the promising results of RELAX-AHF, the RELAX-AHF-2 trial enrolled more than 6600 patients admitted for AHF and evaluated the effects of serelaxin compared to placebo on the independently powered primary endpoints of WHF through 5 days and 180-day CV mortality.[63] In this large global outcomes study, serelaxin did not improve either the primary endpoint of CV mortality at 180 days or WHF through day 5 compared to placebo.[128]

Ongoing analyses of data from RELAX-AHF-2 and prior studies of serelaxin may provide additional insights into these results, but at present the data do not support a role for the routine use of serelaxin in patients with AHF.

Natriuretic Peptides.

Multiple different natriuretic peptides continue to be developed and investigated for the treatment of AHF, including naturally-occurring and alternatively spliced peptides and chimeric designer peptides. *Urodilatin*, a modified version of pro-ANP, is a 32–amino acid hormone synthesized and secreted from the distal tubules of the kidney that regulates renal sodium absorption and water homeostasis via binding to NPR1 receptors and increasing intracellular cGMP levels. *Ularitide*, a synthetically produced urodilatin, has demonstrated beneficial effects on hemodynamics and symptom relief in two studies of patients with AHF.[129] The TRUE-AHF trial enrolled 2157 patients with symptomatic AHF and randomized them to a 48-hour infusion of either ularitide (15 ng/kg/min) or placebo. Ularitide did not significantly improve either primary endpoint of clinical composite through 5 days or CV mortality during the course of the study. Ularitide had no beneficial effect on any secondary endpoint without evidence of end-organ protection and increased creatinine associated with a doubling of hypotension.[130]

Neurohormonal Antagonists.

Direct renin inhibitors (DRIs) block the first enzymatic step in the RAAS cascade, leading to a profound suppression of this neurohormonal system (**see Chapters 23 and 25**). Given the role of RAAS in the pathogenesis and complications of HF, as well as the improved survival associated with its inhibition, further blockade of this system may confer additional survival benefits. *Aliskiren* is the first oral DRI on the market and currently approved for the treatment of hypertension. The ASTRONAUT trial enrolled 1639 hemodynamically stable patients at a median 5 days after admission for AHF with EF less than 40%, elevated natriuretic peptides, and signs or symptoms of fluid overload who were randomized to daily oral aliskiren or placebo.[131] Aliskiren treatment was associated with higher rates of hyperkalemia, hypotension, and renal impairment/failure compared to placebo after a median follow-up of 11.3 months, but there was no difference in CV death or HF rehospitalization at 6 or 12 months.

Endothelin receptor antagonists block the actions of ET-1, the most powerful endogenous vasoconstrictor produced by the vascular endothelial cells. It exerts its effects by binding to two receptors, ET_A and ET_B, located on the vascular smooth muscle cells, resulting in significant systemic arterial vasoconstriction. *Tezosentan*, a nonselective ET_{A-B} antagonist, has been shown to improve hemodynamics in patients with AHF. The Value of Endothelin Receptor Inhibition with Tezosentan in Acute Heart Failure Study (VERITAS) studied more than 1400 patients admitted with AHF in a large international trial. The addition of IV tezosentan to standard therapy did not improve symptoms nor decrease worsening HF or mortality at 7 days after randomization.[132] Another approach to neurohormonal antagonism in AHF included the angiotensin II type I receptor beta-arrestin–biased ligand *TRV027*, which increases signaling of the beta-arrestin–mediated pathways stimulating inotropy while simultaneously antagonizing the classic G-protein angiotensin II–signaling pathways. The BLAST-AHF study enrolled 621 patients admitted with AHF in a dose-ranging study of a 48- to 96-hour infusion of TRV027 compared to placebo.[133] TRV027 conferred no benefit over placebo at any dose with regard to the primary composite endpoint or any of the individual components, although there were no significant safety issues.

Soluble Guanylate Cyclase Activators and Stimulators.

Cinaciguat is the first compound in a new class of vasodilators. Their mechanism of action is similar to that of organic nitrates (and their end product NO), since both classes of drugs activate the soluble form of guanylate cyclase (sGC) in smooth muscle cells, thus leading to the synthesis of cGMP and subsequent vasodilation. Cinaciguat has been shown to improve hemodynamics in patients with AHF; at high doses, however, it has been associated with significant hypotension, which resulted in the termination of early

clinical studies.[134] *Vericiguat* is an oral sGC stimulator studied in patients enrolled within 4 weeks of a WHF event. In the SOCRATES-Reduced study of 456 patients, vericiguat did not significantly improve log-transformed NT-proBNP concentrations compared to placebo, but there was a suggestion of a dose-response effect.[135]

Inotropic Agents

Cardiac Myosin Activators.

A new mechanistic class of agents designed to increase myocardial contractility, cardiac myosin activators increase the transition rate from the weakly bound to the strongly bound state necessary for initiation of a force-generating power stroke. Unlike current inotropes, these agents increase the systolic ejection time without altering the rate of LV pressure development, resulting in increased stroke volume and cardiac output without increases in intracellular cAMP or calcium. *Omecamtiv mecarbil* is the first agent of this class to undergo human testing. In both healthy volunteers and patients with chronic stable HF with reduced EF, administration of omecamtiv mecarbil produced dose-dependent increases in systolic ejection time, fractional shortening, stroke volume, and EF and was well-tolerated over a broad range of plasma concentrations.[136] In a phase IIb dose-finding study of 606 patients with AHF (ATOMIC-AHF), IV omecamtiv mecarbil did not meet the primary endpoint of dyspnea improvement compared to the pooled placebo, but it was generally well tolerated, increased systolic ejection time, and improved dyspnea in the high-dose group.[137]

Istaroxime.

The prototype of a new class of drugs, istaroxime exerts its actions on the myocyte in two ways: by stimulation of the membrane-bound Na^+,K^+-ATPase pathway and by enhancing the activity of the sarcoendoplasmic reticulum Ca^{2+}-ATPase type 2a (SERCA2a). These two distinct mechanisms result, respectively, in increased cytosolic calcium accumulation during systole, with positive inotropic effects, and in rapid sequestration of cytosolic calcium into the sarcoplasmic reticulum during diastole, leading to an enhanced lusitropic effect. The HORIZON-HF study evaluated 120 patients admitted with AHF and decreased EF. The addition of istaroxime to standard therapy lowered PCWP and heart rate and increased SBP. The higher infusion dose increased cardiac index and reduced LV end-diastolic volume. There were no changes in neurohormones, renal function, or troponin I levels during the short, 6-hour infusion.[138,139]

Renoprotective Agents.

Therapeutics to prevent or treat acute kidney injury (AKI) and maintain or improve renal function in the setting of AHF are an important unmet need. *Adenosine A_1 receptor antagonists* have been developed to increase renal blood flow and enhance diuresis without activating the tubuloglomerular feedback. *Rolofylline* is a highly selective adenosine A_1 receptor antagonist that has been studied in patients with HF. Despite the positive trends seen in the PROTECT-Pilot study, the Phase III PROTECT trial failed to show any clinical benefit, including renal protection,[140] and was associated with more seizure and stroke events compared to placebo. Given these results, it is doubtful that these agents will undergo further evaluation in AHF.

Future Perspectives

Acute heart failure remains one of the most challenging cardiovascular problems, with unacceptably high postdischarge rehospitalization and mortality rates. The development of new therapies has been a

persistent challenge over recent decades, and most patients are still treated primarily with intravenous loop diuretics. Current management consists primarily of treating the manifestations of the syndrome rather than central pathophysiologic derangements. Improvement in understanding of underlying pathophysiology and better targeting of treatments to specific patient groups most likely to benefit will potentially provide greater success in developing efficacious new therapies for AHF. Given the heterogeneity of the AHF population, it is unlikely that a “one therapy fits all” approach will lead to an improvement in outcomes. While new therapies are sought, continued efforts to improve and standardize the use of “best practices” in terms of process of care, transitions of care, and postdischarge follow-up, will potentially allow us to better utilize currently available therapies to improve outcomes from this highly morbid condition.

Guidelines

The Hospitalized Patient

G. Michael Felker and John R. Teerlink

The most significant addition to the 2009 American College of Cardiology and American Hospital Association (ACC/AHA) updated guidelines was inclusion of specific new recommendations regarding the hospitalized patient (**Table 24G.1**). Although there were a number of new class I indications involving the diagnosis of heart failure, the use of B-type natriuretic peptide and N-terminal pro-B natriuretic peptide (NT-proBNP), recognition of acute coronary syndromes, recognition of potential precipitating factors, use of supplemental oxygen, use of intravenous inotropic or pressure agents in patients with clinical evidence of hypotension with hypoperfusion, use of pulmonary artery catheters, and transition of intravenous to oral diuretics, the level of evidence supporting each of these recommendations was based on consensus opinion or standard use of care (i.e., level of evidence, C). Stronger class I recommendations (level of evidence, B) were provided for the use of intravenous diuretics to decongest patients, initiation of ACE inhibitors/ARBs, and beta blockers before hospital discharge, as well as the importance of postdischarge systems of care.

TABLE 24G.1

ACC/AHA Recommendations for the Hospitalized Patient with Heart Failure (HF)

CLASS	INDICATION	LEVEL OF EVIDENCE*
I	Thorough history and physical examination to evaluate for adequacy of systemic perfusion, volume status, contribution of precipitating factors and/or comorbidities, and whether HF is associated with preserved ejection fraction.	C
	Concentrations of B-type natriuretic peptide (BNP) or N-terminal pro-B-type natriuretic peptide (NT-proBNP) to evaluate dyspnea if the contribution of heart failure is not known.	A
	Acute coronary syndrome should be promptly identified by electrocardiogram and cardiac troponin testing, and treated, as appropriate to the overall condition and prognosis of patient.	C
	Oxygen therapy should be administered to relieve symptoms related to hypoxemia.	C
	Improve systemic perfusion in patients who present with rapid decompensation and hypoperfusion associated with decreasing urine output and other manifestations of shock.	C
	Treatment of significant fluid overload with intravenous loop diuretics. The diuretic dose should be titrated to relieve symptoms and to reduce extracellular fluid volume excess.	B, C
	Monitored the effects of therapy with careful measurement of fluid intake and output; vital signs; body weight, and symptoms of systemic perfusion and congestion.	C
	Intensify the diuretic regiment when the diuresis is inadequate to relieve congestion.	C
	Intravenous inotropic or vasopressor drugs should be administered to maintain systemic perfusion and preserve end-organ performance in patients with clinical evidence of hypotension associated with hypoperfusion and elevated cardiac filling pressures.	C
	Invasive hemodynamic monitoring to guide therapy in patients who are in respiratory distress or with clinical evidence of impaired perfusion if filling pressures cannot be determined from clinical assessment	C
	Medications should be reconciled and adjusted as appropriate on admission to and discharge from the hospital.	C
	Maintenance treatment with oral therapies known to improve outcomes (ACE inhibitors or ARBs and beta-blocker therapy) in the absence of hemodynamic instability or contraindications.	C
	Initiation of treatment with oral therapies known to improve outcomes (ACE inhibitors or ARBs and beta-blocker therapy) in stable patients prior to hospital discharge.	B
	During transition from intravenous to oral diuretic therapy, patient should be monitored carefully for supine and upright hypotension, worsening renal function, and HF signs/symptoms.	C
	Comprehensive written discharge instructions for patients and their caregivers is strongly recommended.	C
	Postdischarge systems of care, if available, should be used to facilitate the transition to effective outpatient care.	B
IIa	Urgent cardiac catheterization and revascularization in patients with acute HF with known or suspected acute myocardial ischemia due to occlusive coronary disease when there are signs and symptoms of inadequate systemic perfusion and revascularization is likely to prolong meaningful survival.	C
	Intravenous nitroglycerin, nitroprusside, or nesiritide for patients with evidence of severely symptomatic fluid overload in the absence of systemic hypotension.	C
	Ultrafiltration for patients with refractory congestion not responding to medical therapy.	B
IIb	Intravenous inotropic drugs (dopamine, dobutamine, or milrinone) for patients presenting with documented severe systolic dysfunction, low blood pressure, and evidence of low cardiac output, with or without congestion, to maintain systemic perfusion and preserve end-organ performance.	C
III	Use of parenteral inotropes in normotensive patients with acute decompensated HF without evidence of decreased organ perfusion.	B
	Routine use of invasive hemodynamic monitoring in normotensive patients with acute decompensated HF and congestion with symptomatic response to diuretics and vasodilators.	B

*See guidelines text for definition of level of evidence categories.

ACC, American College of Cardiology; *AHA,* American Heart Association.

The updated guidelines offer qualified support (class IIa) for the use of urgent catheterization and revascularization, the use of vasodilators (intravenous nitroglycerin, nitroprusside, nesiritide), invasive hemodynamic monitoring, and ultrafiltration. More muted support (class IIb) was given for the use of inotropic agents (dopamine, dobutamine, or milrinone) in patients with severe left ventricular dysfunction, low blood pressure, and evidence of low cardiac output. In contrast, the use of inotropic agents in patients without evidence of decreased organ perfusion, as well as the routine use of invasive hemodynamic monitoring, was not recommended (class III indication).

Management of Heart Failure Patients with Reduced Ejection Fraction

Douglas L. Mann

The epidemiology and clinical assessment of patients with heart failure (HF) are reviewed in **Chapter 21**. The diagnosis and management of patients with acute HF are discussed in **Chapter 24**. This chapter focuses on the management of HF patients with a reduced ejection fraction (HFrEF). **Chapter 26** discusses he management of HF patients a preserved ejection fraction (HFpEF).

Etiology

Any condition that leads to an alteration in left ventricular (LV) structure or function can predispose a patient to developing HF (**Table 25.1**). Although the etiology of HF in patients with HFrEF differs from that of patients with HFpEF, there is considerable overlap between the etiologies of these two conditions. In industrialized countries, coronary artery disease (CAD) is the predominant cause in men and women and is responsible for 60% to 75% of cases of HF. Hypertension contributes to the development of HF in a significant number of patients, including most patients with CAD. Both CAD and hypertension interact to augment the risk of HF. Rheumatic heart disease remains a major cause of HF in Africa and Asia, especially in the young population. Hypertension is an important cause of HF in the African and African American population. Chagas disease is still a major cause of HF in South America.[1] As developing nations undergo socioeconomic development, the epidemiology of HF is becoming similar to that of Western Europe and North America, with CAD emerging as the single most common cause of HF.

TABLE 25.1

Risk Factors for Cardiac Failure (Olmstead County)

RISK FACTOR	ODDS RATIO (95% CI)	*P* VALUE	POPULATION-ATTRIBUTABLE RISK (95% CI)		
			Overall	Women	Men
Coronary heart disease	3.05 (2.36-3.95)	<.001	0.20 (0.16-0.24)	0.16 (0.12-0.20)	0.23 (0.16-0.30)
Hypertension	1.44 (1.18-1.76)	<.001	0.20 (0.10-0.30)	0.28 (0.14-0.42)	0.13 (0.00-0.26)
Diabetes	2.65 (1.98-3.54)	<.001	0.12 (0.09-0.15)	0.10 (0.06-0.14)	0.13 (0.08-0.18)

From Dunlay SM, Weston SA, Jacobsen SJ, et al. Risk factors for heart failure: a population-based case-control study. Am J Med 2009;122:1023-8.

In 20% to 30% of HFrEF cases, the exact etiologic basis is not known. These patients are referred to as having dilated or “idiopathic” cardiomyopathy if the cause is unknown (**see Chapter 77**). Prior viral infection (**Chapter 79**) or toxin exposure (e.g. alcohol [**Chapter 80**] or use of chemotherapeutic agents [**Chapter 81**]) may also lead to a dilated cardiomyopathy (DCM). Although excessive alcohol consumption can promote cardiomyopathy, alcohol per se is not associated with increased risk for HF and may protect against the development of HF when consumed in moderation.[2] It is also becoming increasingly clear that a large number of DCM cases are secondary to specific genetic defects, most notably those in the cytoskeleton. Most of the forms of familial DCM are inherited in an autosomal dominant manner. Mutations of genes encoding cytoskeletal proteins (desmin, cardiac myosin, vinculin) and nuclear membrane proteins (lamin) have been identified thus far. DCM is also associated with Duchenne, Becker, and limb-girdle muscular dystrophies (**see Chapter 97**). Conditions that lead to a high cardiac output (e.g., arteriovenous fistula, anemia) are seldom responsible for the development of HF in a normal heart. However, in the presence of underlying structural heart disease, these conditions often lead to overt congestive heart failure.

Prognosis

Although several recent reports have suggested that the mortality for HF patients is improving, the overall mortality rate remains higher than for many cancers, including those involving the bladder, breast, uterus, and prostate. In the Framingham Study, the median survival was 1.7 years for men and 3.2 years for women, with only 25% of men and 38% of women surviving 5 years. European studies have confirmed a similar poor long-term prognosis (**Fig. 25.1**).[3] More recent data from the Framingham Study have examined long-term trends in the survival of HF patients and shown improved survival in both men and women, with an overall decline in mortality of approximately 12% per decade from 1950 to 1999. Moreover, recent reports from Scotland, Sweden, and the United Kingdom also suggested that survival rates may be also improving following hospital discharge.[3] Of note, HF mortality in epidemiologic studies is substantially higher than that reported in clinical HF trials involving drug and device therapies, in which the mortality figures are often deceptively low because the patients enrolled in trials are younger, are more stable clinically, and tend to be followed more closely clinically.

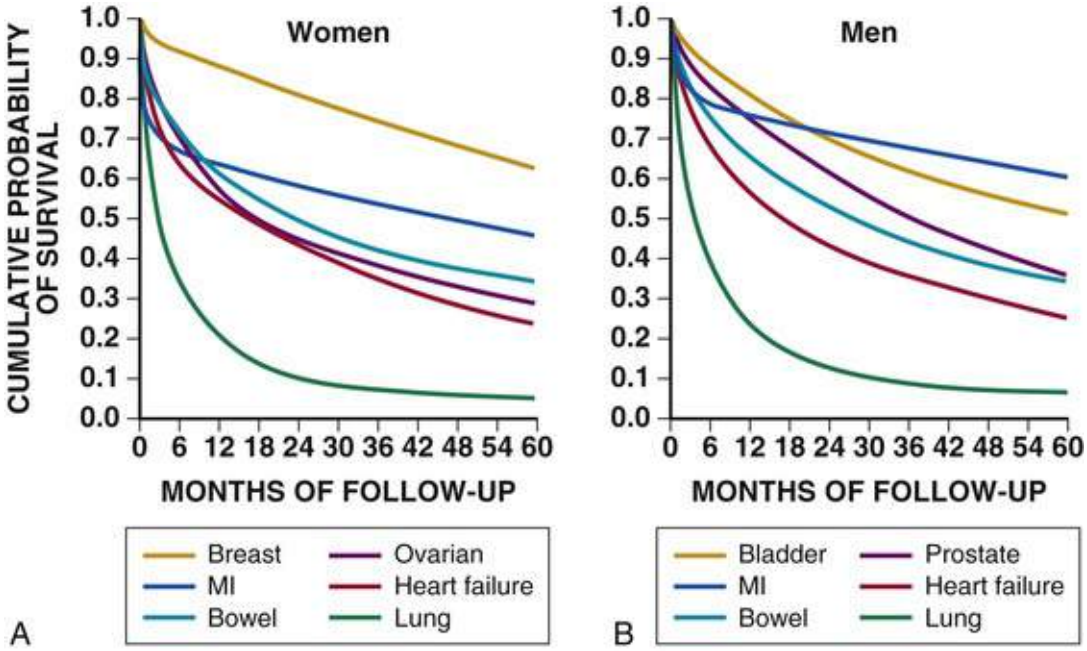

FIGURE 25.1 Survival in HF patients compared to cancer. Five-year survival following a first admission to any Scottish hospital in 1991 for heart failure, myocardial infarction (MI), and the four most common sites of cancer specific to men and women. (Modified from Stewart S, MacIntyre K, Hole DJ, et al. More 'malignant' than cancer? Five-year survival following a first admission for heart failure. Eur J Heart Fail 2001;3:315-22.)

The role of gender and HF prognosis remains a controversial issue with respect to HF outcomes. Nonetheless, the aggregate data suggest that women with HF have a better overall prognosis than do men.[4] However, women appear to have a greater degree of functional incapacity for the same degree of left ventricular (LV) dysfunction and also have higher prevalence of HF with a normal ejection fraction (EF) (**see Chapter 26**). Controversy has also arisen regarding the impact of race on outcome, with higher mortality rates being reported in blacks in some but not all studies. In the United States, HF affects approximately 3% of blacks, whereas in the general population, the prevalence is about 2%.[5] Blacks with HF present at an earlier age and have more advanced LV dysfunction and a worse New York Heart Association (NYHA) class at diagnosis. Although the reasons for these differences are not known, as previously noted, differences in HF etiology might explain some of these observations. Additional socioeconomic factors may influence outcomes in black patients, such as geographic location and access to health care. Age is one of the stronger and most consistent predictors of adverse outcome in HF[6] (see later, Special Populations).

Many other factors have been associated with increased mortality in HF patients (**Table 25.2**). Most of the factors listed as outcome predictors have withstood univariate analysis at least, with many standing out independently when multifactorial analysis techniques are employed. Nonetheless, it is extraordinarily difficult to determine which prognostic variable is most important to predict individual patient outcome in either clinical trials or, more importantly, during the day-to-day management of an individual patient. To this end, several multivariate models for predicting the HF prognosis has been developed and validated. The Seattle Heart Failure Model was derived by retrospectively investigating predictors of survival among HF patients in clinical trials. This model provides an accurate estimate of 1-, 2-, and 3-year survival with the use of easily obtained clinical, pharmacologic, device, and laboratory characteristics and is accessible free of charge to all health care providers as an interactive Internet-based program (http://depts.washington.edu/shfm).

Chronic anemia

*Conditions that can also lead to HF with a preserved ejection fraction.

Biomarkers and Prognosis

The observation that the renin-angiotensin-aldosterone (RAAS), adrenergic, and inflammatory systems are activated in HF has prompted the examination of the relationships between a variety of biochemical measurements and clinical outcomes (**Table 25.3**) (**see Chapters 21 and 23**). Strong inverse correlations have been reported between survival and plasma levels of norepinephrine, renin, arginine vasopressin, aldosterone, atrial (ANP) and brain (B-type) (BNP and NT-proBNP) natriuretic peptides, endothelin (ET)-1, and inflammatory markers such as tumor necrosis factor (TNF), soluble TNF receptors, C-reactive protein, galactin-3, pentraxin-3, and soluble ST2. Markers of oxidative stress, such as oxidized low-density lipoprotein, and serum uric acid, have also been associated with worsening clinical status and impaired survival in patients with chronic HF. Cardiac troponin T and I, sensitive markers of myocyte damage, may be elevated in patients with nonischemic and predict adverse cardiac outcomes. The association between a low hemoglobin/hematocrit (Hb/Hct) and adverse HF outcomes has also long been recognized, with recent renewed attention after several reports illustrated the independent prognostic value of anemia in patients with HF with either reduced or normal EF.[7]

TABLE 25.3

Prognostic Variable in Heart Failure Patients

Demographics	**Exercise Testing**
Gender	Metabolic assessment
Race	BP response
Age	Heart rate response
Heart Failure Etiology	6-min walk
CAD	Peak VO_2
IDCM	Anaerobic threshold
Valvular heart disease	VE/VCO_2
Myocarditis	Oxygen uptake slope
Hypertrophy	**Metabolic**
Alcohol	Serum sodium
Anthracyclines	Thyroid dysfunction
Amyloidosis	Anemia
Hemochromatosis	Acidosis/alkalosis
Genetic factors	**Chest Radiograph**
Comorbidities	Congestion
Diabetes	Cardiothoracic ratio
Systemic hypertension	**Electrocardiogram**
Pulmonary hypertension	Rhythm (atrial fibrillation or arrhythmias)
Sleep apnea	Voltage
Obesity/cachexia (body mass)	QRS width
Renal insufficiency	QT interval
Hepatic abnormalities	Signal-average ECG (T wave alternans)
COPD	HR variability
Clinical Assessment	**Biomarkers**
NYHA class (symptoms)	NE, PRA, AVP, aldosterone
Syncope	ANP, BNP, NT-proBNP, endothelin
Angina pectoris	TNF, sTNFR 1,2, galectin-3, pentraxin-3, sST2
Systolic vs. diastolic dysfunction	Cardiac troponins, hematocrit
Hemodynamics	**Endomyocardial Biopsy**
LVEF	Inflammatory states
RVEF	Degree of fibrosis
PAP	Degree of cellular disarray
PCWP	Infiltrative processes
CI	
PAP-PCWP	
Exercise hemodynamics	

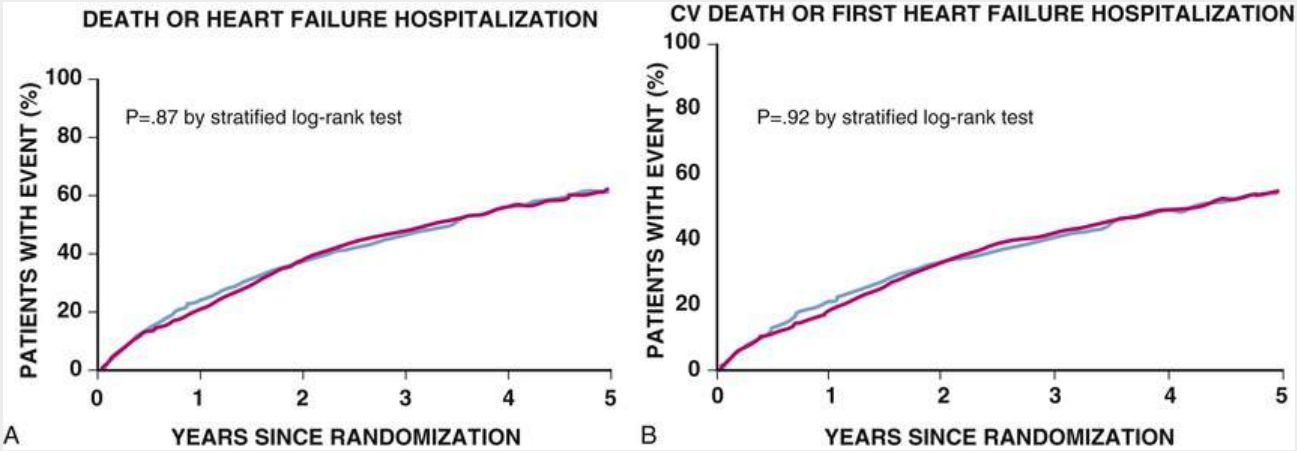
AVP, Arginine vasopressin; *BP,* blood pressure; *CAD,* coronary artery disease; *CI,* cardiac index (width); *COPD,* chronic obstructive pulmonary disease; *CRP,* C-reactive protein; *ESR,* erythrocyte sedimentation rate; *IDCM,* idiopathic dilated cardiomyopathy; *IL,* interleukin; *LVEF,* left ventricular ejection fraction; *NE,* norepinephrine; *NYHA,* New York Heart Association; *PAP,* pulmonary artery pressure; *PAP-PCWP,* gradient across lung; *PCWP,* pulmonary capillary wedge pressure; *RVEF,* right ventricular ejection fraction; *TNF,* tumor necrosis factor.

Modified from Young JB. The prognosis of heart failure. In Mann DL, editor. Heart Failure: A Companion to Braunwald's Heart Disease. Philadelphia: Elsevier; 2004, pp 489-506.

Published estimates of the prevalence of anemia (defined as Hb concentration <13 g/dL in men and <12 g/dL in women) in HF patients vary widely, ranging from 4% to 50% depending on the population studied and definition of anemia used. In general, anemia is associated with more HF symptoms, worse NYHA functional status, greater risk of HF hospitalization, and reduced survival.[8] However, it is unclear whether anemia is a cause of decreased survival or simply a marker of more advanced disease. The underlying cause for anemia is likely multifactorial, including reduced sensitivity to erythropoietin receptors, presence of a hematopoiesis inhibitor, and defective iron supply for erythropoiesis.

A standard diagnostic workup should be undertaken in anemic HF patients, recognizing that no definite etiology is identified in many of these patients. Correctable causes of anemia should be treated according to practice guidelines. The role for blood transfusions in patients with cardiovascular (CV) disease is controversial. Although a “transfusion threshold” for maintaining the Hct above 30% in patients with CV disease has been generally been accepted, this clinical practice has been based more on expert opinion

rather than on direct evidence that documents the efficacy of this form of therapy. Given the risks and costs of red blood cell transfusion, the evanescent benefits of blood transfusions in patients with a chronic anemia, coupled with the unclear benefit in HF patients, the routine use of blood transfusion cannot be recommended for treating the anemia that occurs in stable HF patients. Treatment of anemic HF patients with mild to moderate anemia (Hb level 9.0 to 12.0 g/dL) with the erythropoietin analogue darbepoetin alpha was evaluated in the RED-HF (Reduction of Events with Darbepoetin Alfa in Heart Failure) trial. As shown in **eFig. 25.1**, there was no significant difference in the primary outcome variable of death from any cause or hospitalization for worsening HF (hazard ratio [HR] in darbepoetin alfa group, 1.01; 95% confidence interval [CI] 0.90 to 1.13; *P* = 0.87), nor the secondary outcome (**eFig. 25.1B**) of CV death or time to first hospitalization for worsening HF (HR in darbepoetin alfa group, 10.01; 95% CI 0.89 to 1.14; *P* = 0.2). The lack of effect of darbepoetin alfa was consistent across all prespecified subgroups. Importantly, treatment with darbepoetin alfa led to an early (within 1 month) and sustained increase in Hb level throughout the study.



EFIGURE 25.1 Effect of treatment with darbepoetin alfa on clinical outcomes in patients with HF and mild-to-moderate anemia. **A,** Kaplan-Meier estimate of the probability of the death or heart failure hospitalization (primary endpoint). **B,** Kaplan-Meier estimate of death from cardiovascular (CV) causes or first hospitalization for heart failure (secondary endpoint). (Modified from Swedberg K, Young JB, Anand IS, et al. Treatment of anemia with darbepoetin alfa in systolic heart failure N Engl J Med 2013;368:1210.)

Iron deficiency is a common comorbidity in patients with HFrEF and has been associated with increased mortality and a poorer quality of life, regardless of whether there is concomitant anemia.[9] Correction of iron deficiency in anemic and nonanemic patients with HFrEF (EF <30% to 45%) has been studied in several clinical trials.[9] Two of the three randomized trials conducted thus far have used intravenous (IV) ferric carboxymaltose (FCM). Studies with FCM have shown improvement in symptoms, exercise capacity, and health-related quality of life; however, the effects on major clinical events remain uncertain.[8] The one randomized clinical trial that used an oral iron polysaccharide (Oral Iron Repletion Effects on Oxygen Uptake in Heart Failure [IRONOUT]; NCT02188784), did not show an improvement in peak VO_2 by cardiopulmonary exercise testing at 16 weeks. Based on the results of the randomized trials with IV iron supplementation, the current American College of Cardiology, American Heart Association, and Heart Failure Society of America (ACC/AHA/HFSA) guidelines recommend (class IIb, level of evidence B-R) that IV iron replacement might be reasonable in patients with NYHA Class II and III HF and iron deficiency (ferritin <100 ng/mL or 100 to 300 ng/mL if transferrin saturation <20%) to improve functional status and quality of life.[10]

Renal Insufficiency

Renal insufficiency is associated with poorer outcomes in patients with HF; however, some uncertainty remains whether renal impairment is a simply a marker for worsening HF or whether renal impairment might be causally linked to worsening HF. Although more common in patients hospitalized for HF, at least some degree of renal impairment is still present in about half of stable HF outpatients. Patients with renal hypoperfusion or intrinsic renal disease show an impaired response to diuretics and angiotensin-converting enzymes inhibitors (ACEIs) and are at increased risk of adverse effects during treatment with digitalis. In a recent meta-analysis the majority of HF patients had some degree of renal impairment. These patients represented a high-risk group with an approximately 50% increased relative mortality risk compared with patients who had normal renal function.[11] Similar findings were observed in ADHERE (Acute Decompensated Heart Failure National Registry) (**see Chapter 24**). In the Second Prospective Randomized Study of Ibopamine on Mortality and Efficacy, impaired renal function was a stronger predictor of mortality than impaired LV function and NYHA class in patients with advanced HF (**Fig. 25.2**). Thus, renal insufficiency is a strong, independent predictor of adverse outcomes in HF patients.

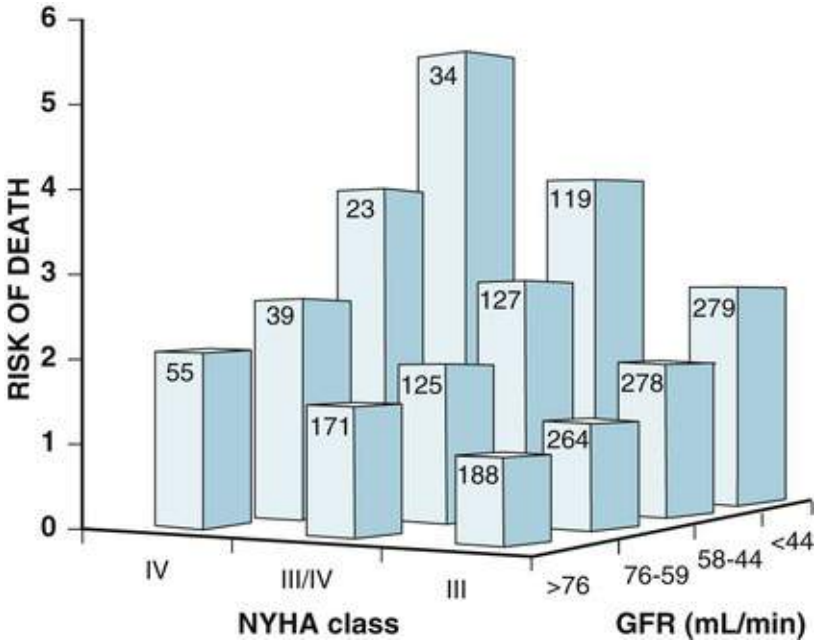


FIGURE 25.2 Effect of renal function on outcomes in heart failure patients. Three-dimensional bar graph showing risk of mortality (*vertical axis*) in relation to decreasing New York Heart Association (NYHA) class (*horizontal axis*) and decreasing quartiles of glomerular filtration rate (GFR; *diagonal axis*). (From Hillege HL, Girbes AR, de Kam PJ, et al. Renal function, neurohormonal activation, and survival in patients with chronic heart failure. Circulation 2000;102:203-10.)

Approach to the Patient

HFrEF should be viewed as continuum comprising four interrelated stages[12] (**Fig. 25.3**). Stage A includes patients at high risk for developing HF, but without structural heart disease or symptoms of HF (e.g., patients with diabetes or hypertension). Stage B includes patients who have structural heart disease but without symptoms of HF (e.g., patients with previous myocardial infarction and asymptomatic LV dysfunction). Stage C includes patients who have structural heart disease who have developed symptoms of HF (e.g., patients with previous MI with shortness of breath and fatigue). Stage D includes patients

with refractory HF requiring special interventions (e.g., patients with refractory HF awaiting cardiac transplantation). **Fig. 25.4** provides a simplified algorithm for approaching patients with HF. **Chapter 21** discusses the clinical assessment of patients with HFrEF, and **Chapter 26** discusses the diagnosis and management of patients with HFpEF.

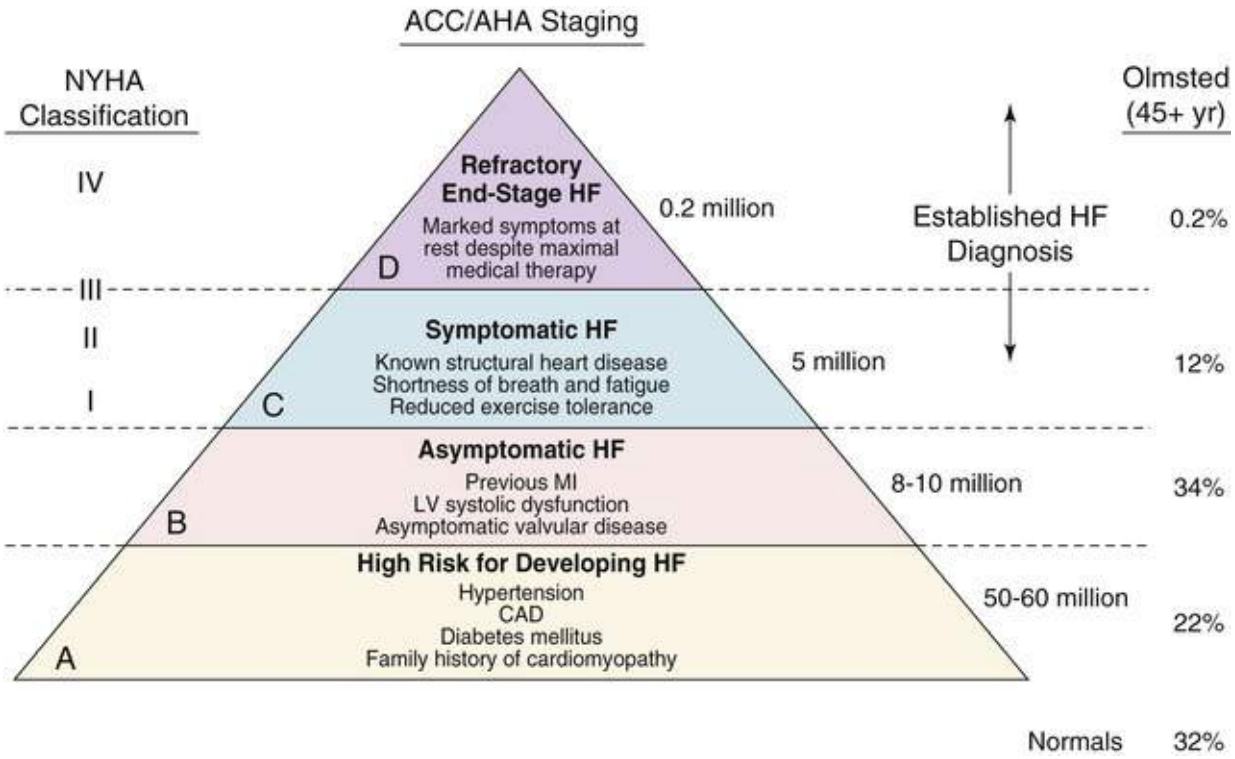

FIGURE 25.3 Stages of heart failure (HF) and prevalence of stages (data from the Olmstead County Epidemiology Study). Patients with stage A HF are at high risk for HF but do not have structural heart disease or symptoms of HF. This group includes patients with hypertension, diabetes, coronary artery disease (CAD), previous exposure to cardiotoxic drugs, or a family history of cardiomyopathy. Patients with stage B HF have structural heart disease but have no symptoms of HF. This group includes patients with left ventricular (LV) hypertrophy, previous myocardial infarction (MI), LV systolic dysfunction, or valvular heart disease, all of whom would be considered to have New York Heart Association (NYHA) Class I symptoms. Patients with stage C HF have known structural heart disease and current or previous symptoms of HF. Their symptoms may be classified as NYHA Class I, II, or III. Patients with stage D HF have refractory symptoms of HF at rest despite maximal medical therapy, are hospitalized, and require specialized interventions or hospice care. All such patients would be considered to have NYHA Class IV symptoms. AHA. American Heart Association; ACC, American College of Cardiology. (Modified from Ammar KA, Jacobsen SJ, Mahoney DW, et al. Prevalence and prognostic significance of heart failure stages: application of the American College of Cardiology/American Heart Association heart failure staging criteria in the community. Circulation 2007;115:1563-70.)

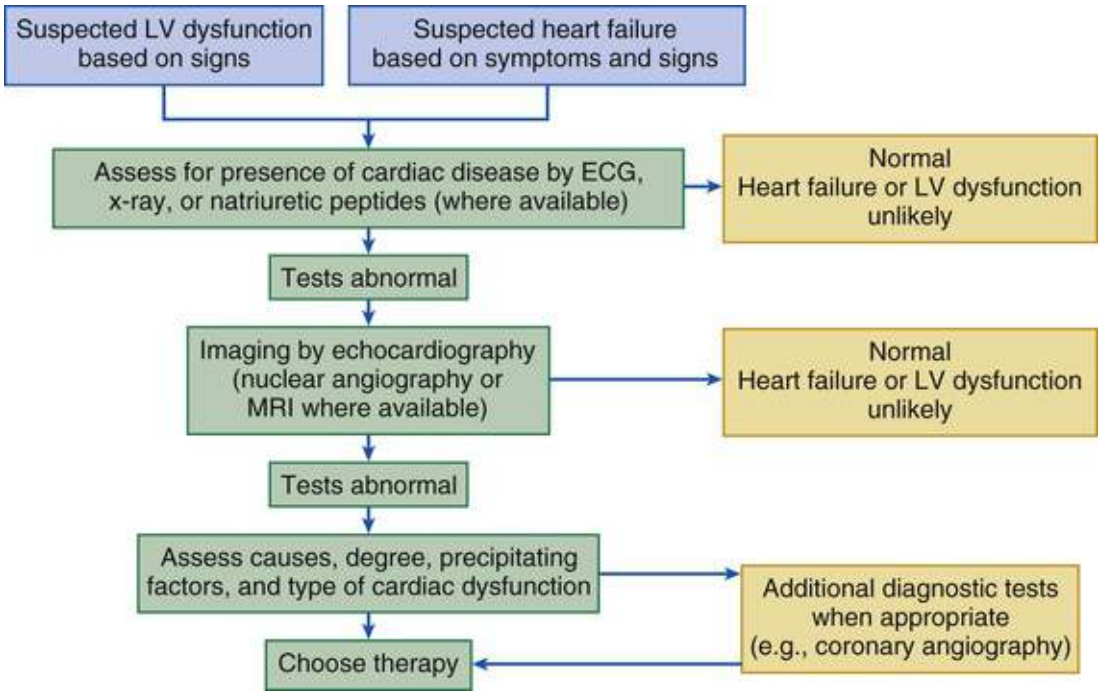

FIGURE 25.4 Algorithm for the diagnosis of heart failure or left ventricular (LV) dysfunction. ECG, Electrocardiogram; MRI, magnetic resonance imaging. (From Swedberg K, Cleland J, Dargie H, et al. Guidelines for the diagnosis and treatment of chronic heart failure: executive summary (update 2005): The Task Force for the Diagnosis and Treatment of Chronic Heart Failure of the European Society of Cardiology. Eur Heart J 2005;26:1115-40.)

Patients at High Risk for Developing Heart Failure (Stage A)

For patients at high risk of developing HFrEF, every effort should be made to prevent HF, using standard practice guidelines to treat preventable conditions that are known to lead to HF, including hypertension (**see Chapter 46**), hyperlipidemia (**Chapter 48**), and diabetes (**Chapter 51**). In this regard, ACEIs are particularly useful in preventing HF in patients who have a history of atherosclerotic vascular disease, diabetes mellitus, or hypertension with associated CV risk factors.

Population Screening.

At present, there is limited information available to support screening broad populations to detect undiagnosed HF and/or asymptomatic LV dysfunction. Although initial studies suggested that determination of BNP or N-terminal (NT) pro-BNP levels might be useful for screening, the positive predictive value (PPV) for these tests in a low-prevalence and asymptomatic population to detect cardiac dysfunction varies among studies, and the possibility of false-positive results has significant cost-effectiveness implications.

Patients who are at very high risk of a developing cardiomyopathy (e.g., those with a strong family history of cardiomyopathy or those receiving cardiotoxic interventions; **see Chapters 80 and 81**) are appropriate targets for more aggressive screening such as two-dimensional echocardiography to assess LV function. The STOP-HF (St. Vincent's Screening To Prevent Heart Failure) showed that, in patients with known CV risk factors, screening with BNP testing followed by collaborative care between internists and CV specialists resulted in a significant reduction in LV dysfunction (odds ratio [OR], 0.55; 95% CI, 0.37 to 0.82; P = .003). Although there was no significant reduction in clinical HF events, there was a significant decrease in the incidence rates of emergency hospitalization for major CV events.[13]

However, the routine periodic assessment of LV function in low-risk patients is not currently recommended. Several sophisticated clinical scoring systems have been developed to screen for HF in population-based studies, including the Framingham Criteria, which screen for HF on the basis of clinical criteria, and the National Health and Nutrition Examination Survey (NHANES), which uses self-reporting of symptoms to identify HF patients (**Table 25.4**). However, as discussed in **Chapter 21**, additional laboratory testing is usually necessary to make a definitive diagnosis of HF when these methodologies are used.

TABLE 25.4

Diagnostic Criteria for Heart Failure (HF) in Population-Based Studies

FRAMINGHAM CRITERIA		
Major Criteria	**Minor Criteria**	**Major or Minor Criteria**
Paroxysmal nocturnal dyspnea or orthopnea Neck vein distention Rales Cardiomegaly Acute pulmonary edema S_3 gallop Increased venous pressure >16 cm H_2O Hepatojugular reflux	Ankle edema Night cough Dyspnea on exertion Hepatomegaly Pleural effusion Vital capacity decreased One-third from maximal capacity Tachycardia (rate >120/min)	Weight loss >4.5 kg in 5 days in response to treatment

NHANES CRITERIA		
Category	**Criteria**	**Score**
History	*Dyspnea:*	
	When hurrying on a hill	1
	When walking at an ordinary pace	1
	Do you stop for breath when walking at an ordinary pace?	2
	Do you stop for breath when after 100 yards on flat ground?	2
Physical examination	*Heart rate:*	
	91-110 beats/min	1
	>110 beats/min	2
	Jugular venous pressure (> 6 cm H_2O):	
	Alone	1
	PLUS hepatomegaly or edema	2
	Rales:	
	Basilar crackles	1
	Crackles more than basilar crackles	2
Chest radiograph	Upper zone flow redistribution	1
	Interstitial pulmonary edema	2
	Interstitial edema plus pleural fluid	3
	Alveolar fluid plus pleural fluid	3

The diagnosis of HF using the Framingham criteria requires the simultaneous presence of at least 2 major criteria or 1 major criterion in conjunction with 2 minor criteria. Minor criteria are acceptable only if they cannot be attributed to another medical condition (e.g., pulmonary hypertension, chronic lung disease, cirrhosis, ascites, nephrotic syndrome). NHANES-1 criteria: diagnosis of HF is score ≥3 points.

NHANES, National Health and Nutrition Survey.

Modified from Ho KK et al. The epidemiology of heart failure: the Framingham Study. J Am Coll Cardiol 1993;22:6A-13A; and Schocken DD et al. Prevalence and mortality rate of congestive heart failure in the United States. J Am Coll Cardiol 1992;20:301-6.

Management of Patients with Symptomatic and Asymptomatic Heart Failure

Transient Left Ventricular Dysfunction

As noted in **Chapter 23**, the clinical syndrome of HF with reduced EF begins after an initial index event

produces a decline in ejection performance of the heart. However, it is important to recognize that LV dysfunction may develop transiently in a variety of different clinical settings that may not invariably lead to development of the clinical syndrome of HF. **Fig. 25.5** illustrates the important relationship between LV dysfunction (transient and sustained) and the clinical syndrome of HF (asymptomatic and symptomatic). LV dysfunction with pulmonary edema may develop acutely in patients with previously normal LV structure and function. This most frequently occurs after cardiac surgery, in the setting of severe brain injury, or after a systemic infection. The general pathophysiologic mechanism involved is either some form of "stunning" of functional myocardium (**see Chapter 67**) or activation of proinflammatory cytokines capable of suppressing LV function. Emotional stress can also precipitate severe, reversible LV dysfunction accompanied by chest pain, pulmonary edema, and cardiogenic shock in patients without CAD (takotsubo syndrome). In these patients, LV dysfunction is thought to result from the deleterious effects of catecholamines after heightened sympathetic stimulation.[14] It is also important to note that exercise-induced LV dysfunction, usually caused by myocardial ischemia, may lead to symptoms by causing an increase in LV filling pressure and a decrease in cardiac output in the absence of discernible LV dysfunction at rest. If LV dysfunction persists after the initial cardiac injury, patients may remain asymptomatic for months to years; however, the weight of epidemiologic and clinical evidence suggests that at some point, these patients will undergo the transition to overt symptomatic HF.

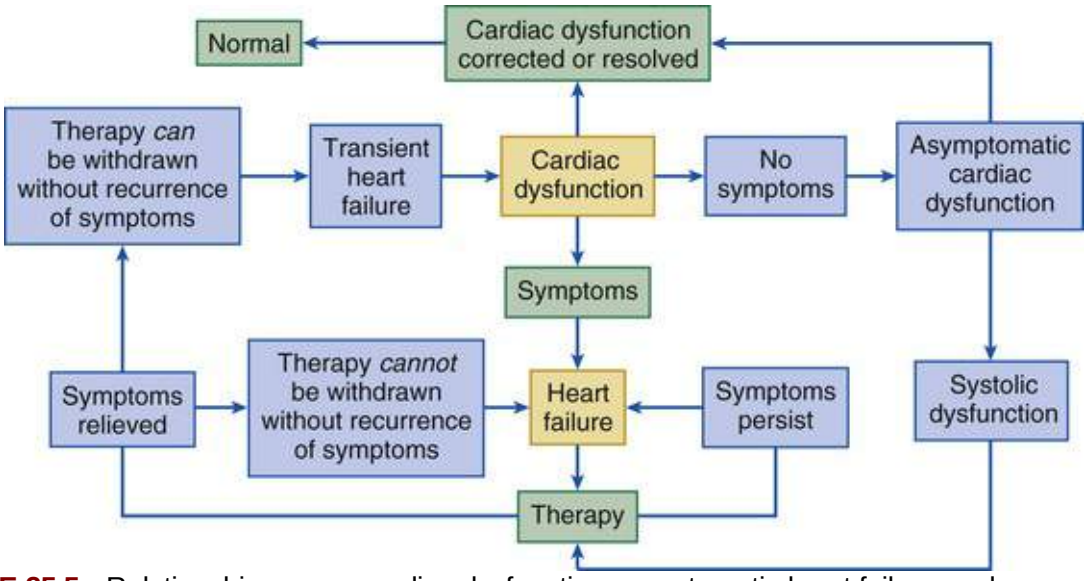

FIGURE 25.5 Relationship among cardiac dysfunction, symptomatic heart failure, and asymptomatic heart failure following appropriate treatment. (From Swedberg K, Cleland J, Dargie H, et al. Guidelines for the diagnosis and treatment of chronic heart failure: executive summary (update 2005): The Task Force for the Diagnosis and Treatment of Chronic Heart Failure of the European Society of Cardiology. Eur Heart J 2005;26:1115-40.)

Defining the Appropriate Strategy

The main goals of treatment for are to reduce symptoms, prolong survival, improve the quality of life, and prevent disease progression. As discussed later, the current pharmacologic, device, and surgical therapeutic armamentarium for the management of HF patients with a reduced EF permit health care providers to achieve each of these goals in the great majority of patients. Once patients have developed structural heart disease (stage B to D), the choice of therapy for patients with HFrEF depends on their NYHA functional classification (**see Chapter 21**, **Table 21.1**). Although this classification system is

notoriously subjective and has large interobserver variability, it has withstood the test of time and continues to be widely applied to patients with HF. For patients who have developed LV systolic dysfunction but who remain asymptomatic (NYHA Class I), the goal should be to slow disease progression by blocking neurohormonal systems that lead to cardiac remodeling (**see Chapter 23**). For patients who have developed symptoms (NYHA Class II to IV), the primary goal should be to alleviate fluid retention, lessen disability, and reduce the risk of further disease progression and death. As discussed subsequently, these goals generally require a strategy that combines diuretics (to control salt and water retention) with neurohormonal interventions (to minimize cardiac remodeling).

General Measures

Identification and correction of the condition(s) responsible for the cardiac structural and functional abnormalities are critical (**see Table 25.2**), because some conditions that provoke LV abnormalities are potentially treatable or reversible. Further, clinicians should aggressively screen for and treat comorbidities such as hypertension and diabetes that are believed to underlie the structural heart disease. In addition to seeking reversible etiologies and comorbidities that contribute to HF development, it is equally important to identify factors that provoke worsening HF in stable patients (**Table 25.5**).

TABLE 25.5

Factors That May Precipitate Acute Decompensation in Patients with Chronic Heart Failure (HF)

Dietary indiscretion
Inappropriate reduction in HF medications
Myocardial ischemia/infarction
Arrhythmias (tachycardia or bradycardia)
Infection
Anemia
Initiation of medications that worsen the symptoms of HF
Calcium antagonists (verapamil, diltiazem)
Beta blockers
Nonsteroidal anti-inflammatory drugs
Thiazolidinediones
Antiarrhythmic agents (all class I agents, sotalol [class III])
Anti-TNF antibodies
Alcohol consumption
Pregnancy
Worsening hypertension
Acute valvular insufficiency

From Mann DL. Heart failure and cor pulmonale, In Kasper DL, Braunwald E, Fauci AS, et al. Harrison's Principles of Internal Medicine. 17th ed. New York: McGraw-Hill; 2007, p 1448.

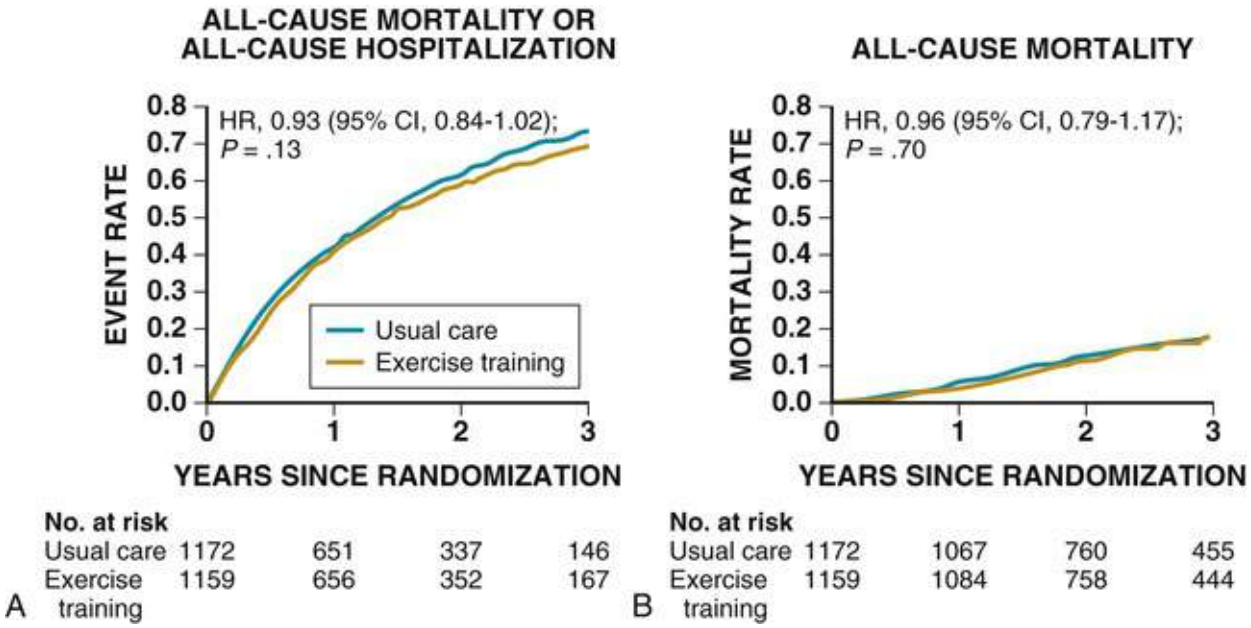
Among the most common causes of acute decompensation in a previously stable patient are dietary indiscretion and inappropriate reduction of HF therapy, either from patient self-discontinuation of medication or from physician withdrawal of effective pharmacotherapy (e.g., because of concern over azotemia). HF patients should be advised to stop smoking and to limit alcohol consumption to two standard drinks per day in men or one standard drink per day in women. Patients suspected of having an alcohol-induced cardiomyopathy should be advised to abstain from alcohol consumption indefinitely. Excessive temperature extremes and heavy physical exertion should be avoided. Certain drugs are known to make HF worse and should also be avoided. For example, nonsteroidal anti-inflammatory drugs (NSAIDs), including cyclooxygenase 2 (COX-2) inhibitors, are not recommended in patients with chronic HF because the risk of renal failure and fluid retention is greatly increased in the setting of reduced renal function and ACEI use. Patients should be advised to weigh themselves regularly to monitor weight gain and to alert a health care provider or adjust their diuretic dose in the event of a sudden unexpected weight

gain of more than 3 to 4 pounds over a 3 day period.

Although there is no documented evidence of the effects of immunization in HF patients, they are at high risk of developing pneumococcal infection and influenza. Accordingly, clinicians should consider recommending influenza and pneumococcal vaccines to their HF patient to prevent respiratory infections. The clinician should also educate the patient and family about HF and the importance of proper diet and compliance with the medical regimen. Supervision of outpatient care by a specially trained nurse or physician assistant and at specialized HF clinics has been found to be helpful, particularly in patients with advanced disease (see later, Disease Management Approach to Heart Failure).

Activity

Although heavy physical labor is not recommended in HF patients, routine modest exercise has been shown to be beneficial in selected patients with NYHA Class I to III HF. HF-ACTION (A Controlled Trial Investigating Outcomes of Exercise Training) was a large, multicenter, randomized controlled trial (RCT) with the primary endpoint of a composite of all-cause mortality and all-cause hospitalization. Secondary endpoints included all-cause mortality, all-cause hospitalization, composite of CV mortality or CV hospitalization, and composite of CV mortality or HF hospitalization. HF-ACTION failed to show a significant improvement in all-cause mortality or all-cause hospitalization (HR, 0.93; 95% CI 0.84 to 1.02; $P = 0.13$) in patients who received a 12-week (three times/week) exercise training program followed by 25- to 30-minute, 5 days/week, home-based, self-monitored exercise workouts on a treadmill or stationary bicycle (**eFig. 25.2A**). Moreover, there was no difference in all-cause mortality (HR, 0.96; 95% CI 0.79 to 1.17; $P = 0.70$) (**eFig. 25.2B**). However, there was a trend toward decreased CV mortality or HF hospitalization (HR, 0.87; 95% CI 0.74 to 0.99; $P = 0.06$), and quality of life was significantly improved in the exercise group.[15] For euvolemic patients, regular isotonic exercise such as walking or riding a stationary-bicycle ergometer may be useful as an adjunctive therapy to improve clinical status after patients have undergone exercise testing to determine suitability for exercise training (patient does not develop significant ischemia or arrhythmias). Exercise training is not recommended, however, in HF patients with a reduced EF who have had a major CV event or procedure within the last 6 weeks, in patients receiving cardiac devices that limit the ability to achieve target heart rates, and in patients with significant arrhythmia or ischemia during baseline cardiopulmonary exercise testing.



EFIGURE 25.2 Kaplan-Meier analysis of the effect of exercise versus usual care on heart failure morbidity and mortality. **A,** Time to all-cause mortality or all-cause hospitalization, and **B,** time to all-cause mortality in the HF-ACTION trial. (From O'Connor CM, Whellan DJ, Lee KL, et al. Efficacy and safety of exercise training in patients with chronic heart failure: HF-ACTION randomized controlled trial. JAMA 2009;301:1439-50.)

Diet

Dietary restriction of sodium (2 to 3 g daily) is recommended in all patients with the clinical syndrome of HF and preserved or depressed EF. Further restriction (<2 g daily) may be considered in moderate to severe HF. Fluid restriction is generally unnecessary unless the patient is hyponatremic (<130 mEq/L), which may develop because of activation of the renin-angiotensin system (RAS), excessive secretion of arginine vasopressin (AVP), or loss of salt in excess of water from prior diuretic use. Fluid restriction (<2 L/day) should be considered in hyponatremic patients (<130 mEq/L), or for those patients whose fluid retention is difficult to control despite high doses of diuretics and sodium restriction. Caloric supplementation is recommended for patients with advanced HF and unintentional weight loss or muscle wasting (cardiac cachexia); however, anabolic steroids are not recommended for these patients because of the potential problems with volume retention. The measurement of nitrogen balance, caloric intake, and prealbumin may be useful in determining appropriate nutritional supplementation. The use of dietary supplements ("nutriceuticals") should be avoided in the management of symptomatic HF because of the lack of proven benefit and the potential for significant interactions with proven HF therapeutics.

Management of Fluid Retention

Many of the clinical manifestations of the syndrome of HF result from excessive salt and water retention that leads to an inappropriate volume expansion of the vascular and extravascular space. The use of implantable devices to monitor HF is discussed in **Chapter 27**. This section focuses on the use of diuretics in chronic HFrEF. Although both digitalis and low doses of ACEIs enhance urinary sodium excretion, few volume-overloaded HF patients can maintain proper sodium balance without the use of diuretic drugs. Indeed, attempts to substitute ACEIs for diuretics have been shown to lead to pulmonary edema and peripheral congestion. As shown in **Fig. 25.6**, diuretic-induced negative sodium and water balance can decrease LV dilation, functional mitral insufficiency, mitral wall stress, and subendocardial ischemia. In short-term clinical trials, diuretic therapy has led to a reduction in jugular venous pressure

(JVP), pulmonary congestion, peripheral edema, and body weight, all of which were observed within days of initiation of therapy. In intermediate-term studies, diuretics have been shown to improve cardiac function, symptoms, and exercise tolerance in HF patients.[16] To date, there have been no long-term studies of diuretic therapy in HF; thus their effects on morbidity and mortality are not clearly known. Although retrospective analyses of clinical trials suggest that diuretic use is associated with worse clinical outcomes,[16] a meta-analysis (Cochrane Review) suggested that treatment with diuretic therapy produced a significant reduction in mortality (OR, 0.24; 95% CI 0.07 to 0.83; $P = 0.02$) and worsening HF (OR 0.07; 95% CI 0.01 to 0.52; $P = 0.01$).[16] However, given the retrospective nature of this review, this analysis cannot be used as formal evidence to recommend the use diuretics to reduce HF mortality.

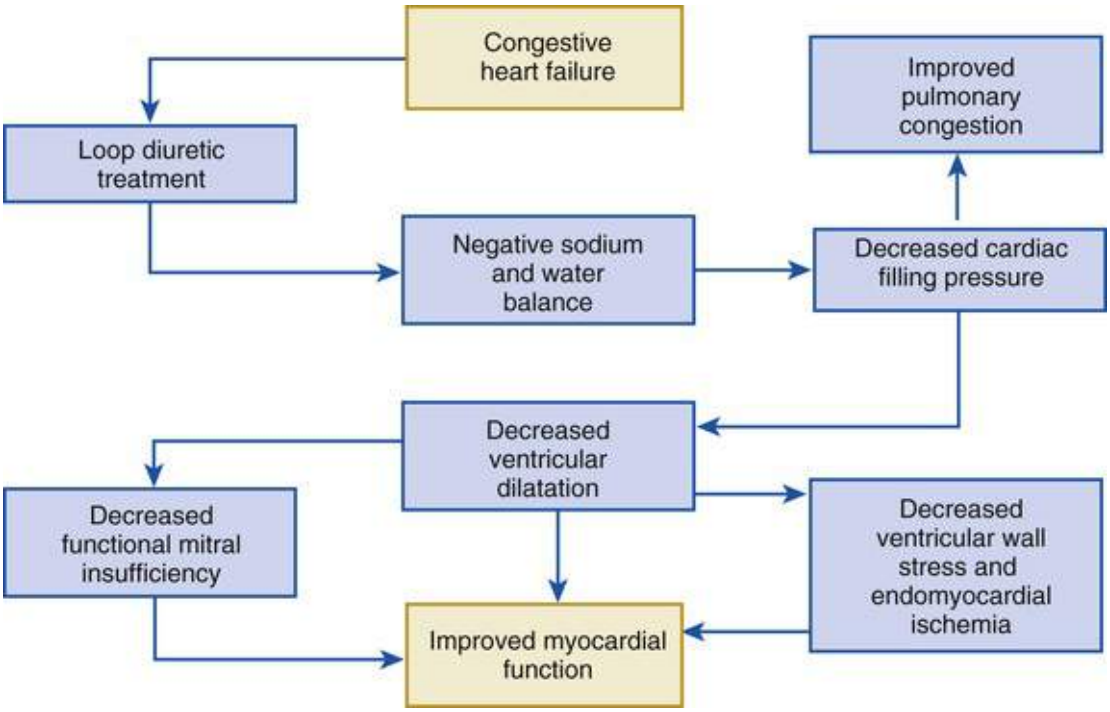


FIGURE 25.6 Potential beneficial effects of diuretics on myocardial function. Diuretic-induced negative sodium and water balance can decrease LV dilation, functional mitral insufficiency, mitral wall stress, and subendocardial ischemia. However, treatment with diuretics can also lead to deterioration of renal function and worsening neurohormonal activation. (Modified from Schrier RW. Use of diuretics in heart failure and cirrhosis. Semin Nephrol 2011;31:503-12.)

Diuretic Classes

A number of classification schemes have been proposed for diuretics on the basis of their mechanism of action, their anatomic locus of action within the nephron, and the form of diuresis that they elicit ("solute" versus "water diuresis"). The most common classification for diuretics employs an admixture of chemical (e.g., *thiazide* diuretic), site of action (e.g., *loop* diuretics), or clinical outcomes (e.g., *potassium-sparing* diuretics). The loop diuretics increase sodium excretion by up to 20% to 25% of the filtered load of sodium, enhance free water clearance, and maintain their efficacy unless renal function is severely impaired. In contrast, the thiazide diuretics increase the fractional excretion of sodium to only 5% to 10% of the filtered load, tend to decrease free water clearance, and lose their effectiveness in patients with impaired renal function (creatinine clearance <40 mL/min). Consequently, the loop diuretics have emerged as the preferred diuretic agents for use in most patients with HF. Diuretics that induce a water

diuresis (“aquaretics”) include demeclocycline, lithium, and vasopressin V_2 receptor antagonists, each of which inhibits the action of AVP on the collecting duct through different mechanisms, thereby increasing free water clearance. Drugs that cause solute diuresis are subdivided into two types: *osmotic* diuretics, which are nonresorbable solutes that osmotically retain water and other solutes in the tubular lumen, and drugs that selectively inhibit ion transport pathways across tubular epithelia, which constitute the majority of potent, clinically useful diuretics. **Table 25.6** lists the classes of diuretics and individual class members, and **Fig. 25.7** shows their renal sites of action.

TABLE 25.6

Diuretics for Treating Fluid Retention in Chronic Heart Failure

DRUG	INITIAL DAILY DOSE(S)	MAXIMUM TOTAL DAILY DOSE	DURATION OF ACTION
Loop Diuretics*			
Bumetanide	0.5-1.0 mg once or twice	10 mg	4-6 hours
Furosemide	20-40 mg once or twice	600 mg	6-8 hours
Torsemide	10-20 mg once	200 mg	12-16 hours
Ethacrynic acid	25-50 mg once or twice	200 mg	6 hours
Thiazide Diuretics**			
Chlorothiazide	250-500 mg once or twice	1000 mg	6-12 hours
Chlorthalidone	12.5-25 mg once	100 mg	24-72 hours
Hydrochlorothiazide	25 mg once or twice	200 mg	6-12 hours
Indapamide	2.5 mg once	5 mg	36 hours
Metolazone	2.5-5.0 mg once	5 mg	12-24 hours
Potassium-Sparing Diuretics			
Amiloride	5.0 mg once	20 mg	24 hours
Triamterene	50 to 100 mg twice	300 mg	7-9 hours
AVP Antagonists			
Satavaptan	25 mg once	50 mg once	NS
Tolvaptan	15 mg once	60 mg once	NS
Lixivaptan	25 mg once	250 mg twice	NS
Conivaptan (IV)	20 mg IV loading dose followed by	100 mg once	7-9 hours
	20 mg continuous IV infusion/day	40 mg IV	
Sequential Nephron Blockade			
Metolazone	2.5-10 mg once PLUS loop diuretic		
Hydrochlorothiazide	25-100 mg once or twice PLUS loop diuretic		
Chlorothiazide (IV)	500-1000 mg once PLUS loop diuretic		

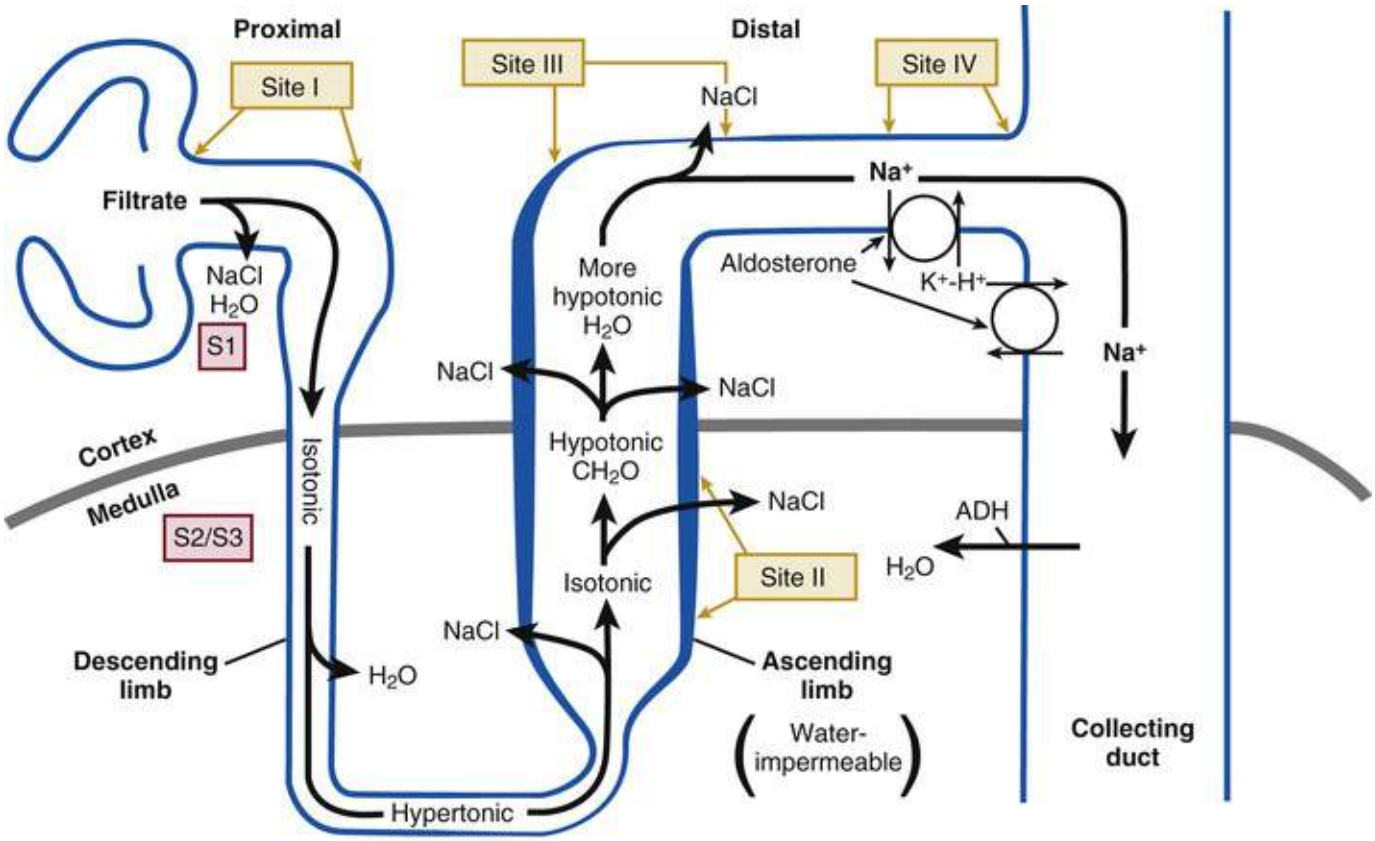
*Equivalent doses: 40 mg furosemide = 1 mg bumetanide = 20 mg torsemide = 50 mg of ethacrynic acid.

**Do not use if estimated glomerular filtration rate is <30 mL/min, or with cytochrome 3A4 inhibitors.

Unless indicated, all doses are for oral diuretics.

IV, Intravenous(ly); *NS,* not specified.

A report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines. J Am Coll Cardiol 2005;46(6):1116.



Site I (proximal convoluted tubule): carbonic anhydrase inhibitors, SGLT2 inhibitors
Site II (ascending loop of Henle): loop diuretics
Site III (distal convoluted tubule): thiazide and thiazide-like diuretics
Site IV (late distal tubule and collecting duct): potassium-sparing diuretics, MRAs

FIGURE 25.7 Sites of action of diuretics in the kidney. (Modified from Wile D. Diuretics: a review. Ann Clin Biochem 2012;49:419-31.)

Loop Diuretics

The agents classified as loop diuretics, including *furosemide*, *bumetanide*, and *torsemide*, act by reversibly inhibiting the Na^+-K^+-$2Cl^-$ symporter (cotransporter) on the apical membrane of epithelial cells in the thick ascending loop of Henle (site II, **Fig. 25.7**). Because furosemide, bumetanide, and torsemide are bound extensively to plasma proteins, delivery of these drugs to the tubule by filtration is limited. However, these drugs are secreted efficiently by the organic acid transport system in the proximal tubule and thereby gain access to their binding sites on the Na^+-K^+-$2Cl^-$ symporter in the luminal membrane of the ascending limb. Thus the efficacy of loop diuretics depends on sufficient renal plasma blood flow and proximal tubular secretion to deliver these agents to their site of action. Probenecid shifts the plasma concentration-response curve for furosemide to the right by competitively inhibiting furosemide excretion by the organic acid transport system. The bioavailability of furosemide ranges from 40% to 70% of the oral dose. In contrast, the oral bioavailability of bumetanide and torsemide exceeds 80%. Accordingly, these agents may be more effective in patients with advanced HF or right-sided HF, although at considerably greater cost. Agents in a second functional class of loop diuretics, typified by ethacrynic acid, exhibit a slower onset of action and have delayed and only partial reversibility. Ethacrynic acid may be safely used in sulfa-allergic HF patients.

Mechanisms of Action.

Loop diuretics are believed to improve symptoms of congestion by several mechanisms. First, loop diuretics reversibly bind to and reversibly inhibit the action of the Na^+-K^+-$2Cl^-$ cotransporter, thereby preventing salt transport in the thick ascending loop of Henle. Inhibition of this symporter also inhibits Ca^{2+} and Mg^{2+} resorption by abolishing the transepithelial potential difference that is the driving force for absorption of these cations. By inhibiting the concentration of solute within the medullary interstitium, these drugs also reduce the driving force for water resorption in the collecting duct, even in the presence of AVP (**see Chapter 23**). The decreased resorption of water by the collecting duct results in the production of urine that is almost isotonic with plasma. The increase in delivery of Na^+ and water to the distal nephron segments also greatly enhances K^+ excretion, particularly in the presence of elevated aldosterone levels.

Loop diuretics also exhibit several characteristic effects on intracardiac pressure and systemic hemodynamics. Furosemide acts as a venodilator and reduces right atrial and pulmonary capillary wedge pressure (PCWP) within minutes when given intravenously (0.5 to 1.0 mg/kg). Similar data, although not as extensive, have accumulated for bumetanide and torsemide. This initial improvement in hemodynamics may be secondary to the release of vasodilatory prostaglandins, because animal and human studies have demonstrated that the venodilatory actions of furosemide are inhibited by indomethacin. There have also been reports of an acute rise in systemic vascular resistance in response to loop diuretics, which has been attributed to transient activation of the systemic or intravascular RAS. The potentially deleterious rise in LV afterload reinforces the importance of initiating vasodilator therapy with diuretics in patients with acute pulmonary edema and adequate blood pressure (**see Chapter 24**).

Thiazide and Thiazide-Like Diuretics.

The benzothiadiazides, also known as thiazide diuretics, were the initial class of drugs that were synthesized to block the Na^+-Cl^- transporter in the cortical portion of the ascending loop of Henle and the distal convoluted tubule (site III, **Fig. 25.7**). Subsequently, drugs that share similar pharmacologic properties became known as “thiazide-like diuretics,” even though they were technically not benzothiadiazine derivatives. *Metolazone,* a quinazoline sulfonamide, is a thiazide-like diuretic that is used in combination with furosemide in patients who become resistant to diuretics (see later). Because thiazide and thiazide-like diuretics prevent maximal dilution of urine, they decrease the kidney's ability to increase free water clearance and may therefore contribute to the development of hyponatremia. Thiazides increase Ca^{2+} resorption in the distal nephron (**see Fig. 25.7**) by several mechanisms, occasionally resulting in a small increase in serum Ca^{2+} levels. In contrast, Mg^{2+} resorption is diminished, and hypomagnesemia may occur with prolonged use. Increased delivery of NaCl and fluid into the collecting duct directly enhances K^+ and H^+ secretion by this segment of the nephron, which may lead to clinically important hypokalemia.

Mechanisms of Action.

The site of action of thiazide diuretics within the distal convoluted tubule has been identified as the Na^+-Cl^- symporter of the distal convoluted tubule. Although this cotransporter shares about 50% amino acid homology with the Na^+-K^+-$2Cl^-$ symporter of the ascending limb of the loop of Henle, it is insensitive to the effects of furosemide. This cotransporter (or related isoforms) is also present on cells within the vasculature and many cell types within other organs and tissues and may contribute to other actions of these agents, such as their utility as antihypertensive agents. Similar to the loop diuretics, the efficacy of

thiazide diuretics depends, at least in part, on proximal tubular secretion to deliver these agents to their site of action. Unlike the loop diuretics, however, the plasma protein binding varies considerably among the thiazide diuretics; accordingly, this parameter will determine the contribution of glomerular filtration to tubular delivery of a specific diuretic.

Mineralocorticoid Receptor Antagonists

Mineralocorticoids such as *aldosterone* cause retention of salt and water and increase the excretion of K^+ and H^+ by binding to specific mineralocorticoid receptors. *Spironolactone* (first-generation MRA) and *eplerenone* (second-generation MRA) are synthetic mineralocorticoid receptor antagonists (MRAs) that act on the distal nephron to inhibit Na^+/K^+ exchange at the site of aldosterone action (**see Fig. 25.7**).

Mechanisms of Action.

Spironolactone has antiandrogenic and progesterone-like effects, which may cause gynecomastia or impotence in men and menstrual irregularities in women. To overcome these side effects, eplerenone was developed by replacing the 17α-thioacetyl group of spironolactone with a carbomethoxy group. As a result, eplerenone has greater selectivity for the mineralocorticoid receptor than for steroid receptors and has less sex hormone side effects than spironolactone. Eplerenone is further distinguished from spironolactone by its shorter half-life and having no active metabolites. Although spironolactone and eplerenone are both weak diuretics, clinical trials have shown that both have profound effects on CV morbidity and mortality by virtue of their ability to antagonize the deleterious effects of aldosterone in the CV system (**Fig. 25.8**) (**see Chapter 23**). Therefore, these agents are used in HF for their ability to antagonize the RAAS (see later) rather than for their diuretic properties. Spironolactone (**see Table 25.6**) and its active metabolite, canrenone, competitively inhibit the binding of aldosterone to mineralocorticoid or type I receptors in many tissues, including epithelial cells of the distal convoluted tubule and collecting duct. These cytosolic receptors are ligand-dependent transcription factors, which on binding of the ligand (e.g., aldosterone), translocate to the nucleus, where they bind to hormone response elements present in the promoter of some genes, including several involved in vascular and myocardial fibrosis, inflammation, and calcification.

FIGURE 25.8 Kaplan-Meier analysis of the probability of survival among patients in the placebo and treatment groups in the RALES trial **(A)** with spironolactone and the EMPHASIS trial **(B)** using eplerenone. (Modified from Pitt B et al. The effect of spironolactone on morbidity and mortality in patients with severe heart failure. Randomized Aldactone Evaluation Study Investigators. N Engl J Med 1999;341:709-17, and Zannad F et al. Eplerenone in patients with systolic heart failure and mild symptoms. N Engl J Med 2011;364:11-21.)

Although first- and second-generation steroid-based MRAs have been shown to reduce HF mortality rates, the broader use of these agents in HF patients has been limited by significant side effects, most notably hyperkalemia. Novel, potent, and selective "third-generation" nonsteroidal MRAs that combine the potency and efficacy of spironolactone with the selectivity of eplerenone, and that have less hyperkalemia, have recently entered clinical trials (**Fig. 25.9**). *Finerenone* (BAY 94-8862) is a nonsteroidal MRA that was compared to eplerenone in patients with worsening chronic HF and type 2 diabetes mellitus and/or chronic kidney disease in the phase IIb ARTS-HF (Mineralocorticoid-Receptor Antagonist Tolerability Study).[17] ARTS-HF was a randomized, double-blind, comparator-controlled multicenter trial in 1066 patients with heart failure (LVEF ≤40%). The primary endpoint was the percentage of individuals with a decrease of more than 30% in plasma NT-proBNP from baseline to day 90. When compared to eplerenone, finerenone was well tolerated and resulted in a 30% or greater decrease in NT-proBNP levels, which was similar to the proportion of patients observed in the eplerenone group. The composite clinical endpoint of death from any cause, CV hospitalizations, or emergency presentation for worsening HF until day 90, which was a prespecified secondary endpoint, occurred less frequently in all finerenone groups except for the lowest doses.

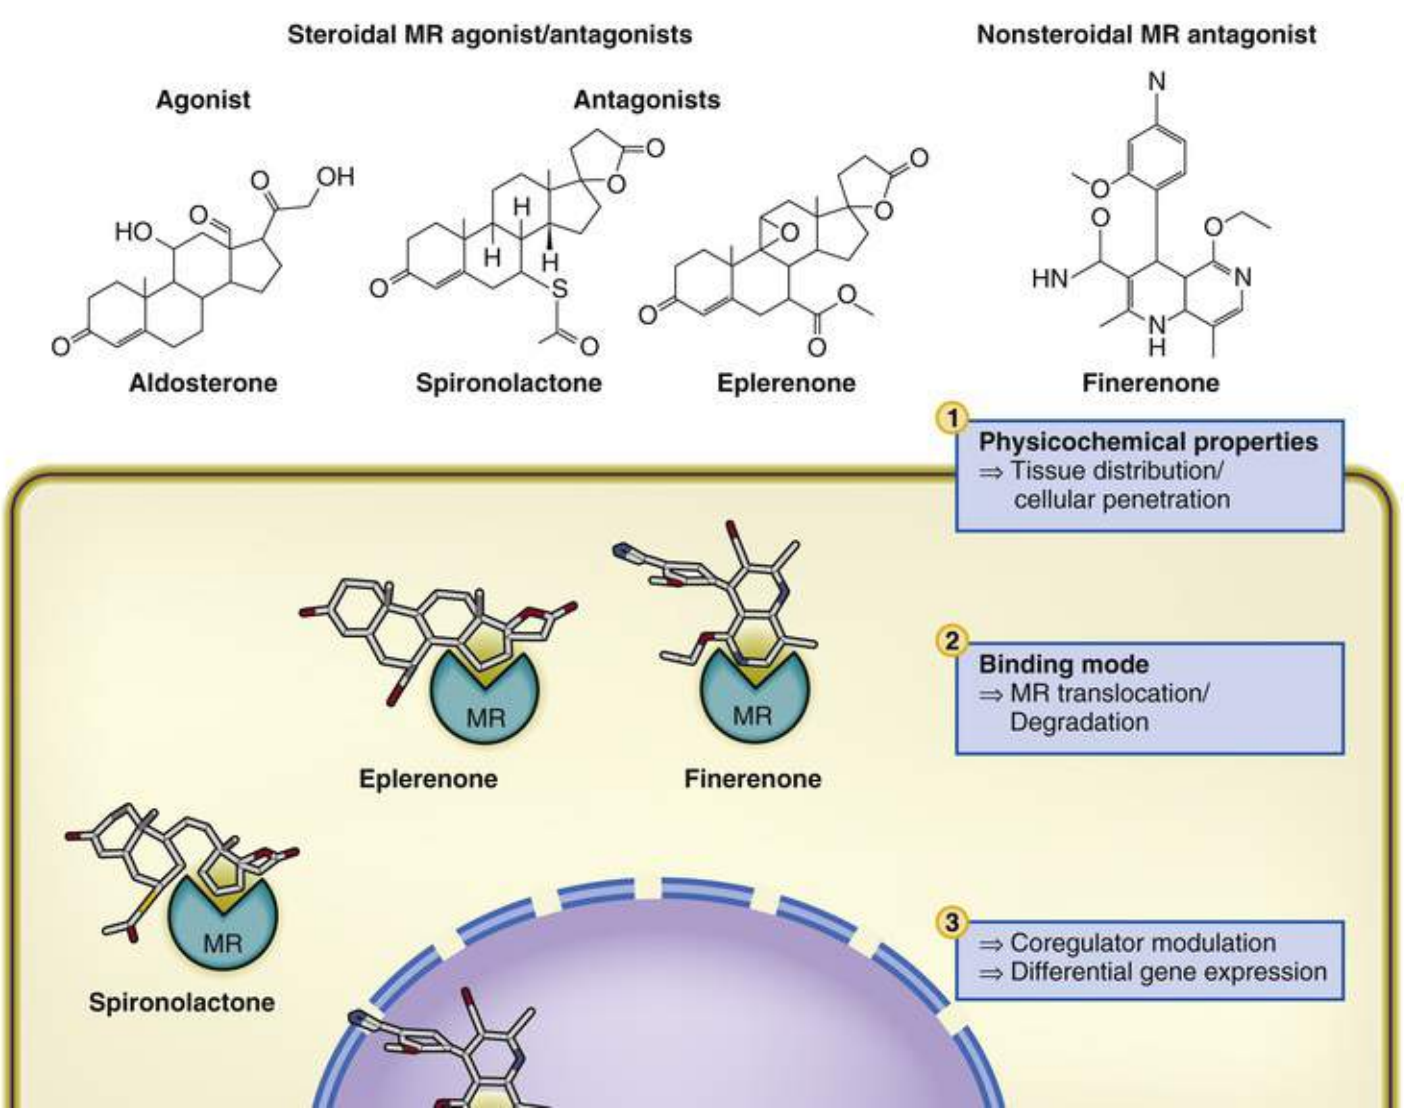

FIGURE 25.9 Nonsteroidal mineralocorticoid receptor antagonists (MRAs). The nonsteroidal MRA finerenone has a unique pharmacodynamic profile considered to be a consequence of several individual key differences compared with steroidal MRAs, including physicochemical properties, tissue distribution, mode of mineralocorticoid receptor inactivation, and differential regulation of downstream antihypertrophic gene expression. Differential modes of action exist between the steroidal MRAs and the nonsteroidal finerenone. The steroidal MRA aldosterone and antagonists spironolactone and eplerenone are structurally distinct from the nonsteroidal MRA finerenone, as shown at the top of the figure. The key cellular localizations, which determine the final pharmacologic profile of steroidal MRAs and finerenone, are as follows: first, the extracellular space and plasma membrane (determination of tissue distribution and cellular penetration); second, the cytoplasm (binding mode determines the nuclear translocation of mineralocorticoid receptor or its degradation); and third, the nucleus (ligand-dependent coregulator modulation determines differential gene expression). (From Kolkhof P, Nowack C, Eitner F. Nonsteroidal antagonists of the mineralocorticoid receptor. Curr Opin Nephrol Hypertens 2015;24:417-24.)

Potassium-Sparing Diuretics

Triamterene and *amiloride* are referred to as potassium-sparing diuretics and share the common property of causing a mild increase in NaCl excretion, as well as having anti-kaliuretic properties. Triamterene is a pyrazinoylguanidine derivative, whereas amiloride is a pteridine. Both drugs are organic bases that are transported into the proximal tubule, where they block Na^+ reabsorption in the late distal tubule and collecting duct (site IV, **Fig. 25.7**). However, since Na^+ retention occurs in more proximal nephron sites in HF, neither amiloride nor triamterene is effective in achieving a net negative Na^+ balance when given alone in HF patients. Both amiloride and triamterene appear to share a similar mechanisms of action. Considerable evidence suggests that amiloride blocks Na^+ channels in the luminal membrane of the

principal cells in the late distal tubule and collecting duct, perhaps by competing with Na^+ for negatively charged areas within the pore of the Na^+ channel. Blockade of Na^+ channels leads to hyperpolarization of the luminal membrane of the tubule, which reduces the electrochemical gradient that provides the driving force for K^+ secretion into the lumen. Amiloride and its congeners also inhibit Na^+/H^+ antiporters in renal epithelial cells and in many other cell types, but only at concentrations that are higher than those used clinically.

Carbonic Anhydrase Inhibitors

The zinc metalloenzyme carbonic anhydrase plays an essential role in the $NaHCO_3$ resorption and acid secretion in the proximal tubule (site I, **Fig. 25.7**). Although weak diuretics, carbonic anhydrase inhibitors (**see Table 25.6**) such as acetazolamide potently inhibit carbonic anhydrase, resulting in near complete loss of $NaHCO_3$ resorption in the proximal tubule. The use of these agents in patients with HF is confined to temporary administration to correct the metabolic alkalosis that occurs as a "contraction" phenomenon in response to the administration of other diuretics. When used repeatedly, these agents can lead to metabolic acidosis as well as severe hypokalemia.

Sodium-Glucose Transporter-2 Inhibitors

The sodium-glucose cotransporter-2 (SGLT-2) is a high-capacity, low-affinity transporter located in the S_1 and S_2 segments of the proximal tubule in the kidneys (**see Fig. 25.7**). SGLT-2 accounts for 90% of glucose reabsorption by the kidney, whereas the lower-capacity higher-affinity sodium-glucose transporter-1 (SGLT-1), located in the S_3 segment of the proximal tubules, accounts for the remaining 10% of glucose absorption. SGLT-2 is also responsible for proximal tubular reabsorption of sodium and the passive absorption of chloride that is driven by the resulting electrochemical gradient in the proximal tubule lumen. The increased absorption of sodium and chloride in the proximal tubule results in lower chloride concentration delivered to the distal tubule, which in turn results in dilation of the afferent arteriole and increase glomerular filtration through "tubuloglomerular feedback." SGLT-2 inhibitors result in a 1 : 1 stoichiometric inhibition of sodium and glucose uptake in the proximal tubule of the kidney. This leads to increased concentration of chloride in the distal tubule, and a resetting of the tubulo-glomerular feedback mechanism, that results in a contraction of the plasma volume without activation of the sympathetic nervous system. Agents in the SGLT-2 class of inhibitors include *canagliflozin*, *dapagliflozin*, and *empagliflozin*.

The landmark EMPA-REG OUTCOME (Empagliflozin Cardiovascular Outcome Event Trial in Type 2 Diabetes Mellitus Patients) showed that empagliflozin reduced death from CV causes by 38%, hospitalization for HF by 35%, and progression to end-stage kidney disease in patients with type 2 diabetes and established CV disease[18] (**see Chapter 51**). Although the precise mechanism(s) that resulted in the striking reduction in HF hospitalization in the empagliflozin treatment arm is not known, it is likely more than simply glucose lowering and may be secondary to additional mechanisms of action, including renal-protective effects, enhanced diuretic efficiency, improved cardiac metabolism, and improved vascular stiffness.[19] Based on these promising results, there are a number of planned or ongoing clinical trials with SGLT-2 inhibitors in heart failure (NCT02653482, NCT02862067, NCT02920918).

Vasopressin Antagonists

Increased circulating levels of the pituitary hormone arginine vasopressin contribute to the increased

systemic vascular resistance and positive water balance in HF patients (**see Chapter 23**). The cellular effects of AVP are mediated by interactions with three types of receptors, V_{1a}, V_{1b} and V_2. Selective V_{1a} antagonists block the vasoconstricting effects of AVP in peripheral vascular smooth muscle cells, whereas V_2-selective receptor antagonists inhibit recruitment of *aquaporin* water channels into the apical membranes of collecting duct epithelial cells, reducing the ability of the collecting duct to resorb water (**see Fig. 25.12**). Combined V_{1a}/V_2 antagonists lead to a decrease systemic vascular resistance and prevent the dilutional hyponatremia that occurs in HF patients.[20]

The AVP antagonists or "vaptans" (**see Table 25.6**) were developed to selectively block the V_2 receptor (e.g., *tolvaptan, lixivaptan, satavaptan*) or nonselectively block both the V_{1a} and the V_2 receptor (e.g., *conivaptan*). All four AVP antagonists increase urine volume, decrease urine osmolarity, and have no effect on 24-hour sodium excretion.[20] Long-term therapy with the V_2-selective AVP antagonist tolvaptan did not improve mortality but appears to be safe in patients with advanced HF.[21] Currently, two AVP antagonists are approved by the U.S. Food and Drug Administration (FDA), conivaptan and tolvaptan, for the treatment of clinically significant hypervolemic and euvolemic hyponatremia (serum $Na^+ \leq 125$) that is symptomatic and resisted correction with fluid restriction in patients with HF; however, neither of these agents is currently specifically approved for the treatment of HF. Use of these agents is appropriate after traditional measures to treat hyponatremia have been tried, including water restriction and maximization of medical therapies such as ACEIs or ARBs, which block or decrease angiotensin II. The use of vaptans in hospitalized HF patients is discussed in **Chapter 24**.

Diuretic Treatment of Heart Failure

Patients with evidence of volume overload or a history of fluid retention should be treated with a diuretic to relieve their symptoms. In symptomatic patients, diuretics should be always used in combination with neurohormonal antagonists that are known to prevent disease progression. When patients have moderate to severe symptoms or renal insufficiency, a loop diuretic is generally required. Diuretics should be initiated in low doses (**see Table 25.6**) and then titrated upward to relieve signs and symptoms of fluid overload. A typical starting dose of furosemide for patients with systolic HF and normal renal function is 40 mg, although doses of 80 to 160 mg are often necessary to achieve adequate diuresis. Because of the steep dose-response curve and effective threshold for loop diuretics, it is critical to find an adequate dose of loop diuretic that leads to a clear-cut diuretic response (**Fig. 25.10A**). One common method for finding the appropriate dose is to double the dose until the desired effect is achieved, or until the maximum dose of diuretic is reached. Once patients have achieved an adequate diuresis, it is important to document their "dry weight" and make certain that patients weigh themselves daily to maintain their dry weight.

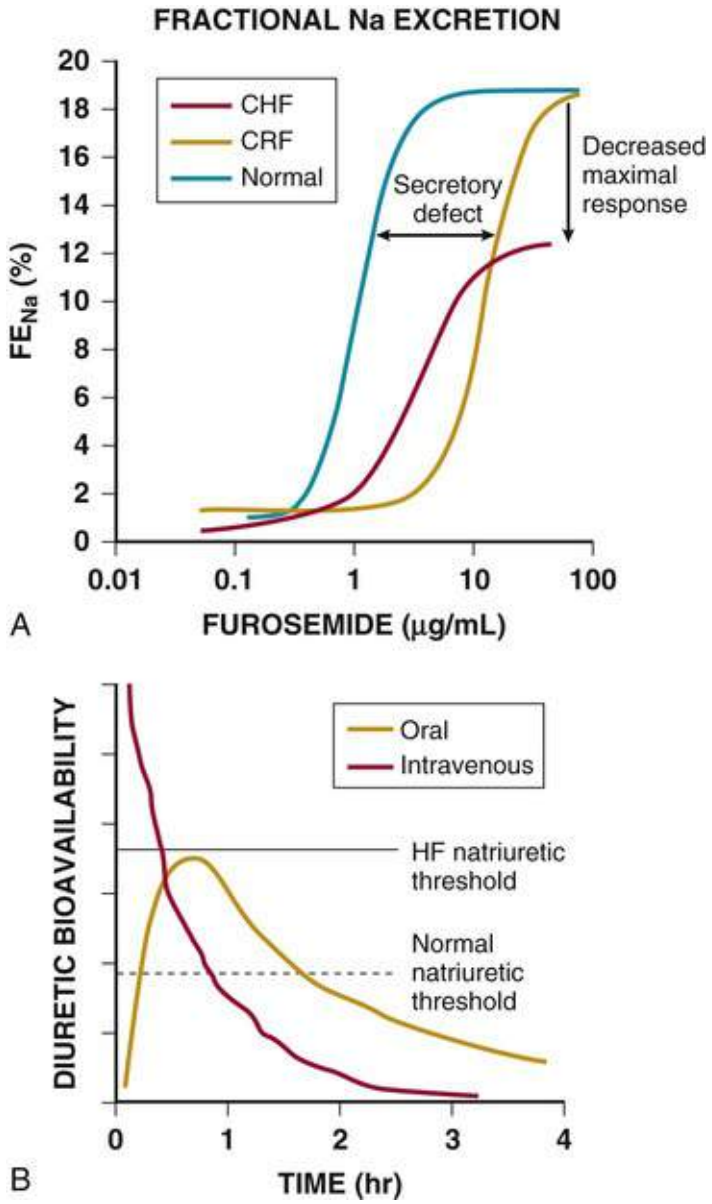

FIGURE 25.10 Dose-response curves for loop diuretics. **A,** Fractional sodium (Na) excretion (FE_{Na}) as a function of loop diuretic concentration. Compared with normal patients, patients with chronic renal failure (CRF) show a rightward shift in the curve because of impaired diuretic secretion. The maximal response is preserved when expressed as FE_{Na}, but not when expressed as absolute Na excretion. Patients with chronic heart failure (CHF) demonstrate a rightward and downward shift, even when the response is expressed as FE_{Na}, and thus are relatively diuretic resistant. **B,** Comparison of the response to intravenous and oral doses of loop diuretics in normal individuals and HF patients. Diuretic bioavailability is shown for normal patients and HF patients. The natriuretic threshold necessary to produce a diuresis in shown for normal individuals (*dotted line*) and for HF patients (*solid line*). In a normal individual, an oral dose may be as effective as an IV dose because the diuretic bioavailability (area under the curve) that is above the natriuretic threshold for IV and oral diuretics is approximately equal. However, if the natriuretic threshold increases in a patient with HF, the oral dose may not provide a high enough serum level to elicit a significant natriuresis. (Modified from Ellison DH. Diuretic therapy and resistance in congestive heart failure. Cardiology 2001;96:132-43.)

Although furosemide is the most frequently used loop diuretic, the oral bioavailability of furosemide is approximately 40% to 79%. Therefore, bumetanide or torsemide may be preferable because of their increased bioavailability. With the exception of torsemide, the common loop diuretics are short-acting (<3 hours). For this reason, loop diuretics usually need to be given at least twice daily. Some patients may develop hypotension or azotemia during diuretic therapy. While the rapidity of diuresis should be slowed in these patients, diuretic therapy should be maintained at a lower level until the patient becomes euvolemic, since persistent volume overload may compromise the effectiveness of some neurohormonal

antagonists. IV administration of diuretics may be necessary to relieve congestion acutely and can be done safely in the outpatient setting (**Fig. 25.10B**) (**see Chapter 24**). After a diuretic effect is achieved with short-acting loop diuretics, increasing administration frequency to twice or even three times per day will provide more diuresis with less physiologic perturbation than larger single doses. Once the congestion has been relieved, treatment with diuretics is continued to prevent the recurrence of salt and water retention in order to maintain the patient's ideal dry weight.

Complications of Diuretic Use

Patients with HF who are receiving diuretics should be monitored regularly for complications. The major complications of diuretic use include electrolyte and metabolic disturbances, volume depletion, and worsening azotemia. The interval for reassessment should be individualized based on severity of illness and underlying renal function, use of concomitant medications such as ACEIs, angiotensin receptor blockers (ARBs), and aldosterone antagonists, past history of electrolyte imbalances, and need for more aggressive diuresis.

Electrolyte and Metabolic Disturbances

Diuretic use can lead to potassium (K^+) depletion, which can predispose the patient to significant cardiac arrhythmias. Renal K^+ losses from diuretic use can be also exacerbated by the increase in circulating levels of aldosterone observed in patients with advanced HF, as well by the marked increases in distal nephron Na^+ delivery that follow use of either loop or distal nephron diuretics. The level of dietary salt intake may also contribute to the extent of renal K^+ wasting with diuretics.

In the absence of formal guidelines with respect to the level of maintenance of serum K^+ levels in HF patients, many experienced HF clinicians have advocated that the serum K^+ should be maintained between 4.0 and 5.0 mEq/L, because HF patients are often treated with pharmacologic agents that are likely to provoke proarrhythmic effects in the presence of hypokalemia (e.g., digoxin, type III antiarrhythmics, beta agonists, phosphodiesterase inhibitors). Hypokalemia can be prevented by increasing the oral intake of potassium chloride (KCl). The normal daily dietary K^+ intake is approximately 40 to 80 mEq. Therefore, to increase this by 50% requires an additional 20 to 40 mEq K^+ supplementation daily. However, in the presence of alkalosis, hyperaldosteronism, or Mg^{2+} depletion, hypokalemia is quite unresponsive to increased dietary intake of KCl, and more aggressive replacement is necessary. If supplementation is necessary, oral potassium supplements in the form of KCl extended-release tablets or liquid concentrate should be used whenever possible. IV potassium is potentially hazardous and should be avoided except in emergencies. Where appropriate, the use of an MRA may also prevent the development of hypokalemia.

The use of aldosterone receptor antagonists is often associated with the development of life-threatening hyperkalemia, particularly when combined with ACEIs, ARBs, or angiotensin receptor neprilysin inhibitors (ARNIs).[22] Potassium supplementation is generally stopped after the initiation of aldosterone antagonists, and patients should be counseled to avoid high–potassium-containing foods. The management of acute hyperkaliemia (>6.0 mEq/L) may require a short-term cessation of potassium-retaining agents and/or RAAS inhibitors; however, RAAS inhibitors should be carefully reintroduced as soon as possible while monitoring K^+ levels. Two new K^+ binders, patiromer and sodium zirconium cyclosilicate, have

been studied in HF patients with hyperkalemia. *Patiromer* is a nonabsorbed, cation-exchange polymer that contains a calcium-sorbitol counterion and works by binding K^+ in the lumen of the gastrointestinal tract, resulting in a reduction of serum K^+ levels within 7 hours of the first dose. Patiromer is FDA approved for the treatment of hyperkalemia but should not be used as an emergency treatment for life-threatening hyperkalemia because of its delayed onset of action. The initial clinical studies in patients with HF have shown that these therapies reduce serum K^+ and prevent recurrent hyperkalemia in HF patients with chronic kidney disease who were receiving RAAS inhibitors.[23]

Diuretics may be associated with multiple other metabolic and electrolyte disturbances, including hyponatremia, hypomagnesemia, metabolic alkalosis, hyperglycemia, hyperlipidemia, and hyperuricemia. Hyponatremia is usually observed in HF patients with very high degrees of RAAS activation and high AVP levels. Aggressive diuretic use can also lead to hyponatremia. Hyponatremia can typically be treated by more stringent water restriction. Both loop and thiazide diuretics can cause hypomagnesemia, which can aggravate muscle weakness and cardiac arrhythmias. Magnesium replacement should be administered for signs or symptoms of hypomagnesemia (arrhythmias, muscle cramps) and can be routinely given (with uncertain benefit) to all patients receiving large doses of diuretics or requiring large amounts of K^+ replacement. The modest hyperglycemia or hyperlipidemia produced by thiazide diuretics is not usually clinically important, and blood glucose and lipids are usually easily controlled using standard-practice guidelines. Metabolic alkalosis can generally be treated by increasing KCl supplementation, lowering diuretic doses, or transiently using acetazolamide.

Hypotension and Azotemia

The excessive use of diuretics can lead to a decreased blood pressure, decreased exercise tolerance, and increased fatigue, as well as impaired renal function. Hypotensive symptoms usually resolve after a decrease in the dose or frequency of diuretics in patients who are volume depleted. In most patients, however, use of diuretics is associated with decreased blood pressure and mild azotemia, which do not lead to patient symptoms. In these cases, reductions in the diuretic dose are not necessary, particularly if the patient remains edematous. In some patients with advanced, chronic HF, elevated blood urea nitrogen (BUN) and creatinine concentrations may be necessary to maintain control of congestive symptoms.

Neurohormonal Activation

Diuretics may increase the activation of endogenous neurohormonal systems in HF patients, which can lead to disease progression unless patients are receiving treatment with a concomitant neurohormonal antagonist (e.g., ACEI, beta blocker).

Ototoxicity

Ototoxicity, which is more frequent with ethacrynic acid than the other loop diuretics, can manifest as tinnitus, hearing impairment, and deafness. Hearing impairment and deafness are usually, but not invariably, reversible. Ototoxicity occurs most frequently with rapid IV injections and least frequently with oral administration.

Diuretic Resistance

One of the inherent limitations of diuretics is that they achieve water loss through excretion of solute at the expense of glomerular filtration, which in turn activates a set of homeostatic mechanisms that ultimately

limit their effectiveness. In normal patients the magnitude of natriuresis following a given dose of diuretic declines over time as a result of the "braking phenomenon" (**Fig. 25.11**). Studies have shown that the time-dependent decline in natriuresis for a given diuretic dose is critically dependent on reduction of the extracellular fluid (ECF) volume, which leads to an increase in solute and fluid reabsorption in the proximal tubule. In addition, contraction of the ECF volume can lead to stimulation of efferent sympathetic nerves, which reduces urinary Na^+ excretion by reducing renal blood flow, stimulating renin (and ultimately aldosterone) release, which in turn stimulates Na^+ reabsorption along the nephron (**see Chapter 23**). The magnitude of the natriuretic effect of potent loop diuretics may also decline in HF patients, particularly as HF progresses. Although the bioavailability of these diuretics is generally not decreased in HF, the potential delay in their rate of absorption may result in peak drug levels within the tubular lumen in the ascending loop of Henle that are insufficient to induce maximal natriuresis. The use of IV formulations may obviate this problem (**see Chapter 24**). However, even with IV dosing, a rightward shift of the dose-response curve is observed between the diuretic concentration in the tubular lumen and its natriuretic effect in HF (**see Fig. 25.10A**). Moreover, the maximal effect (ceiling) is lower in HF. This rightward shift has been referred to as "diuretic resistance" and is likely caused by several factors in addition to the braking phenomenon.

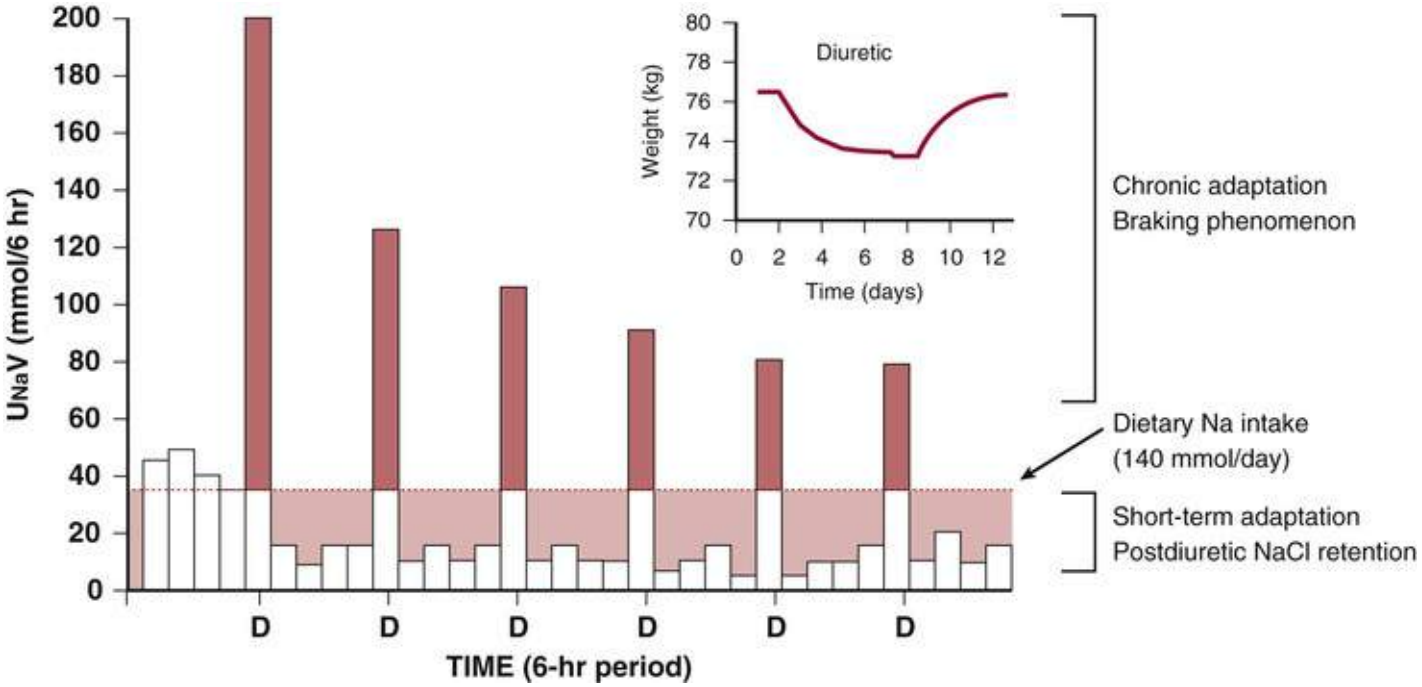

FIGURE 25.11 Effects of diuretics on urinary sodium (Na) excretion and extracellular fluid (ECF) volume. **Main graph,** Effects of a loop diuretic on urinary Na excretion ($U_{Na}V$). Bars represent 6-hour periods before (in Na balance) and after doses of loop diuretic (*D*). The *dotted line* indicates dietary Na intake. The *solid red* portion of the *open bars* indicates the amount by which Na excretion exceeds intake during natriuresis. The *hatched areas* indicate the amount of positive Na balance after the diuretic effect has worn off. Net Na balance during 24 hours is the difference between the *shaded area below the stippled line* (postdiuretic NaCl retention) and the *solid areas within the bars* (diuretic-induced natriuresis). Chronic adaptation is indicated by progressively smaller peak natriuretic effects (the braking phenomenon) and is mirrored by a return to neutral balance. **Inset,** Effect of a diuretic on body weight, taken as an index of ECF volume. Note that steady state is reached within 6 to 8 days despite continued diuretic administration.
(Modified from Ellison DH. Diuretic therapy and resistance in congestive heart failure. Cardiology. 2001;96:132-143.)

First, most loop diuretics, with the exception of torsemide, are short-acting drugs. Accordingly, after a period of natriuresis, the diuretic concentration in plasma and tubular fluid declines below the diuretic threshold. In this situation, renal Na^+ reabsorption is no longer inhibited, and a period of antinatriuresis or

postdiuretic NaCl retention ensues. If dietary NaCl intake is moderate to excessive, postdiuretic NaCl retention may overcome the initial natriuresis in patients with excessive activation of the adrenergic nervous system and RAS. This observation forms the rationale for administering short-acting diuretics several times per day to obtain consistent daily salt and water loss. Second, there is a loss of renal responsiveness to endogenous natriuretic peptides as HF advances (**see Chapter 23**). Third, diuretics increase solute delivery to distal segments of the nephron, causing epithelial cells to undergo both hypertrophy and hyperplasia. Although the diuretic-induced signals that initiate changes in distal nephron structure and function are not well understood, chronic loop diuretic administration increases the Na^+,K^+-ATPase activity in the distal collecting duct and cortical collecting tubule, as well as increases the number of thiazide-sensitive Na^+-Cl^- cotransporters in the distal nephron, which increases the solute resorptive capacity of the kidney as much as threefold.

In patients with HF, an abrupt decline in cardiac and/or renal function or patient noncompliance with the diuretic regimen or diet may lead to diuretic resistance. Apart from these more obvious causes, it is important to query the patient with regard to concurrent use of drugs that adversely affect renal function, such as NSAIDs and COX-2 inhibitors (**see Table 25.5**), and certain antibiotics (trimethoprim and gentamicin). The relative risk of increased HF hospitalization varies between individual NSAIDs; including a 1.16 (95% CI 1.07 to 1.27) increase for naproxen, a 1.18 (1.12 to 1.23) increase for ibuprofen, a 1.19 (1.15 to 1.24) increase for diclofenac and a 1.51 (1.33 to 1.71) increase for indomethacin. The use of the COX-2 inhibitors etoricoxib and rofecoxib was also associated with increased risk of hospitalization.[24] The insulin-sensitizing thiazolidinediones (TZDs) have also been linked to increased fluid retention in patients with HF, although the clinical significance of this finding is not known. It has been suggested that TZDs activate proliferator-activated receptor-gamma expression in the renal collecting duct, which enhances expression of cell surface epithelial Na^+ channels. Moreover, studies in healthy men have shown that pioglitazone stimulates plasma renin activity, which may contribute to increased Na^+ retention. Rarely, drugs such as probenecid or high plasma concentrations of some antibiotics may compete with the organic ion transporters in the proximal tubule responsible for the transfer of most diuretics from the recirculation into the tubular lumen. The use of increasing doses of vasodilators, with or without a marked decline in intravascular volume as a result of concomitant diuretic therapy, may lower renal perfusion pressure below that necessary to maintain normal autoregulation and glomerular filtration in patients with renal artery stenosis from atherosclerotic disease. Therefore, a reduction in renal blood flow may occur despite an increase in cardiac output, thereby leading to a decrease in diuretic effectiveness.

A patient with HF may be considered to be resistant to diuretic drugs when moderate doses of a loop diuretic do not achieve the desired reduction of the ECF volume. In outpatients, a common and useful method for treating the diuretic-resistant patient is to administer two classes of diuretic concurrently. Adding a proximal tubule diuretic or a distal collecting tubule diuretic to a regimen of loop diuretics is often dramatically effective. As a general rule, when adding a second class of diuretic, the dose of loop diuretic should not be altered because the shape of the dose-response curve for loop diuretics is not affected by the addition of other diuretics, and the loop diuretic must be given at an effective dose for it to be effective. The combination of loop and distal collecting tubule diuretics has been shown to be effective through several mechanisms.[25] One is that distal collecting tubule diuretics have longer half-lives than

loop diuretics and may thus prevent or attenuate postdiuretic NaCl retention. A second mechanism by which distal collecting tubule diuretics potentiate the effects of loop diuretics is by inhibiting Na^+ transport along the proximal tubule, since most thiazide diuretics also inhibit carbonic anhydrase, as well as by inhibiting NaCl transport along the distal renal tubule, which may counteract the increased solute resorptive effects of the hypertrophied and hyperplastic distal epithelial cells.

The selection of distal collecting tubule diuretic to use as second diuretic is a matter of choice. Many clinicians choose metolazone because its half-life is longer than that of some other distal collecting tubule diuretics, and because it has been reported to remain effective even when the glomerular filtration rate (GFR) is low. However, direct comparisons between metolazone and several traditional thiazides have shown little difference in natriuretic potency when they are included in a regimen with loop diuretics in HF patients.[26] Distal collecting tubule diuretics may be added in full doses (50 to 100 mg/day hydrochlorothiazide or 2.5 to 10 mg/day metolazone; **see Table 25.6**) when a rapid and robust response is needed. However, such an approach is likely to lead to excessive fluid and electrolyte depletion if patients are not followed extremely closely. One reasonable approach to combination therapy is to achieve control of fluid overload by initially adding full doses of distal collecting tubule diuretic on a daily basis and then decreasing the dose of the distal collecting tubule diuretic to three times weekly to avoid excessive diuresis. An alternative strategy in hospitalized patients is to administer the same daily parenteral dose of a loop diuretic by continuous IV infusion, which leads to sustained natriuresis because of the continuous presence of high drug levels within the tubular lumen (**see Chapter 24**) and avoids postdiuretic ("rebound") resorption of Na^+ (**see Fig. 25.11**). This approach requires the use of a constant-infusion pump but permits more precise control of the natriuretic effect achieved over time, particularly in carefully monitored patients. It also diminishes the potential for too rapid a decline in intravascular volume and hypotension as well as the risk of ototoxicity in patients given large-bolus IV doses of a loop diuretic. A typical continuous furosemide infusion is initiated with a 20- to 40-mg IV loading dose as a bolus injection, followed by a continuous infusion of 5 to 10 mg/hr for a patient who had been receiving 200 mg of oral furosemide per day in divided doses. The DOSE (Diuretic Optimal Strategy Evaluation in Acute Heart Failure) study showed that there was no significant difference in symptoms or renal function when patients with acute decompensated heart failure (ADHF) were treated by an IV bolus of furosemide compared to IV infusion of furosemide, suggesting that whichever approach is most likely to reliably produce the desired dieresis should be used.

Another common reason for diuretic resistance in advanced HF is the development of the *cardiorenal syndrome* (see also **Chapters 24 and 98**), which is recognized clinically as worsening renal function that limits diuresis in patients with obvious clinical volume overload.[27] In patients with advanced HF, the cardiorenal syndrome is frequently present in those who have repeated HF hospitalizations, and in whom adequate diuresis is difficult to obtain because of worsening indices of renal function. This impairment in renal function often is dismissed as "pre-renal"; however, when measured carefully, neither cardiac output nor renal perfusion pressure have been shown to be reduced in diuretic-treated patients who develop the cardiorenal syndrome. Importantly, worsening indices of renal function contribute to longer hospital stays and predict higher rates of early rehospitalization and death[28] (**see Fig. 25.2**). The mechanisms for and treatment of the cardiorenal syndrome remain poorly understood.

Device-Based Therapies

Mechanical methods of fluid removal may be needed to achieve adequate control of fluid retention, particularly in patients who become resistant and/or refractory to diuretic therapy(**see Chapter 24**). *Extracorporeal ultrafiltration* (UF) removes salt and water isotonically by driving the patient's blood through a highly permeable filter via an extracorporeal circuit in an arteriovenous or venovenous mode. Alternative extracorporeal methods include continuous hemofiltration, hemodialysis, or hemodiafiltration. With slow, continuous UF, the patient's intravascular fluid volume remains stable as fluid shifts from the extravascular space into the intravascular space, with no deleterious activation of neurohormonal systems. UF has been shown to reduce right atrial and pulmonary artery wedge pressures and increase cardiac output, diuresis, and natriuresis without changes in heart rate, systolic blood pressure, renal function, electrolytes, or intravascular volume.[29]

The Relief for Acutely Fluid-Overloaded Patients with Decompensated Congestive Heart Failure (RAPID-CHF) trial, which was the first RCT of ultrafiltration for ADHF, enrolled 40 patients who were randomized to receive usual care (diuretic) or a single 8-hour period of UF therapy (using a proprietary device) in addition to usual care. The primary endpoint was weight loss 24 hours after enrollment. Fluid removal after 24 hours was approximately twofold greater in the UF group.[29] The Ultrafiltration versus IV Diuretics for Patients Hospitalized for Acute Decompensated Congestive Heart Failure (UNLOAD) study compared the long-term safety and efficacy of UF therapy (using a proprietary device) to IV diuretics in a multicenter trial involving 200 patients, who were assessed at entry and at intervals to 90 days. The primary endpoint was total weight loss during the first 48 hours of randomization and the change in dyspnea score during the first 48 hours of randomization. Although the two treatments were similar in ability to relieve dyspnea, UF was associated with significantly greater fluid loss over 48 hours and a lower rate of rehospitalization during the next 90 days.[29] The use of UF in high-risk patients developing the cardiorenal syndrome was explored in CARRESS (Cardiorenal Rescue Study in Acute Decompensated Heart Failure) trial, which showed that UF resulted in similar weight loss, but an increase in creatinine levels, compared to standard care, and was associated with more serious adverse events and IV catheter–related complications.[29]

Given the cost, need for venous access, and the nursing support necessary to implement UF, additional studies are needed to determine its role in the management of volume overload in HF patients. In addition to extracorporeal methods for relieving volume overload, peritoneal dialysis can be used as a viable alternative therapy for the short-term management of refractory congestive symptoms for patients in whom vascular access cannot be obtained, or for whom appropriate extracorporeal therapies are not available.

Prevention of Disease Progression

Drugs that interfere with the excessive activation of renin-angiotensin-aldosterone system (RAAS) and the adrenergic nervous system can relieve the symptoms of HF with a depressed EF by stabilizing and/or reversing cardiac remodeling (**see Fig. 25G.1**). In this regard, ACEIs/ARBs and beta-adrenergic blockers have emerged as cornerstones of modern HF therapy for patients with a depressed EF (**Table 25.7**).

TABLE 25.7

Drugs for the Prevention and Treatment for Chronic Heart Failure

AGENT	INITIATING DOSE	MAXIMAL DOSE
Angiotensin-Converting Enzyme Inhibitors		
Captopril	6.25 mg 3 times	50 mg 3 times
Enalapril	2.5 mg twice	10 mg twice
Lisinopril	2.5-5.0 mg once	20 mg once
Ramipril	1.25-2.5 mg once	10 mg once
Fosinopril	5-10 mg once	40 mg once
Quinapril	5 mg twice	40 mg twice
Trandolapril	0.5 mg once	4 mg once
Angiotensin Receptor Blockers		
Valsartan	40 mg twice	160 mg twice
Candesartan	4-8 mg once	32 mg once
Losartan	12.5-25 mg once	50 mg once
Angiotensin Receptor Neprilysin Inhibitor		
Sacubitril/valsartan	24 mg/26 mg twice	97 mg/103 mg twice
Beta-Adrenergic Receptor Blockers		
Carvedilol	3.125 mg twice	25 mg twice (50 mg twice if >85 kg)
Carvedilol-CR	10 mg once	80 mg once
Bisoprolol	1.25 mg twice	10 mg once
Metoprolol succinate CR	12.5-25 mg qd	Target dose 200 mg qd
Mineralocorticoid Receptor Antagonists		
Spironolactone	12.5-25 mg once	25-50 mg once
Eplerenone	25 mg once	50 mg once
Other Agents		
Combination of hydralazine/isosorbide dinitrate	10-25 mg/10 mg 3 times	75 mg/40 mg 3 times
Fixed dose of hydralazine/isosorbide dinitrate	37.5 mg/20 mg (one tablet) 3 times	75 mg/40 mg (two tablets) 3 times
Digoxin*	0.125 mg qd	≤0.375 mg/once†
Ivabradine	5 mg twice daily	7.5 mg twice‡

*Dosing should be based on ideal body weight, age, and renal function; *qd,* every day.

†Trough level should be 0.5 to 1 ng/mL, although absolute levels have not been established.

‡Approved in the European Union for the treatment of heart failure but is not FDA approved.

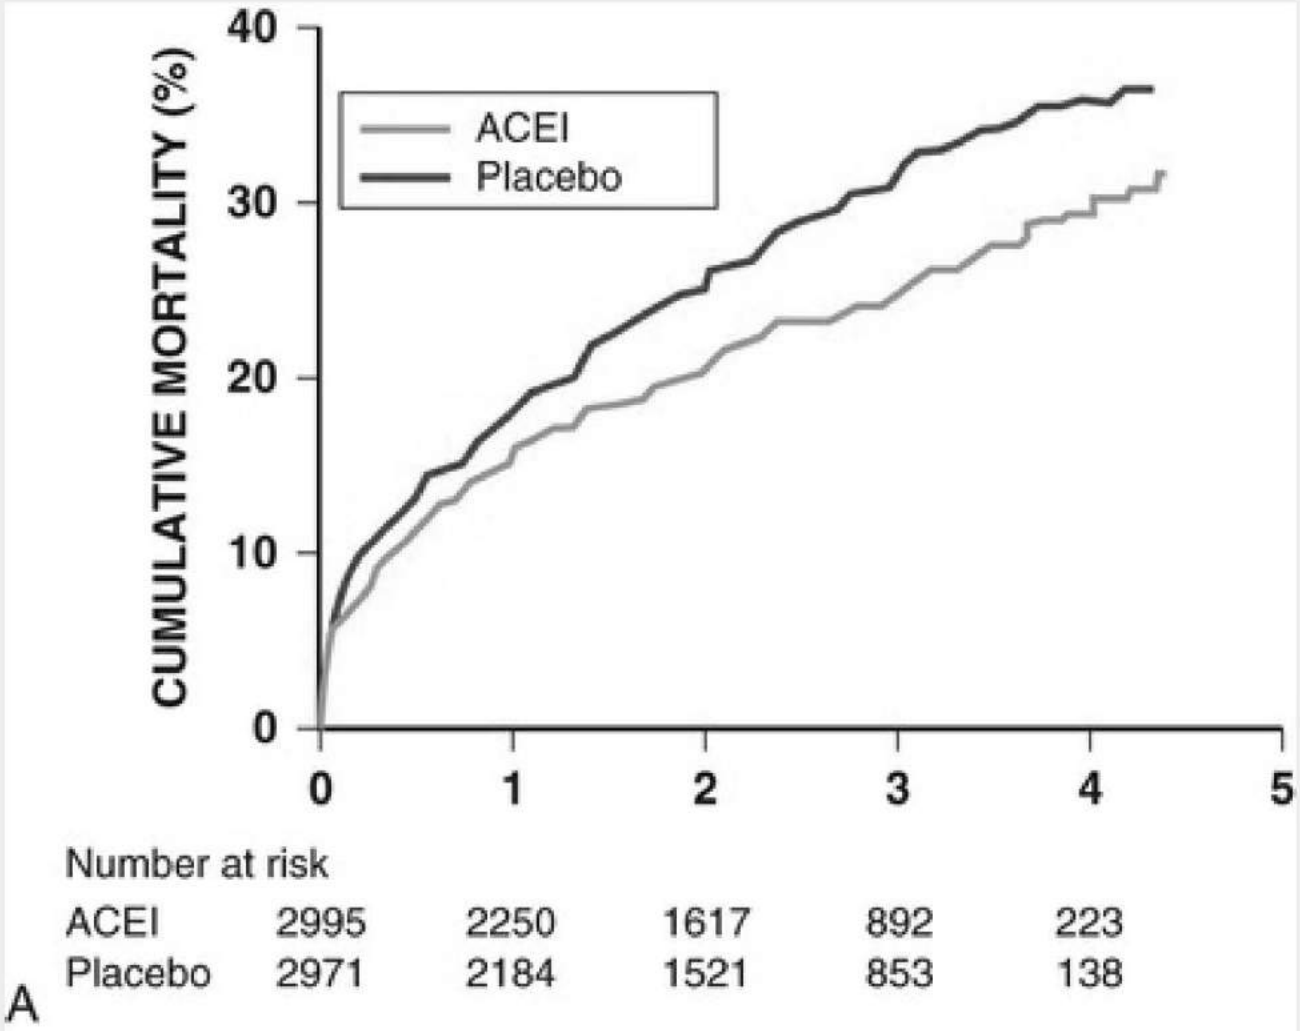
Angiotensin-Converting Enzyme Inhibitors

There is overwhelming evidence that ACEIs should be used in symptomatic and asymptomatic patients with a reduced EF (<40%). ACEIs interfere with the RAS by inhibiting the enzyme that is responsible for the conversion of angiotensin I to angiotensin II (**see Chapter 23**). However, because ACEIs also inhibit kininase II, they may lead to the upregulation of bradykinin, which may further enhance the effects of angiotensin suppression. ACEIs stabilize LV remodeling, improve patient symptoms, prevent hospitalization, and prolong life. Because fluid retention can attenuate the effects of ACEIs, it is preferable to optimize the dose of diuretic first, before starting the ACEI. However, it may be necessary

to reduce the dose of diuretic during the initiation of an ACEI, to prevent symptomatic hypotension. ACEIs should be initiated in low doses, followed by increments in dose if lower doses have been well tolerated. Titration is generally achieved by doubling doses every 3 to 5 days. The dose of ACEI should be increased until the doses used are similar to those that have been shown to be effective in clinical trials (**Table 25.7**). Higher doses are more effective than lower doses in preventing hospitalization. For stable patients, it is acceptable to add therapy with beta-blocking agents before full target doses of either ACEIs are reached. Blood pressure (including postural changes), renal function, and potassium should be evaluated within 1 to 2 weeks after initiation of ACEIs, especially in patients with preexisting azotemia, hypotension, hyponatremia, or diabetes mellitus or taking potassium supplements. Abrupt withdrawal of treatment with an ACEI may lead to clinical deterioration and therefore should be avoided in the absence of life-threatening complications (e.g., angioedema, hyperkalemia).

The efficacy of ACEIs has been consistently demonstrated in clinical trials with patients with asymptomatic and symptomatic LV dysfunction[8,12] (**Fig. 25.12**). These trials recruited a broad variety of patients, including women and the elderly, as well as patients with a wide range of causes and severity of LV dysfunction. The consistency of data from the Studies on Left Ventricular Dysfunction (SOLVD) Prevention Study, Survival and Ventricular Enlargement (SAVE), and the Trandolapril Cardiac Evaluation (TRACE) has shown that asymptomatic patients with LV dysfunction will have less development of symptomatic HF and fewer hospitalizations when treated with an ACEI. ACEIs have also consistently shown benefit for patients with symptomatic LV dysfunction (**Table 25.8**). All placebo-controlled chronic HF trials have demonstrated a reduction in mortality. Further, the absolute benefit is greatest in patients with the most severe HF. Indeed, the patients with NYHA Class IV HF in the Cooperative North Scandinavian Enalapril Survival Study (CONSENSUS I) had a much larger effect size than the SOLVD Treatment Trial, which in turn had a larger effect size than the SOLVD Prevention Trial.



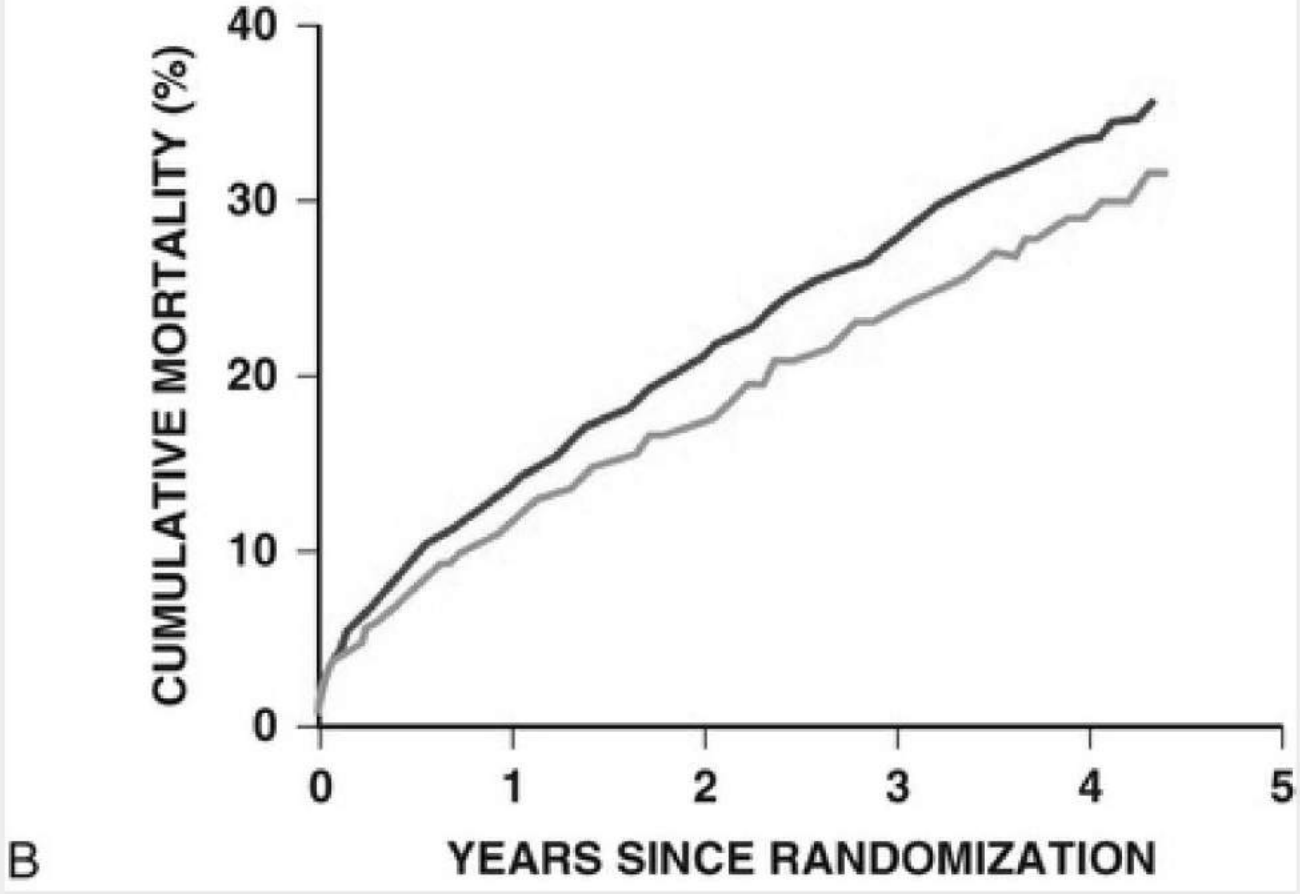


FIGURE 25.12 Meta-analysis of angiotensin-converting enzyme inhibitor (ACEI) in HFrEF. **A,** Kaplan-Meier curves for mortality for patients with HF with a depressed ejection fraction (EF) treated with an ACEI

following acute myocardial infarction (three trials). **B,** Kaplan-Meier curves for mortality for patients with HF with a depressed EF treated with an ACEI in five clinical trials, including postinfarction trials. The benefits of ACEI were observed early and persisted long term. (Modified from Flather MD et al. Long-term ACE-inhibitor therapy in patients with heart failure or left-ventricular dysfunction: a systematic overview of data from individual patients. ACE-Inhibitor Myocardial Infarction Collaborative Group. Lancet 2000;355:1575-80.)

Modified from Bristow MR, Linas S, Port DJ. Drugs in the treatment of heart failure. In Zipes DP et al, editors: Braunwald's Heart Disease. 7th ed. Philadelphia: Elsevier; 2004, p 573.

Although only three placebo-controlled mortality trials have been conducted in patients with chronic

HF, the aggregate data suggest that ACEIs reduce mortality in direct relation to the degree of severity of chronic HF. The Vasodilator in Heart Failure II (V-HeFT-II) trial provided evidence that ACEIs improve the natural history of HF through mechanisms other than vasodilation. Participants treated with enalapril had significantly lower mortality than those treated with the vasodilatory combination of hydralazine plus isosorbide dinitrate (which does not directly inhibit neurohormonal systems). Although enalapril is the only ACEI that has been used in placebo-controlled mortality trials in chronic HF (**see Table 25.8**), multiple ACEIs have proved to be more or less equally effective when administered orally within the first week of the ischemic event in myocardial infarction (MI) trials. ACEIs markedly enhance survival in patients with signs or symptoms of HF after MI. In addition to these effects on mortality, ACEIs improve the functional status of patients with HF. In contrast, ACEIs only produce small benefits in exercise capacity. Taken together, these observations support the conclusion that the effects of ACEIs on the natural history of chronic HF, the incidence of post-MI LV dysfunction, or patients at high risk of developing HF represent “class effects” of these agents. Nonetheless, it should be emphasized that patients with a low blood pressure (<90 mm Hg systolic), or impaired renal function (serum creatinine >2.5 mg/mL) were not recruited or represent a small proportion of patients who participated in these trials. Thus the efficacy of these agents for this latter patient population is less well established.

Side Effects of ACEI Use

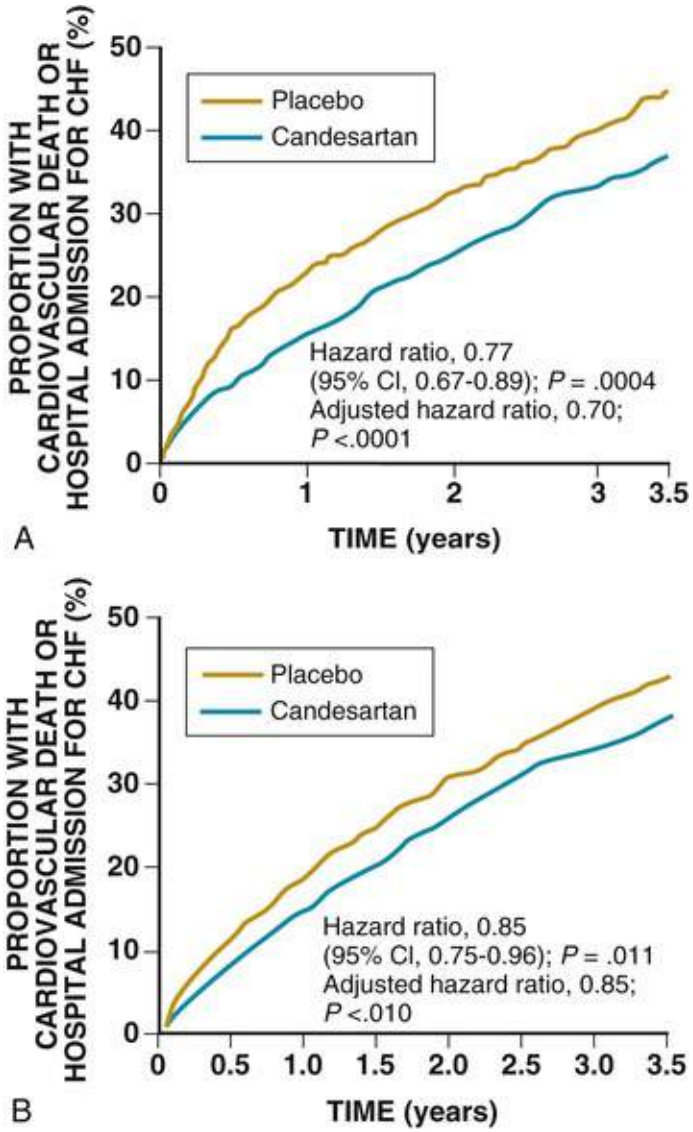
The majority of the adverse effects of ACEIs are related to suppression of the RAS. The decreases in blood pressure and mild azotemia often seen during initiation of therapy are generally well tolerated and do not require a decrease in ACEI dose. However, if hypotension is accompanied by dizziness or if the renal dysfunction becomes severe, it may be necessary to decrease the dose of the diuretic if significant fluid retention is not present, or alternatively decrease the ACEI dose if significant fluid retention is present. Potassium retention may also become problematic if the patient is receiving potassium supplements or a potassium-sparing diuretic. Potassium retention that is not responsive to these measures may require a reduction in ACEI dose. The side effects of ACEIs related to kinin potentiation include a nonproductive cough (10% to 15% of patients) and angioedema (1%). In patients who cannot tolerate ACEIs because of cough or angioedema, ARBs are the next recommended line of therapy. Patients intolerant to ACEIs because of hyperkalemia or renal insufficiency are likely to experience the same side effects with ARBs. The combination of hydralazine and an oral nitrate should be considered for these latter patients (**see Table 25.7**).

Angiotensin Receptor Blockers

ARBs are well tolerated in patients who are intolerant of ACEIs because of cough, skin rash, or angioedema and therefore should be used in symptomatic and asymptomatic patients with an EF less than 40% who are ACE intolerant for reasons other than hyperkalemia or renal insufficiency (**see Table 25.7**). Although ACEIs and ARBs inhibit the RAAS, they do so by a different mechanism. Whereas ACEIs block the enzyme responsible for converting angiotensin I to angiotensin II, ARBs block the effects of angiotensin II on the angiotensin type 1 receptor, the receptor subtype responsible for virtually all the adverse biologic effects relevant to angiotensin II on cardiac remodeling (**see Chapter 22**). Multiple ARBs approved for treatment of hypertension are now available to clinicians. Three of these, *losartan*, *valsartan*, and *candesartan*, have been extensively evaluated in the setting of HF (**see Table 25.8**). Several studies have shown that there is added modest therapeutic benefit for the addition of ARB to an

ACEI in patients with chronic HF. ARBs should be initiated with the starting doses shown in **Table 25.7**, which can be uptitrated every 3 to 5 days by doubling the dose of ARB. As with ACEIs, blood pressure, renal function, and potassium should be reassessed within 1 to 2 weeks after initiation and followed closely after changes in dose.

In symptomatic HF patients intolerant to ACEIs, the aggregate clinical data suggest that ARBs are as effective as ACEIs in reducing HF morbidity and mortality. Candesartan significantly reduced all-cause mortality, CV death, or hospital admission in the Candesartan Heart Failure: Assessment of Reduction in Mortality and Morbidity trial (CHARM-Alternative)[8,12] (**eFig. 25.3**). Importantly, candesartan reduced all-cause mortality, irrespective of background ACEI or beta-blocker therapy. Similar findings were shown with valsartan in the small subgroup of patients not receiving an ACEI in the Valsartan Heart Failure Trial (Val-HeFT). A direct comparison of ACEIs and ARBs was assessed in the Losartan Heart Failure Survival Study (ELITE-II), which showed that losartan was not associated with improved survival in elderly HF patients compared to captopril but was significantly better tolerated. Two trials have evaluated ARBs compared to ACEIs in post-MI patients who developed LV dysfunction or signs of HF. The direct comparison of losartan with captopril indicated that losartan was not as effective as captopril on all-cause mortality, whereas valsartan was noninferior to captopril on all-cause mortality in the Valsartan in Acute Myocardial Infarction Trial (VALIANT).[8,12] The combination of captopril and valsartan produced no further reduction in mortality in VALIANT, although the number of adverse events increased. When given in addition to ACEIs in general cohorts of patients with symptomatic HF, the effects of ARBs were shown to have a modest beneficial effect in the CHARM-Added trial.[8,12] However, the addition of valsartan to ACEIs had no beneficial effect on mortality in Val-HeFT, although the combined endpoint of mortality and morbidity was significantly (13.2%) lower with valsartan than with placebo because of a reduction in the number of patients hospitalized for HF.[12] The question of high-dose versus low-dose angiotensin receptor antagonism on clinical outcomes was evaluated in the Heart Failure Endpoint Evaluation of Angiotensin II Antagonist Losartan (HEAAL) trial.[8,12] This study showed that high-dose losartan was not associated with a significant reduction in the primary endpoint of all-cause death or admission for HF (HR 0.94; 95% CI 0.84 to 1.04; $P = 0.24$) compared to low-dose losartan, but was associated with a significant reduction in HF admissions (HR 0.94; 95% CI 0.84 to 1.04; $P = 0.24$), suggesting that uptitration of ARBs may confer clinical benefit.



EFIGURE 25.3 Effect of candesartan on cardiovascular mortality or hospital admission for congestive heart failure (CHF) in the CHARM-Alternative **(A)** and CHARM-Added **(B)** trials. Two groups of patients who were randomized to candesartan or placebo are depicted: **A,** patients who were not receiving an angiotensin-converting enzyme (ACE) inhibitor, and **B,** patients who were receiving an ACE inhibitor. The effect size of candesartan was reduced in the group of patients receiving an ACEI. (Modified from Granger CB et al. Effects of candesartan in patients with chronic heart failure and reduced left-ventricular systolic function intolerant to angiotensin-converting-enzyme inhibitors: the CHARM-Alternative trial. Lancet 2003;362:772-6, and McMurray JJ et al. Effects of candesartan in patients with chronic heart failure and reduced left-ventricular systolic function taking angiotensin-converting-enzyme inhibitors: the CHARM-Added trial. Lancet 2003;362:767-71.)

Although one meta-analysis suggests that ARBs and ACEIs have similar effects on all-cause mortality and HF hospitalizations,[30] and although ARBs may be considered as initial therapy rather than ACEIs following MI, the general consensus is that ACEIs remain first-line therapy for the treatment of HF, whereas ARBs were recommended for ACEI-intolerant patients.[8,12]

Side Effects of ARB Use

Both ACEIs and ARBs have similar effects on blood pressure, renal function, and potassium. Therefore the problems of symptomatic hypotension, azotemia, and hyperkalemia will be similar for both these agents. Although less frequent that with ACEIs, angioedema has also been reported in some patients who receive ARBs. In patients intolerant of ACEIs and ARBs, the combined use of hydralazine and isosorbide dinitrate may be a therapeutic option (**see Table 25.7**). However, compliance with this combination has generally been poor because of the large number of tablets required and the high incidence of adverse

reactions.

Angiotensin Receptor Neprilysin Inhibitors

A new therapeutic class of agents that antagonizes RAAS and inhibits the neutral endopeptidase system has been recently developed. The first agent is a molecule that combines valsartan (an AT1 receptor antagonist) with sacubitril (a neprilysin inhibitor) in a 1 : 1 mixture. The combination of an angiotensin receptor neprilysin inhibitor (ARNI) slows the degradation of natriuretic peptides, bradykinin, and adrenomedullin, thereby enhancing diuresis, natriuresis, and myocardial relaxation. It also inhibits renin and aldosterone secretion, while selectively blocking the angiotensin type 1 (AT1) receptor reduces vasoconstriction, sodium, and water retention and myocardial hypertrophy[31] (**see Chapter 23**).

In the Prospective Comparison of ARNI with ACEI to Determine Impact on Global Mortality and Morbidity in Heart Failure Trial (PARADIGM-HF),[32] the use of fixed-dose sacubitril/valsartan resulted in striking reductions in all-cause mortality, CV mortality, and HF hospitalizations compared with an ACEI (enalapril) alone in patients with mild to moderate HF (NYHA Class II to IV; LVEF 35%) (**Fig. 25.13**). This was characterized by either mildly elevated natriuretic peptide levels (BNP >150 pg/mL or NT-proBNP ≥600 pg/mL) or hospitalization in the preceding 12 months and elevated natriuretic peptide levels (BNP ≥100 pg/mL or NT-proBNP ≥400 pg/mL) in patients who were also able to tolerate both a target dose of enalapril (10 mg twice daily) and then subsequently sacubitril/valsartan (200 mg twice daily). ARNIs should be administered in low doses (sacubitril 24 mg/valsartan 26 mg twice daily) in ACEI/ARB-naive patients or moderate doses (sacubitril 49 mg/valsartan 51 mg twice daily) in patients tolerant of ACEIs/ARBs. The target dose of sacubitril/valsartan in PARADIGM-HF was 97 mg/103 mg twice daily. Although the most recent update of the ACC/AHA/HFSA guidelines do not recommend starting HFrEF patients on ARNIs (**see Fig. 25G.1** and **Table 25G.3**), in patients with HFrEF NYHA Class II or III who are tolerating an ACEI or ARB, ARNIs are recommended as a replacement for ACEI/ARB to further reduce morbidity and mortality.[10]

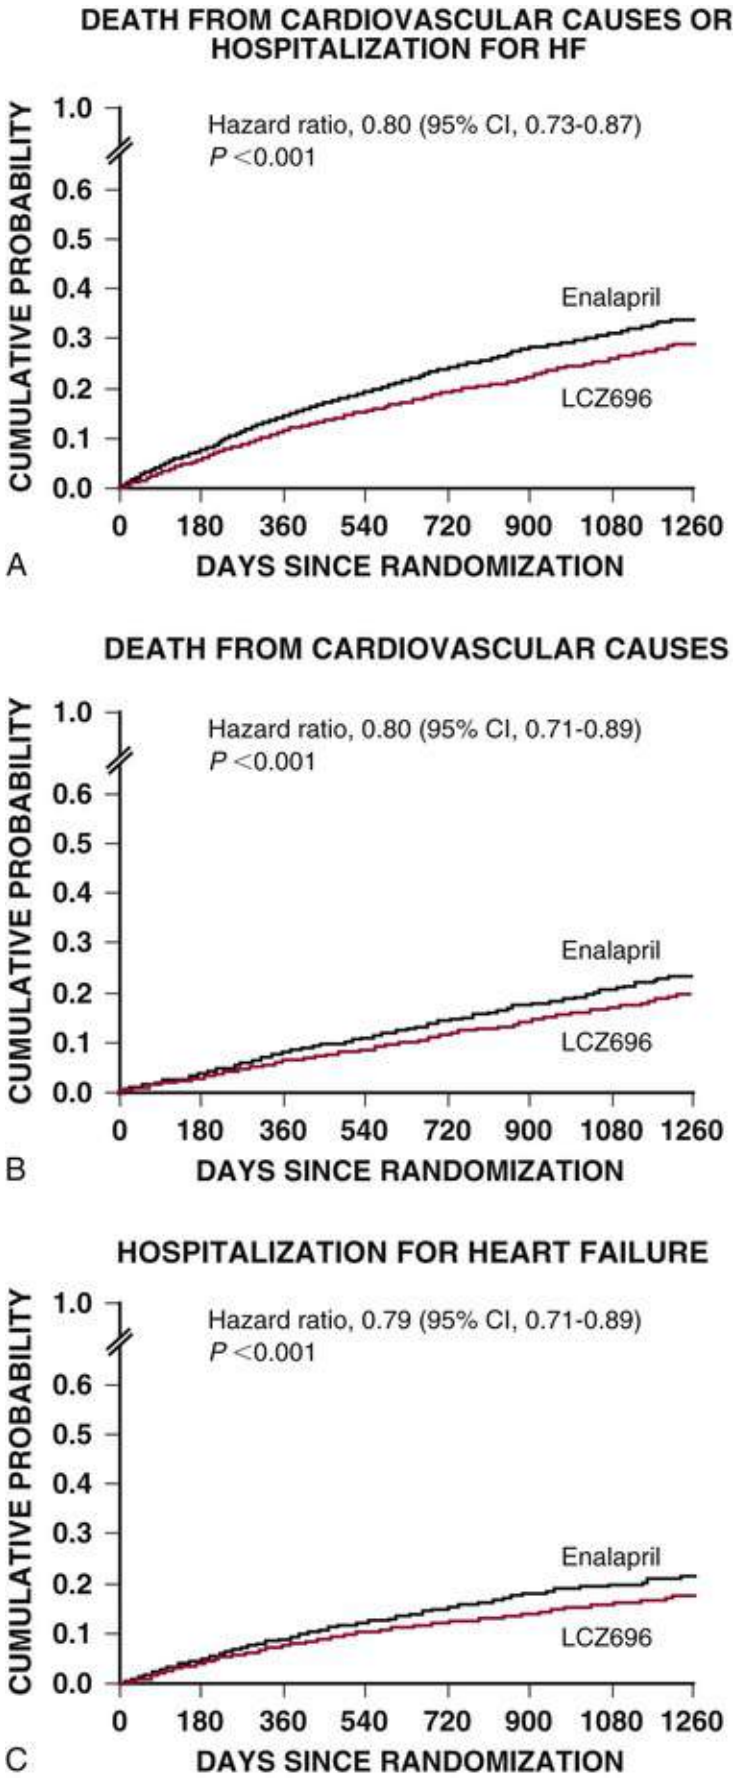


FIGURE 25.13 Kaplan-Meier analysis of outcomes in the PARADIGM trial. **A,** Death from cardiovascular causes or hospitalization for heart failure (the primary endpoint). **B,** Death from cardiovascular cause. **C,** Hospitalization for heart failure. (Modified from McMurray JJ, Packer M, Desai AS, et al. Angiotensin-neprilysin inhibition versus enalapril in heart failure. N Engl J Med 2014;317:993-1004.)

Side Effects of ARNIs

The use of an ARNI is associated with hypotension (approximately 18% of patients), hyperkalemia (12%), cough (5%), and extremely low incidence of angioedema. Oral neprilysin inhibitors, used in combination with ACEIs, can lead to angioedema; thus the concomitant use of ACEIs and ARNIs is contraindicated (class III recommendation). For patients who are switching from ACEIs to sacubitril/valsartan, the ACEI should be withheld for at least 36 hours before initiating sacubitril/valsartan, to minimize the risk of angioedema caused by overlapping ACE and neprilysin inhibition. There are additional concerns about effects of sacubitril/valsartan on the degradation of beta-amyloid peptide in the brain, which could theoretically accelerate amyloid deposition. The optimal titration and tolerability of ARNIs, particularly with regard to blood pressure and adjustment of concomitant HF medications, will require addition clinical experience.

Beta Blockers

Beta-adrenergic blocker therapy represents a major advance in the treatment of HF patients with a depressed EF. Beta blockers interfere with the harmful effects of sustained activation of the central nervous system by competitively antagonizing one or more alpha- and beta-adrenergic receptors (α_1, β_1, and β_2). Although there are a number of potential benefits to blocking all three receptors, most of the deleterious effects of sympathetic activation are mediated by the β_1-adrenergic receptor. When given in concert with ACEIs, beta blockers reverse the process of LV remodeling, improve patient symptoms, prevent hospitalization, and prolong life. Therefore, beta blockers are indicated for patients with symptomatic or asymptomatic HF and a depressed EF less than 40%. Three beta blockers have been shown to be effective in reducing the risk of death in patients with chronic HF: *bisoprolol* and sustained-release *metoprolol succinate* both competitively block the β_1 receptor, and *carvedilol* competitively blocks the α_1, β_1, and β_2 receptors.

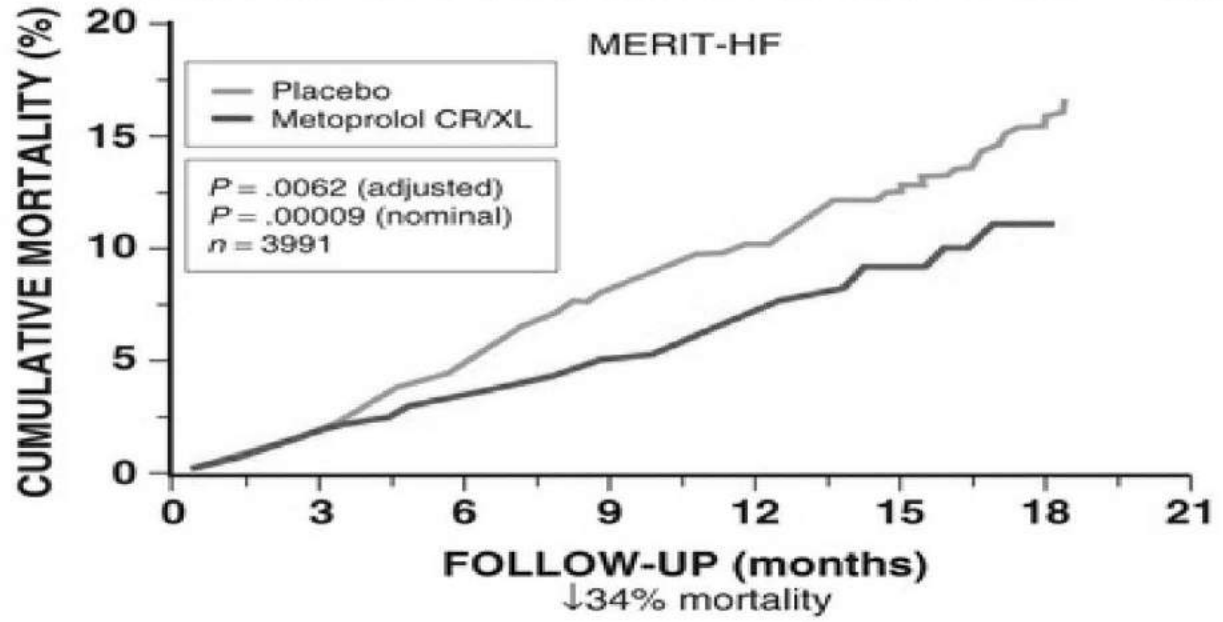
Analogous to the use of ACEIs, beta blockers should be initiated in low doses, followed by gradual increments if lower doses have been well tolerated. The dose of beta blocker should be increased until the doses used are similar to those reported to be effective in clinical trials (**see Table 25.7**). However, unlike ACEIs, which may be uptitrated relatively rapidly, the dose titration of beta blockers should proceed no sooner than 2-week intervals, since the initiation and increased dosing of these agents may lead to worsening fluid retention because of the abrupt withdrawal of adrenergic support to the heart and circulation. Therefore, it is important to optimize the dose of diuretic before starting therapy with beta blockers. If worsening fluid retention does occur, it is likely to be within 3 to 5 days of initiating therapy and to manifest as increased body weight or symptoms of worsening HF. The increased fluid retention can usually be managed by increasing the diuretic dose. Patients need not be taking high-dose ACEIs before being considered for treatment with a beta blocker, because most patients enrolled in the beta-blocker trials were not taking high doses of ACEIs. Furthermore, in patients taking a low-dose ACEI, the addition of a beta blocker produces a greater improvement in symptoms and a further reduction in mortality risk than an increase in the ACEI dose. Recent data show that beta blockers can be safely started before discharge even in patients hospitalized for HF, provided that the patient is stable and does not require IV HF therapy.

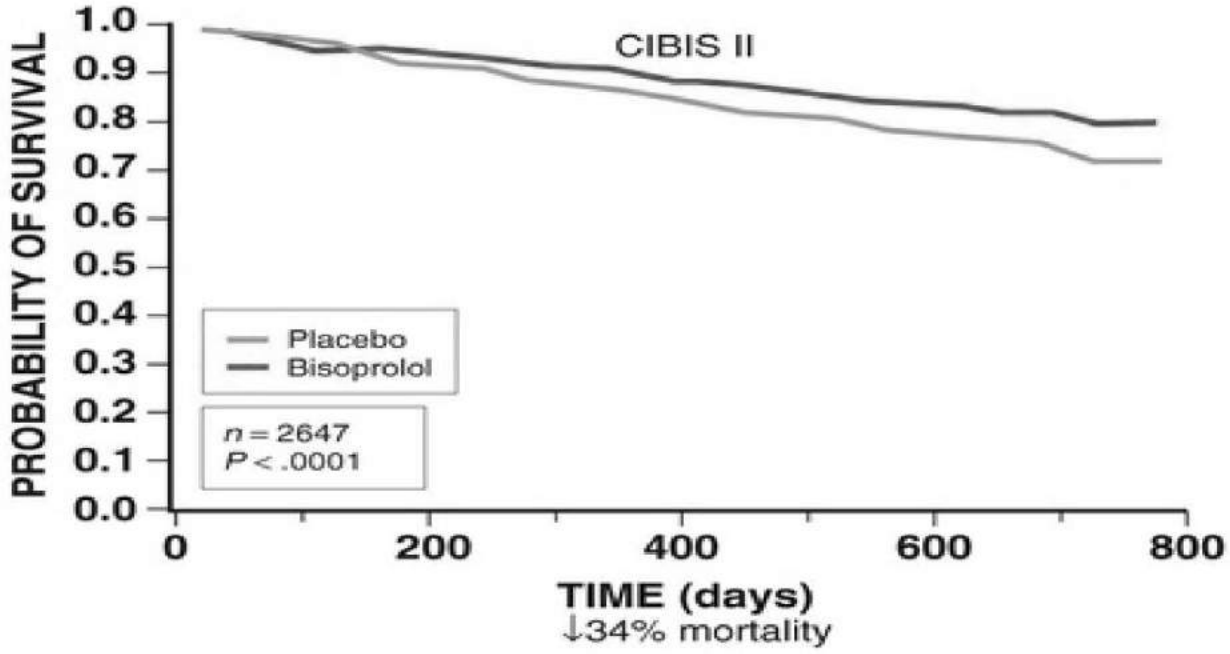
Contrary to early reports, the aggregate results of clinical trials suggest that beta-adrenergic blocker therapy is well tolerated by the great majority of HF patients (>85%), including patients with comorbidities such as diabetes mellitus, chronic obstructive lung disease, and peripheral vascular disease. Nonetheless, a subset of patients (10% to 15%) remain intolerant to beta blockers because of

worsening fluid retention or symptomatic hypotension.

The first placebo-controlled multicenter trial with a beta-blocking agent was the Metoprolol in Dilated Cardiomyopathy (MDC) trial, which used the shorter-acting tartrate preparation at a target dose of 50 mg three times a day in symptomatic HF patients with idiopathic DCM. Metoprolol tartrate at an average dose of 108 mg/day reduced the prevalence of the primary endpoint of death or need for cardiac transplantation by 34%, which did not quite reach statistical significance ($P = 0.058$). The benefit resulted entirely from a reduction by metoprolol in the morbidity component of the primary endpoint, with no favorable trends in the mortality component. A more efficacious formulation of metoprolol was subsequently developed, metoprolol (succinate) CR/XL, which has a better pharmacologic profile than metoprolol tartrate because of its controlled-release (CR) profile and longer half-life. In the Metoprolol CR/XL Randomized Intervention Trial in Congestive Heart Failure (MERIT-HF), metoprolol CR/XL provided a significant relative risk reduction of 34% reduction in mortality in patients with mild to moderate HF and moderate to severe systolic dysfunction compared with the placebo group[8,12] (**Fig. 25.14**). Importantly, metoprolol CR/X reduced mortality from both sudden death and progressive pump failure. Further, mortality was reduced across most demographic groups, including older versus younger subjects, nonischemic versus ischemic etiology, and lower versus higher EFs.

EFFECT OF BETA BLOCKADE ON MORTALITY IN CHF





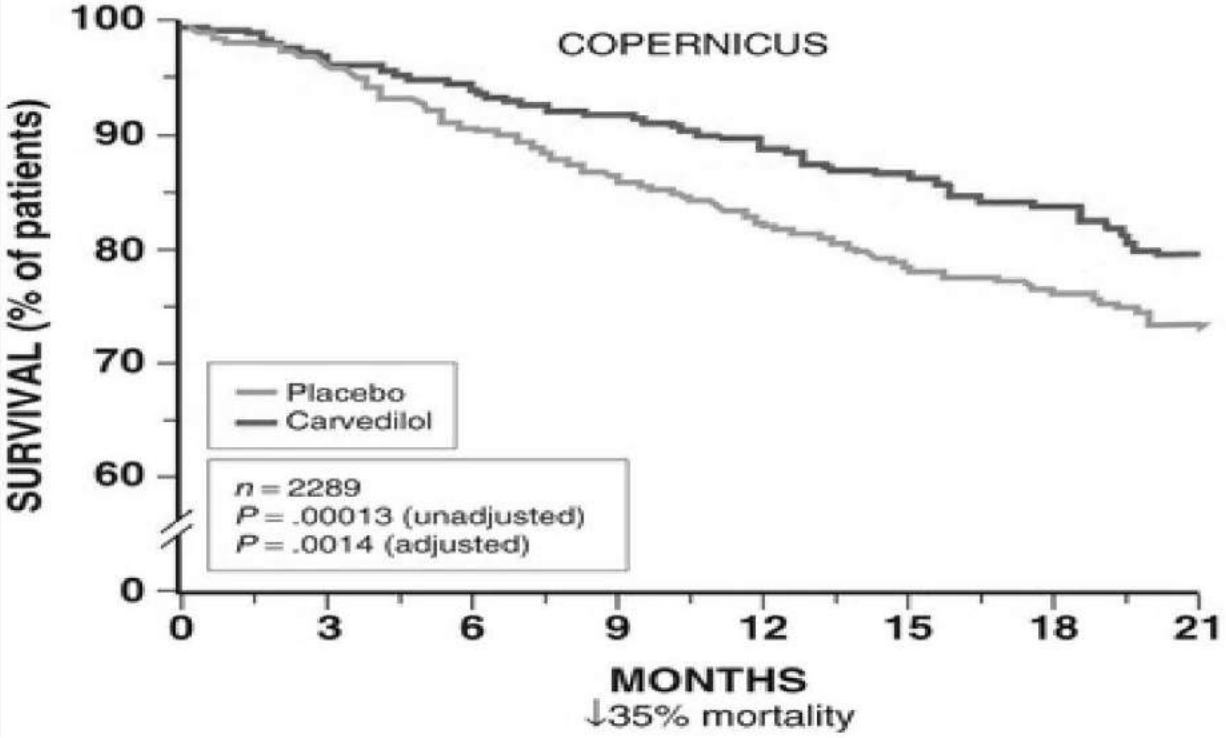


FIGURE 25.14 Kaplan-Meier analysis of the probability of survival among patients in the placebo and beta-blocker groups in the MERIT-HF **(top),** CIBIS II **(middle),** and COPERNICUS **(bottom)** trials. *CHF,* Chronic heart failure; *CI*, confidence interval. (Data from The Cardiac Insufficiency Bisoprolol Study II [CIBIS II]. Lancet 1999;353:9-13; Metoprolol CR/XL Randomized Intervention Trial in Congestive Heart Failure [MERIT-HF]. Lancet 1999;353:2001-7; and Packer M et al, for The Carvedilol Prospective Randomized Cumulative Survival Study Group. Effect of carvedilol on survival in severe chronic heart failure. N Engl J Med 2001;344:1651-8.)

Bisoprolol is a second-generation β_1 receptor–selective blocking agent with approximately 120-fold higher affinity for human β_1 versus β_2 receptors. The first trial performed with bisoprolol was the Cardiac Insufficiency Bisoprolol Study I (CIBIS-I), which examined the effects of bisoprolol on mortality in patients with symptomatic ischemic or nonischemic cardiomyopathy. CIBIS-I showed a nonsignificant ($P = 0.22$) 20% risk reduction for mortality at 2 years' follow-up. Because the sample size for CIBIS-I was based on an unrealistically high expected event rate in the control group, a follow-up trial with more conservative effect size estimates and sample size calculations was conducted. In CIBIS-II, bisoprolol reduced all-cause mortality by 34% (11.8% bisoprolol versus 17.3% placebo; $P = 0.002$), sudden cardiac death by 45% (3.6% versus 6.4%; $P = 0.001$), HF hospitalizations by 30% (11.9% versus 17.6%; $P < 0.001$), and all-cause hospitalizations by 15% (33.6% versus 39.6%; $P = 0.002$) (**Fig. 25.14**). The CIBIS-III trial addressed the important question of whether an initial treatment strategy using the beta blocker bisoprolol was noninferior to a treatment strategy of using an ACEI (enalapril) first, among patients with newly diagnosed mild to moderate HF. The two strategies were compared in a blinded manner with regard to the combined primary endpoint of all-cause mortality or hospitalization, as well as with regard to each of the components of the primary endpoint individually. Although the per-protocol primary endpoint analysis of death or rehospitalization did not meet the prespecified criteria for noninferiority, the intent-to-treat analysis showed that bisoprolol was noninferior to enalapril (HR, 0.94; 95% CI 0.77 to 1.16; $P = 0.019$ for noninferiority). Although CIBIS-III did not provide clear-cut evidence to justify starting with a beta blocker, the overall safety profile of the two strategies was similar. Current guidelines continue to recommend starting with an ACEI, followed by the addition of a beta blocker.

Of the three beta blockers approved for the treatment of HF, carvedilol has been studied most extensively (**see Table 25.8**). The phase III U.S. Trials Program, composed of four individual trials managed by single Steering and Data and Safety Monitoring Committee, was stopped prematurely because of a highly significant ($P < 0.0001$) 65% reduction in mortality by carvedilol that was observed across all four trials. This was followed by a second study, the Australia-New Zealand Heart Failure Research Collaborative Group Carvedilol Trial (ANZ-Carvedilol), which showed there was a significant improvement in LVEF ($P < 0.0001$) and a significant ($P = 0.0015$) reduction in LV end-diastolic volume index in the carvedilol-treated group at 12 months, as well a significant relative risk reduction of 26% in the clinical composite of death or hospitalization for the carvedilol group at 19 months. Rates of hospitalization were also significantly lower for patients treated with carvedilol (48%) compared to placebo (58%). The Carvedilol Prospective Randomized Cumulative Survival (COPERNICUS) study extended these benefits to patients with more advanced HF; patients with advanced HF symptoms needed to be clinically euvolemic and to have an LV EF less than 25%. When compared with placebo, carvedilol reduced the mortality risk at 12 months by 38% and the relative risk of death or HF hospitalization by 31% (**Fig. 25.14**). Carvedilol has also been evaluated in a post-MI trial in which patients had to exhibit LV dysfunction. The Carvedilol Post-Infarct Survival Controlled Evaluation (CAPRICORN) trial was an RCT designed to test the long-term efficacy of carvedilol on

morbidity and mortality in patients with LV dysfunction after MI already treated with ACEIs. Although carvedilol did not reduce the prespecified primary endpoint of mortality plus CV hospitalization, it did significantly reduce total mortality by 23% ($P = 0.03$), CV mortality by 25% ($P < 0.05$), and nonfatal MI by 41% ($P = 0.014$). Lastly, in the Carvedilol or Metoprolol European Trial (COMET), carvedilol (target dose, 25 mg twice daily) was compared with immediate-release metoprolol tartrate (target dose, 50 mg twice daily) with respect to the primary endpoint of all-cause mortality. Carvedilol was associated with a significant 33% reduction in all-cause mortality compared with metoprolol tartrate (33.9% versus 39.5%; HR, 0.83; 95% CI 0.74 to 0.93; $P = 0.0017$).[8,12] Based on the results of the COMET trial, short-acting metoprolol tartrate is not recommended in the treatment of HF. The results of COMET emphasize the importance of using doses and formulations of beta blockers that have been shown to be effective in clinical trials. There have been no trials to ascertain whether the survival benefits of carvedilol are greater than those of metoprolol (succinate) CR/XL when both drugs are used at the appropriate target doses.

Not all studies with beta blockers have been universally successful, suggesting that their effects should not necessarily be viewed broadly as a class effect. Indeed, early studies with the first-generation of nonspecific β_1 and β_2 receptors without ancillary vasodilating properties (e.g., propranolol) resulted in significant worsening of HF and death. The Beta-blocker Evaluation of Survival Trial (BEST) evaluated the third-generation beta-blocking agent *bucindolol,* which is a completely nonselective β_1 and β_2 blocker with some α_1 receptor blockade properties. Although BEST showed that there was a nonsignificant ($P = 0.10$) 10% reduction in total mortality in the bucindolol-treated group, there as a statistically significant ($P = 0.01$) 19% reduction in mortality in white patients. The differential response of bucindolol in white patients has been suggested to be secondary to a polymorphism (Arginine 389) in the β_1-adrenergic receptor that is more prevalent in white patients (see online supplement, Pharmacogenomics in Heart Failure). *Nebivolol* is a selective β_1 receptor antagonist with ancillary vasodilatory properties that are mediated, at least in part, by nitric oxide (NO). In the Study of Effects of Nebivolol Intervention on Outcomes and Rehospitalization in Seniors with Heart Failure (SENIORS), nebivolol significantly reduced the composite outcome of death or CV hospitalizations (HR, 0.86; 95% CI 0.74 to 0.99; $P < 0.04$), which was the primary endpoint of the trial, but did not but did not reduce mortality. Although approximately 35% of the patients in SENIORS had an LVEF greater than 35%; more than half these patients had an EF ranging from 35% to 50%, and thus would not be considered as HFpEF patients. Nebivolol is not FDA approved for the treatment of HF.

Side Effects of Beta Blockers

The adverse effects of beta blockers are generally related to the predictable complications that arise from interfering with the adrenergic nervous system. These reactions generally occur within several days of initiating therapy and are generally responsive to adjusting concomitant medications, as previously described. The problem of fluid retention is discussed earlier. Treatment with a beta blocker can be accompanied by feelings of general fatigue or weakness. In most patients, the increased fatigue spontaneously resolves within several weeks or months; in some, however, it may be severe enough to limit the dose of beta blocker or require the withdrawal or reduction of treatment. Therapy with beta blockers can lead to bradycardia and can exacerbate heart block. Moreover, beta blockers (particularly those that block the α_1 receptor) can lead to vasodilatory side effects. Thus the dose of beta blockers should be decreased if the heart rate decreases to less than 50 beats/min and/or second- or third-degree heart block develops, or symptomatic hypotension develops. Continuation of beta blocker treatment

during an episode of acute decompensation is safe, although dose reduction may be necessary.[33] Beta blockers are not recommended for patients with asthma who have active bronchospasm.

Mineralocorticoid Receptor Antagonists

Although classified as potassium-sparing diuretics, MRAs that block the effects of aldosterone (e.g., spironolactone) have beneficial effects that are independent of their effects on sodium balance (**see Fig. 25.8**). Although ACEIs may transiently decrease aldosterone secretion, with chronic therapy there is a rapid return of aldosterone to levels similar to those before ACEI therapy, referred to as "aldosterone breakthrough."[34] The administration of an MRA is recommended for patients with NYHA Class II to IV HF who have a depressed EF (≤35%) and who are receiving standard therapy, including diuretics, ACEIs, and beta blockers.[35] The dose of aldosterone antagonist should be increased until the doses used are similar to those shown to be effective in clinical trials (**see Table 25.7**). *Spironolactone* should be initiated at a dose of 12.5 to 25 mg daily and uptitrated to 25 to 50 mg daily, whereas *eplerenone* should be initiated as doses of 25 mg/day and increased to 50 mg daily (**see Table 25.7**). As previously noted, potassium supplementation is generally stopped after the initiation of aldosterone antagonists, and patients should be counseled to avoid high–potassium-containing foods. Potassium levels and renal function should be rechecked within 3 days and again at 1 week after initiation of an aldosterone antagonist. Subsequent monitoring should be dictated by the general clinical stability of renal function and fluid status but should occur at least monthly for the first 6 months.

The first evidence that MRAs could produce a major clinical benefit in HF was demonstrated by the Randomized Aldactone Evaluation Study (RALES) trial,[8,12] which evaluated spironolactone (25 mg/day initially, titrated to 50 mg/day for signs of worsening HF) versus placebo in NYHA Class III or IV HF patients with LVEF less than 35% being treated with an ACEI, a loop diuretic, and in most cases, digoxin. As shown in **Fig. 25.8A**, spironolactone led to a 30% reduction in total mortality compared with placebo ($P = 0.001$). The frequency of hospitalization for worsening HF was also 35% lower in the spironolactone group than in the placebo group. Although the mechanism for the beneficial effect of spironolactone has not been fully elucidated, prevention of extracellular matrix remodeling (**see Chapter 23**) and prevention of hypokalemia levels are plausible mechanisms. Although spironolactone was well tolerated in RALES, gynecomastia was reported in 10% of men treated with spironolactone, compared with 1% in the placebo group ($P < 0.001$). The Eplerenone in Mild Patients Hospitalization and Survival Study in Heart Failure (EMPHASIS-HF) trial, performed in patients with NYHA Class II HF with EF less than 30% (or 35% if the QRS width was >130 msec), demonstrated that eplerenone (titrated to 50 mg/day) led to a significant 27% decrease in CV death or HF hospitalization (HR, 0.63; 95% CI 0.54 to 0.74; $P < 0.001$) (**Fig. 25.8B**).[8,12] There were also significant decreases in all-cause death (24%), CV death (24%), all-cause hospitalization (23%), and HF hospitalizations (43%). Importantly, the effect of eplerenone was consistent across all prespecified subgroups. In contrast to the RALES trial, which was conducted prior to the widespread adoption of beta blockers, the background therapy for EMPHASIS-HF included ACEIs or ARBs and beta blockers. The findings in RALES and EMPHASIS-HF are consistent with findings in randomized clinical trials in patients with acute MI and LV dysfunction. The Eplerenone Post-Acute Myocardial Infarction Heart Failure Efficacy and Survival Study (EPHESUS) evaluated the effect of eplerenone (titrated to a maximum of 50 mg/day) on morbidity and mortality among patients with

acute MI complicated by LV dysfunction and HF. Treatment with eplerenone led to a 15% decrease in all-cause death (RR, 0.85; 95 CI 0.75 to 0.96; *P* = 0.008). Based on the results of the RALES and EMPHASIS-HF trials,[8,12] aldosterone antagonists are currently recommended for all patients with persistent NYHA Class II to IV symptoms and an EF of 35% or less, despite treatment with an ACEI (or ARB if ACEI not tolerated) and a beta blocker.

Side Effects of MRAs

The major problem with the use of aldosterone antagonists is the development of life-threatening hyperkalemia, which is more prone to occur in patients who are receiving potassium supplements or who have underlying renal insufficiency. Aldosterone antagonists are not recommended when the serum creatinine is greater than 2.5 mg/dL (or creatinine clearance <30 mL/min) or the serum potassium is greater than 5.5 mmol/L. The development of worsening renal function should lead to consideration of stopping aldosterone antagonists because of the potential risk of hyperkalemia. Painful gynecomastia may develop in 10% to 15% of patients who use spironolactone, for whom eplerenone may be substituted.

Combination of Hydralazine and Isosorbide Dinitrate

The combination of hydralazine and isosorbide dinitrate is recommended for blacks with NYHA Class III or IV HFrEF who remain symptomatic despite concomitant use of ACEIs, beta blockers, and aldosterone antagonists. There is no evidence to suggest that the combination of hydralazine and isosorbide dinitrate is beneficial as a first-line therapy in nonblacks with HFrEF, although this has never been formally tested in a clinical trial.[12] Nonetheless, the combination of hydralazine and isosorbide dinitrate has been shown to reduce mortality in symptomatic HFrEF patients who tolerate an ACEI or ARB because of drug intolerance, hypotension, or renal insufficiency.

I_f Channel Inhibitor

Ivabradine is a heart rate–lowering agent that acts by selectively blocking the cardiac pacemaker I_f ("funny") channel current that controls the spontaneous diastolic depolarization of the sinoatrial node. Ivabradine blocks I_f channels in a concentration-dependent manner by entering the channel pore from the intracellular side, and thus it can only block the channel when it is open. The magnitude of I_f inhibition is directly related to the frequency of channel opening and would therefore be expected to be most effective at higher heart rates. Initially developed and approved as an antianginal agent in Europe, ivabradine was also shown to improve outcomes in The Systolic Heart Failure Treatment with the I_f inhibitor Ivabradine Trial (SHIFT), which enrolled symptomatic patients with and an LV EF of 35% or less who were in sinus rhythm with heart rate of 70 beats/min or more and receiving standard medical therapy for HF (including beta blockers). SHIFT showed that ivabradine (uptitrated to maximum dose of 7.5 mg twice daily) reduced the primary composite outcome of CV death or HF hospitalization by 18% (HR, 0.82; 95% CI 0.75 to 0.90; *P* < 0.0001) (**Fig. 25.15**). The composite endpoint was driven primarily by reducing hospital admissions for worsening HF (HR, 0.74; CI 0.66 to 0.83; *P* < 0.0001), since there was no decrease in CV deaths (HR, 0.91; 95% CI 0.80 to 1.03; *P* = 0.13) or all-cause death.[36] Given that ivabradine lowered heart rate by approximately 10 beats/min, and that only 26% of patients in the trial were taking optimal doses of beta blockers, it is possible that titrating beta blockers to recommended doses may have reduced the HF hospitalizations to a similar degree. Additional safety evidence for ivabradine comes from the

morbidity-mortality evaluation of the I_f inhibitor ivabradine in patients with coronary disease and left ventricular dysfunction (BEAUTIFUL) trial, in which more than 10,000 patients with coronary heart disease and an EF less than 40% were randomized to treatment with ivabradine, 7.5 mg twice daily. Although this trial did not meet its primary endpoint of reducing CV death, MI, or HF hospitalization, ivabradine was well tolerated in this patient population.[37]

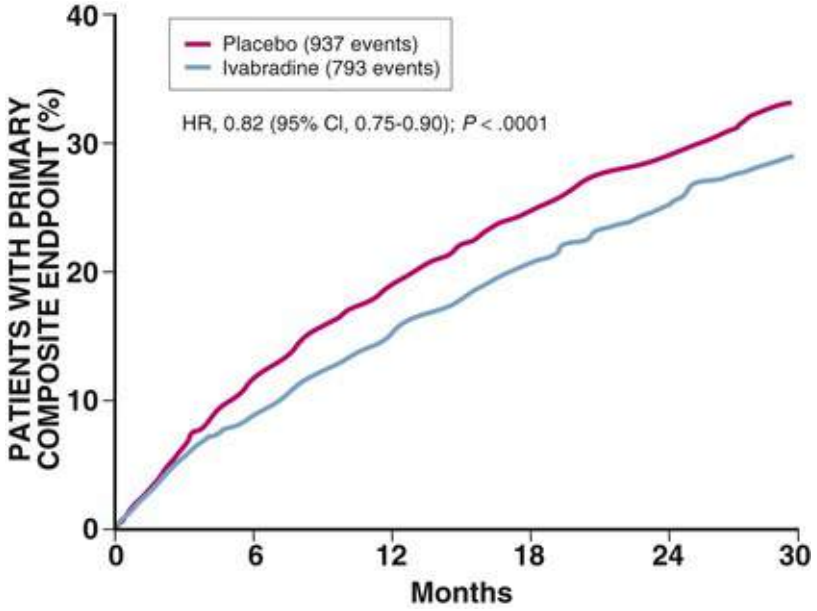

FIGURE 25.15 Kaplan-Meier cumulative event curves for the primary composite endpoint of cardiovascular death or hospitalization for worsening HF in patients treated with ivabradine compared to placebo. (Modified from Swedberg K, Komajda M, Bohm M, et al. Ivabradine and outcomes in chronic heart failure (SHIFT): a randomised placebo-controlled study. Lancet 2010;376:875-85.)

Renin Inhibitors

Aliskiren is an orally active direct renin inhibitor that appears to suppress RAS to a similar degree as ACEIs.[38] Although the benefits of ACEIs and ARBs in HF have been clearly established, these agents provoke a compensatory increase in renin and downstream intermediaries of the RAAS that may attenuate the effects of ACEIs and ARBs (aldosterone breakthrough). Aliskiren is a nonpeptide inhibitor that binds to the active site (S_1/S_3 hydrophobic binding pocket) of renin, preventing the conversion of angiotensinogen to angiotensin I (**see Chapter 23, Fig. 23.3**). In the Aliskiren Observation of Heart Failure Treatment (ALOFT) trial, aliskiren was shown to decrease significantly ($P < 0.01$) NT-proBNP in urinary aldosterone excretion.[39] Based on these promising early results, several large pivotal outcomes trials were initiated to determine whether adding aliskiren to standard HF therapy would improve clinical outcomes. However, both the Aliskiren Trial on Acute Heart Failure Outcomes (ASTRONAUT)[40] and the Efficacy and Safety of Aliskiren and Aliskiren/Enalapril Combination on Morbidity-Mortality in Patients with Chronic Heart Failure (ATMOSPHERE)[41] clinical trials failed to improve outcomes in HFrEF patients, and renin inhibitors such as aliskiren are not presently recommended as an alternative to an ACEI or ARB or in combination with ACEIs.

Management of Patients Who Remain Symptomatic

As noted earlier, an ACEI/ARB or ARNI, a beta blocker, and an MRA should be standard background therapy for patients with HFrEF. However, the addition of an ARB to the combination of an ACEI and an MRA is not recommended in HFrEF patients because of the risk of hyperkalemia. Moreover, the combination of ARNI with an ACEI is not recommended because of the risk of angioedema. Additional pharmacologic therapy (polypharmacy) or device therapy (see later) should be considered in patients who have persistent symptoms or progressive worsening despite optimized therapy with evidence-based medical and device therapies. Digoxin is recommended for patients with symptomatic HFrEF to reduce hospitalizations despite receiving standard therapy, including ACEIs (or ARBs), ARNIs, beta blockers, and MRAs.

Cardiac Glycosides

Digoxin and *digitoxin* are the most frequently used cardiac glycosides. Given that digoxin is used most often and is the only glycoside evaluated in placebo-controlled trials, there is little reason to prescribe other cardiac glycosides for the management of patients with chronic HF. Digoxin exerts its effects by inhibiting the Na^+,K^+-ATPase pump in cell membranes, including the sarcolemmal pump of cardiac myocytes (**see Chapter 22**). Inhibition of the Na^+,K^+-ATPase pump results in increased intracellular Ca^{2+} and thus increased cardiac contractility, which led to the suggestion that beneficial effects of digoxin were secondary to its inotropic properties. However, the more likely mechanism of digoxin in HF patients is to sensitize Na^+,K^+-ATPase activity in vagal afferent nerves, leading to an increase in vagal tone that counterbalances the increased activation of the adrenergic system in advanced HF. Digoxin also inhibits Na^+,K^+-ATPase activity in the kidney and therefore may blunt renal tubular resorption of sodium. Therapy with digoxin is usually initiated and maintained at a dose of 0.125 to 0.25 mg daily. For the great majority of patients, the dose should be 0.125 mg daily and the serum digoxin level less than 1.0 ng/mL, especially in elderly patients, patients with impaired renal function, and patients with a low lean body mass. Higher doses (e.g., digoxin >0.25 mg/day) are rarely used and or not recommended for the management of HF patients in sinus rhythm or who have atrial fibrillation. Further details about digitalis, including mechanism of action, pharmacokinetics, and interaction with other common drugs, can be found in the online supplement for this chapter (Digoxin).”

Although clinicians have used cardiac glycosides to treat patients with chronic HF for more than 200 years, there is still considerable despite debate regarding the effectiveness of the cardiac glycosides in HF patients. Whereas small and medium-sized trials conducted in the 1970s and 1980s yielded equivocal results, two relatively large digoxin withdrawal studies in the early 1990s, the Randomized Assessment of Digoxin and Inhibitors of Angiotensin-Converting Enzyme (RADIANCE) and the Prospective Randomized Study of Ventricular Function and Efficacy of Digoxin (PROVED), provided strong support for clinical benefit from digoxin.[12] In these studies, worsening HF and HF hospitalizations developed in more patients who were withdrawn from digoxin than in patients who were maintained on digoxin. Because withdrawal studies are difficult to interpret with respect to efficacy of a given therapeutic agent, the Digoxin Investigator Group (DIG) trial was conducted to address prospectively the role of digitalis in chronic HF. Although the DIG trial showed that digoxin had a neutral effect on the primary endpoint of mortality, digoxin reduced hospitalizations (including 30-day readmission for HF)[12] and favorably affected the combined endpoints of death or hospitalization due to worsening HF. Data from the DIG trial

indicated a strong trend ($P = 0.06$) toward a decrease in deaths secondary to progressive pump failure, which was offset by an increase in sudden and other non–pump failure cardiac deaths ($P = 0.04$). One of the most important findings to emerge from the DIG trial was that mortality was directly related to the digoxin serum level.[12] In men, trough levels between 0.6 and 0.8 ng/mL were associated with decreased mortality, suggesting that trough levels of digitalis should be maintained between 0.5 and 1.0 ng/mL. There is also evidence that digoxin may be potentially harmful in women. In a post hoc multivariable analysis of the DIG trial, digoxin was associated with a significantly higher risk (23%) of death from any cause among women, but not men, possibly because of the relatively lower body weight in women, who were prescribed doses of digoxin on the basis of a nomogram rather than trough levels.[12] The DIG trial was conducted before the widespread use of beta blockers, and no large trial of digoxin in addition to therapy with both ACEIs and beta blockers is available.

Complications of Digoxin Use

The principal adverse effects of digoxin are (1) cardiac arrhythmias, including heart block (especially in elderly patients) and ectopic and reentrant cardiac rhythms; (2) neurologic complaints, such as visual disturbances, disorientation, and confusion; and (3) gastrointestinal (GI) symptoms such as anorexia, nausea, and vomiting. As noted, these side effects can generally be minimized by maintaining trough levels of 0.5 to 1.0 ng/mL. In patients with HF, overt digitalis toxicity tends to emerge at serum concentrations greater than 2.0 ng/mL; however, digitalis toxicity may occur with lower digoxin levels, particularly if hypokalemia or hypomagnesemia coexist. Oral potassium administration is often useful for atrial, atrioventricular (AV) junctional, or ventricular ectopic rhythms, even when the serum K^+ is in the normal range, unless high-grade AV block is also present. However, serum K^+ levels must be monitored carefully to avoid hyperkalemia, especially in patients with renal failure or those taking aldosterone receptor antagonists. Potentially life-threatening digoxin toxicity can be reversed by antidigoxin immunotherapy using purified Fab fragments (see online supplement). The concomitant use of quinidine, verapamil, spironolactone, flecainide, propafenone, and amiodarone can increase serum digoxin levels and may increase the risk of adverse reactions. Patients with advanced heart block should not receive the digitalis unless a pacemaker is in place.

n-3 Polyunsaturated Fatty Acids

A large body of experimental evidence suggests that n-3 polyunsaturated fatty acids (PUFAs) have favorable effects on inflammation, including a reduction of endothelial activation and production of inflammatory cytokines, platelet aggregation, autonomic tone, blood pressure, heart rate, and LV function. The GISSI-HF (Gruppo Italiano per lo Studio della Sopravvivenza nell'Insufficienza Cardiaca–Heart Failure) showed that long-term administration of 1 g/day of omega-3 PUFAs resulted in a significant reduction in both all-cause mortality (adjusted HR, 0.91; 95.5% CI 0.83 to 0.99; $P = 0.041$) and all-cause mortality and CV admissions (adjusted HR, 0.92; 99% CI 0.849 to 0.999; $P = 0.009$), in all the predefined subgroups, including HF patients with nonischemic cardiomyopathy.[42] The most recent European Society of Cardiology (ESC) guidelines endorse the use of PUFAs as adjunctive therapy for HFrEF patients who are receiving optimal evidence-based medical therapy.[8]

Pharmacogenomics and Personalized Medicine

As discussed in **Chapter 8**, *pharmacogenomics* is the study of how genetic variations affect drug response, including genetic variants of enzymes that metabolize drugs, variants in drug receptors or drug transporters, and variants in drug targets. These variations can result in gain or loss of therapeutic efficacy, can influence optimal drug dosing, or can favor alternative drug treatment. Given the tremendous heterogeneity in HF patients, genetic variations likely play a significant role in determining drug metabolism, disposition, and functional activity in HF patients. Recent advances in the field of pharmacogenetics suggest an analysis of underlying gene polymorphism in disease-causing pathways may enable clinicians to develop personalized therapeutic regimens for HF patients. Indeed, polymorphisms have been identified in the genes that appear to influence the therapeutic efficacy of ACEIs, beta blockers, nitrates, and diuretics. An overview of the major genetic variations in these pathways and the proposed functional impact of these polymorphisms is presented in the online supplement for this chapter (Pharmacogenomics in Heart Failure).

Personalized medicine seeks to use genetic information to "personalize" and improve diagnosis, prevention, and therapy. The personalized management of HF patients involves a large spectrum of potential applications, from diagnosis of monogenic disorders (**see Chapters 77 and 78**) to prevention and management strategies based on modifier genes, as well as to pharmacogenomics. However, the major challenge in applying pharmacogenomics to everyday clinical practice in patients with HFrEF is the absence of robust clinical data that support the differential use of neurohormonal antagonists in the management of HFrEF patients with specific gene polymorphisms.[43] Indeed, all the extant pharmacogenomic analyses in HFrEF have come from post hoc retrospective analyses of clinical trial data or from observational patient series studies, rather than prospective outcomes studies that randomized HFrEF patients to pharmacogenomic-guided therapy versus standard of care. Of note, the ongoing GENETIC-AF (Genetically Targeted Therapy for the Prevention of Symptomatic Atrial Fibrillation in Patients with Heart Failure [NCT01970501]) will prospectively compare the effects of bucindolol to metoprolol succinate on the recurrence of symptomatic atrial fibrillation/atrial flutter in HF patients (LVEF <0.50) who have a specific genotype for the β_1-adrenergic receptor (β1389 Arg/Arg genotype).

Management of Atherosclerotic Disease

The clinical evaluation of atherosclerotic cardiovascular heart disease in HF patients is discussed in **Chapter 21**. In patients with a prior MI and HF without angina, the use of ACEIs and beta blockers has been shown to decrease the risk of reinfarction and death. Although the role of *aspirin* in HF patients of ischemic etiology has not been clearly established in randomized trials and remains controversial because of the concern that aspirin may attenuate the beneficial effects of ACEIs, long-term treatment with an antiplatelet agent, including aspirin (75 to 81 mg), is recommended for patients with HF due to ischemic etiology, regardless of whether they are receiving ACEIs.[44] Alternative antiplatelet agents (e.g., clopidogrel) may not interact adversely with ACEIs and may have superior effects in preventing clinical events; however, their ability to favorably affect outcomes in HF has not been demonstrated. Both beta blockers and ivabradine (in selected patients) are effective for controlling angina in HFrEF patients.[45]

Coronary artery bypass grafting (CABG) has not been shown to improve cardiac function or symptoms or to prevent reinfarction or death in HF patients without angina. In contrast, CABG has been shown to improve symptoms and survival in patients with modestly reduced EF and angina, although patients with clinical HF or markedly depressed ventricular function have generally been excluded from

most studies. The STICH (Surgical Treatment for Ischemic Heart Failure) trial showed that CABG did not reduce all-cause death (HR, 0.86; 95% CI 90.7to 1.04; *P* = 0.12), which was the primary endpoint of the trial. However, CABG did reduce the composite endpoint of CV death, death from any cause, or hospitalization for CV causes (HR for CABG, 0.74; 95% CI 0.64 to 0.85; *P* < 0.001), which was a prespecified secondary analysis. The 10-year follow-up to the original STICH trial demonstrated a significantly lower mortality in patients who underwent CABG compared to medical therapy (**see Chapter 28**, **Fig. 28.2**). The results of STICH suggest that CABG is beneficial in HF patients of ischemic etiology who are otherwise suitable for surgery (**see Table 25G.6**). Although the data are less robust, percutaneous coronary intervention (PCI) may be considered as an alternative to CABG in patients unsuitable for surgery. The surgical management of patients with CAD and HF is discussed in **Chapter 28**.

Special Populations

Women

Although women account for a significant proportion of the growing heart failure epidemic, they have been poorly represented in clinical trials. Women with HF are more likely to be older (**see Fig. 21.1**), have a preserved EF (**see Chapter 26**), and have a nonischemic etiology for their HF. Although some studies have reported that HF outcomes are worse for women than men, the aggregate data suggest that women have a survival advantage when they develop HF. Although the explanation for this is unclear, it may be related to gender differences in etiology for HF. Nonetheless, although women appear to have a survival advantage after the diagnosis of HF, they experience increased morbidity, with worse quality of life, and have increased depression. Moreover, women are at increased risk of developing HF after acute MI.[46] Pooled analysis of several large-scale prospective clinical trials with beta blockers and ACEIs suggest that these agents provide similar survival benefits in women with reduced EF as in men.[46] (See also **Chapter 89**.)

Race/Ethnicity

Epidemiologic and clinical trial data have raised awareness of potential areas of concern regarding the evaluation and treatment of HF in specific racial and ethnic groups (**see Chapter 21**). The efficacy of pharmacologic treatments in such subgroups is somewhat controversial because so few randomized clinical trials of HF treatment have prespecified a subgroup analysis of outcomes stratified by race or ethnicity and had sufficient participants for meaningful statistical analysis. Several retrospective analyses have highlighted that differences between African American and white populations in response to some standard HF therapies. Unfortunately, few data exist for Hispanic and Asian HF populations. Retrospective analyses from SOLVD and the Vasodilator in Heart Failure Trial (V-HeFT) trials suggested that African Americans do not benefit from ACEIs. In contrast, post hoc analysis of studies with approved beta blockers have shown that African American patients benefit from beta-blocker therapy, although the magnitude of the effect appears to be diminished.[47] The African American Heart Failure Trial (A-HeFT) compared the adjunctive use of a proprietary formulation of isosorbide dinitrate and hydralazine to a standard HF regimen of ACEIs, beta blockers, and diuretics in African Americans with NYHA Class III or IV HF.[12] The primary endpoint was a composite score of weighted values for death from any cause, first hospitalization for HF, and change in quality of life. The study was terminated early because there

was a significant 43% reduction in the rate of death from any cause and a significant 33% relative reduction in the rate of first hospitalization for HF (**Fig. 25.16**). The mechanism for the beneficial effect of the hydralazine/isosorbide regimen may be related to an improvement in NO bioavailability; however, the combination therapy group also had a small (but significant) effect on blood pressure lowering. The effect of the hydralazine/isosorbide combination in other HF patients receiving standard therapy is not known because the population studied in A-HeFT was limited to African Americans. However, there is no reason to believe that this benefit is limited to blacks. The results of the A-HeFT trial have led to the suggestion that the addition of isosorbide dinitrate and hydralazine to a standard medical regimen for HF, including ACEIs, ARNIs, beta blockers, and MRAs, is reasonable and can be effective in African Americans with NYHA Functional Class III or IV HF.

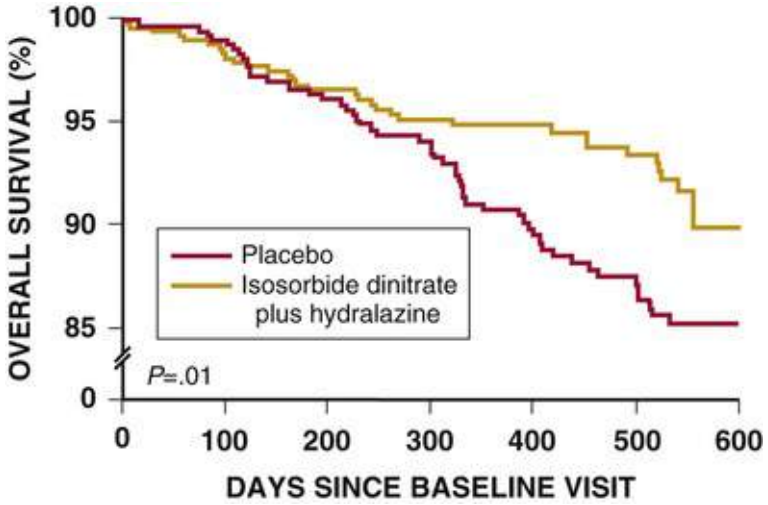

FIGURE 25.16 Kaplan-Meier analysis of the probability of survival among patients in the placebo and isosorbide dinitrate plus hydralazine treatment arms of the A-HeFT study. (Modified from Taylor AL, Ziesche S, Yancy C, et al. Combination of isosorbide dinitrate and hydralazine in blacks with heart failure. N Engl J Med 2004;351:2049-57.)

Elderly Persons

Prevalence of HF increases with age (**see Fig. 21.1**) and is the most common reason for hospitalization in elderly patients. Of note, the presentation of HF may differ in elderly patients with HF. Although they typically present with the classic symptoms of dyspnea and fatigue, elderly are more likely than younger patients to present with atypical symptoms such as altered mental status, depression, or poor executive functioning.[6] The therapeutic approach to HF with a reduced EF in elderly patients should be, in principal, identical to that in younger patients regarding the choice of pharmacologic therapy. However, altered pharmacokinetic and pharmacodynamic properties of CV drugs in the elderly population may require that these therapies be applied more cautiously, with reductions in drug dosages when appropriate (**see Chapter 88**). Other complicating factors may include blunting of baroreceptor function and orthostatic dysregulation of blood pressure, which may make it difficult to use target doses of some neurohormonal antagonists. Multidisciplinary HF programs have been successful in decreasing the rate of readmission and associated morbidity in elderly patients (see later).

Patients with Cancer

Patients with cancer are particularly predisposed to the development of HF as a result of the cardiotoxic effects of many cancer chemotherapeutic agents. The management of these patients is discussed in **Chapter 81**.

Anticoagulation and Antiplatelet Therapy

Patients with HF have an increased risk for arterial or venous thromboembolic events. In clinical HF trials the rate of cerebrovascular accident (stroke) ranges from 1.3% to 2.4% per year. Depressed LV function is believed to promote relative stasis of blood in dilated cardiac chambers with increased risk of thrombus formation. Thromboembolism prophylaxis in patients with HF and atrial fibrillation (AF) should be individualized and based on an assessment of the risk of stroke versus the risk of bleeding on an anticoagulant. In general, most patients with HFrEF will have an increased risk of stroke, as assessed by a variety of risk scores (e.g., *c*ardiac failure, *h*ypertension, *a*ge ≥75 (doubled), *d*iabetes, *s*troke (doubled), *v*ascular disease, *a*ge 65-74, and *s*ex category (female) [CHA2DS2-VASc]; **see Chapter 38**). A recent meta-analysis of clinical trials in patients with nonvalvular AF suggests that, compared to warfarin, novel oral anticoagulants (NOACs) have a favorable risk-benefit profile, with significant reductions in stroke, intracranial hemorrhage, and mortality and with similar major bleeding as for warfarin, but increased GI bleeding.[48] Other studies have suggested comparable efficacy but fewer major bleeding events. On the basis of these studies, the ESC heart failure guidelines recommend NOACs, recognizing that their safety in older patients and those with impaired renal function is not known.[8] Anticoagulation is also recommended for all patients with a history of systemic or pulmonary emboli, including stroke or transient ischemic attack (TIA). Patients with symptomatic or asymptomatic ischemic cardiomyopathy and documented recent, large, anterior MI, or recent MI with documented LV thrombus should be treated with warfarin (goal INR, 2.0 to 3.0) for the initial 3 months after MI unless there are contraindications. The question of whether HF patients who are in sinus rhythm should be treated with anticoagulants to reduce stroke was addressed in the WARCEF (Warfarin Versus Aspirin in Reduced Cardiac Ejection Fraction) trial, which showed that treatment with warfarin compared with aspirin did not reduce the composite outcome of time to ischemic stroke, intracerebral hemorrhage, or death from any cause (HR, 0.93; 95% CI 0.79 to 1.10; $P = 0.40$).[49] Although treatment with warfarin was associated with a significant reduction in the rate of ischemic stroke (HR, 0.52; 95% CI 0.33 to 82; $P = 0.005$), this benefit was offset by a significant increase in the rate of major hemorrhage. Interestingly, the rates of intracerebral and intracranial hemorrhage did not differ significantly between the two treatment groups. Based on the results of the WARCEF trial, there is no compelling reason to use warfarin rather than aspirin in HF patients with a reduced LVEF who are in sinus rhythm.

Management of Cardiac Arrhythmias

Atrial fibrillation is the most common arrhythmia in HF and occurs in 15-30% of patients (**see Chapters 37 and 38**). AF may lead to worsening HF symptoms (**see Table 25.5**) and increases the risk of thromboembolic complications, particularly stroke. The AF-CHF (Atrial Fibrillation and Congestive Heart Failure) trial tested rate control versus rhythm control in patients with chronic HFrEF (EF <35%) and a history of AF. A strategy of rhythm control (pharmacologic or electrical cardioversion) was not shown to be superior to a strategy of controlling ventricular rate with respect to reducing death from CV causes (HR rhythm control group, 1.06; 95% CI 0.86 to 1.30; $P = 0.59$).[50] Secondary outcomes were also

similar in the rate and rhythm control groups, including death from any cause, stroke, worsening HF, and the composite of death from CV causes, stroke, or worsening HF.[50] Therefore a rhythm control strategy is best suited for patients with a reversible secondary cause of AF or in patients who cannot tolerate AF symptoms after optimization of rate control and HF therapy.

For control of heart rate in HF AF patients, beta blockers are preferred over digoxin because digoxin does not provide rate control during exercise. Although the effectiveness of beta blockers in HFrEF patients with coexisting AF was cast in doubt by a patient-level meta-analysis, a recent substudy of the AF-CHF trial showed that the use of beta blockers was associated with significantly lower mortality but no difference in CV and non-CV hospitalizations in patients with HFrEF and AF. The mortality reduction was not altered by the type of AF (i.e., paroxysmal or persistent) or the proportion of time spent in AF.[51] Importantly, the combination of digoxin and a beta blocker is more effective than a beta blocker alone in controlling the ventricular rate at rest. When beta-adrenergic blockers cannot be used, amiodarone has been used by some physicians, but chronic use has potentially significant risks, including thyroid disease and lung toxicity (see later). The short-term IV administration of diltiazem or amiodarone has been used for the acute treatment of AF patients with very rapid ventricular response; however, the negative inotropic effects of nondihydropyridine calcium channel blockers such as diltiazem and verapamil must be considered if these agents are used.

The optimum control of ventricular rate in patients with HF and AF is unclear at present. Although a resting ventricular response of 60 to 80 beats/min and a ventricular response of 90 to 115 beats/min during moderate exercise have been suggested, the RACE II study (Rate Control Efficacy in Permanent Atrial Fibrillation: a Comparison between Lenient versus Strict Rate Control II) did not show a difference in a composite of clinical outcomes when a strategy of strict rate control (<80 beats/min at rest and <110 beats/min during 6 minute walk) was compared with lenient rate control.[52] Recognizing that sustained tachycardia can lead to a cardiomyopathy, AV node ablation and cardiac resynchronization therapy (CRT) have been suggested for control of ventricular rate (<100 to 110 beats/min) in extreme cases of a rapid ventricular response in patients with AF.[8]

Most antiarrhythmic agents, with the exception of amiodarone and dofetilide, have negative inotropic effects and are proarrhythmic. *Amiodarone* is a class III antiarrhythmic that has little or no negative inotropic or proarrhythmic effects and is effective against most supraventricular arrhythmias (**see Chapter 38**). Amiodarone is the preferred drug for restoring and maintaining sinus rhythm and may improve the success of electrical cardioversion in patients with HF. Amiodarone increases the level of phenytoin and digoxin and will prolong the international normalized ratio (INR) in patients taking warfarin. Therefore, it is often necessary to reduce the dose of these drugs by as much as 50% when initiating therapy with amiodarone. The risk of adverse events, such as hyperthyroidism, hypothyroidism, pulmonary fibrosis, and hepatitis, are relatively low, particularly when lower doses of amiodarone are used (100 to 200 mg/day).

Dronedarone is a novel antiarrhythmic drug that reduces the incidence of AF and atrial flutter and has electrophysiologic properties similar to those of amiodarone but does not contain iodine and thus does not cause iodine-related adverse reactions. Although dronedarone was significantly more effective than placebo in maintaining sinus rhythm in several studies, the ANDROMEDA trial (European Trial of Dronedarone in Moderate to Severe Congestive Heart Failure) had to be terminated prematurely because of a twofold increase in mortality (HR, 2.13; 95% CI 1.07 to 4.25; $P = 0.167$) in the dronedarone-treated

HF patients.[53] The excess mortality was predominantly related to worsening HF. As a result of this study, dronedarone is contraindicated in patients with NYHA Class IV HF or those with Class II or III HF who have had a recent HF decompensation.

Because of the risk of proarrhythmic effects of antiarrhythmic agents in patients with LV dysfunction, it is preferable to treat ventricular arrhythmias with implantable cardioverter-defibrillators (ICDs), either alone or in combination with amiodarone (**see Chapter 26**).

Device Therapy

Cardiac Resynchronization Therapy

CRT is discussed in detail in **Chapters 27 and 41**. When CRT is added to optimal medical therapy in patients in sinus rhythm there is a significant decrease in patient mortality and hospitalization, a reversal of LV remodeling, as well as improved quality of life and exercise capacity (**see Chapter 27**).[8,12] CRT should be considered for patients NYHA Class II-IV HF with a depressed EF <30% to 35% and a wide QRS (**see Table 27.G1** for details), who are already on optimal background therapy including an ACEI/ARB, beta-blocker, and an MRA for several months, and may be considered in select patients with NYHA class I HF with a wide QRS (**see Table 27G.1**). For eligible patients, consideration should be given for implantation of CRT with an ICD (CRT-ICD).

Implantable Cardioverter-Defibrillators

ICDs are discussed in detail in **Chapters 27, 41, and 44**. Briefly, the prophylactic implantation of ICDs in patients with mild to moderate HF (NYHA Class II or III) has been shown to reduce the incidence of sudden cardiac death (SCD) in patients with ischemic or nonischemic cardiomyopathy. Thus, implantation of an ICD should be considered for patients NHA Class II or III HF with a depressed EF less than 30% to 35% who are already receiving optimal background therapy, including an ACEI/ARB, beta blocker, and MRA for several months, and who have a reasonable expectation of survival with a good functional status for more than 1 year. CRT-ICD should be considered for NYHA Class IV patients.

Sleep-Disordered Breathing

The general topic of sleep disorders in CV disease is discussed in **Chapter 87**. HF patients with a reduced EF (<40%) typically exhibit sleep-disordered breathing; approximately 40% exhibit central sleep apnea (CSA), commonly referred to as “Cheyne-Stokes breathing” (**see Chapter 21**); whereas another 10% exhibit obstructive sleep apneas (OSA). CSA associated with Cheyne-Stokes respiration is a form of periodic breathing in which central apneas and hypopneas alternate with periods of hyperventilation that have a waxing-waning pattern of tidal volume. Risk factors for the development of CSA in HF patients include male gender, age older than 60 years, presence of AF, and hypocapnia.[54] **Fig. 25.17** illustrates the proposed mechanisms that underlie periodic oscillations in ventilation in HF, including heightened sensitivity to arterial partial pressure and long circulation time. The main clinical significance of CSA in HF is its association with increased mortality. Whether this is simply because Cheyne-Stokes respiration with CSA is a reflection of advanced disease with poor LV function, or whether its presence constitutes a separate and additive adverse influence on outcomes, is not clear. Regardless, multivariate analyses suggest that CSA remains an independent risk factor for death or

cardiac transplantation, even after controlling for potentially confounding risk factors. The potential mechanism(s) for adverse outcomes in HF patients with CSA may be attributed to marked neurohumoral activation (especially norepinephrine). Studies have suggested that Cheyne-Stokes respirations can resolve with proper treatment of HF. However, if the patient continues to have symptoms related to sleep-disordered breathing for the treatment of nocturnal hypoxemia in OSA despite optimization of HF therapies, a comprehensive overnight sleep study–polysomnography is indicated.

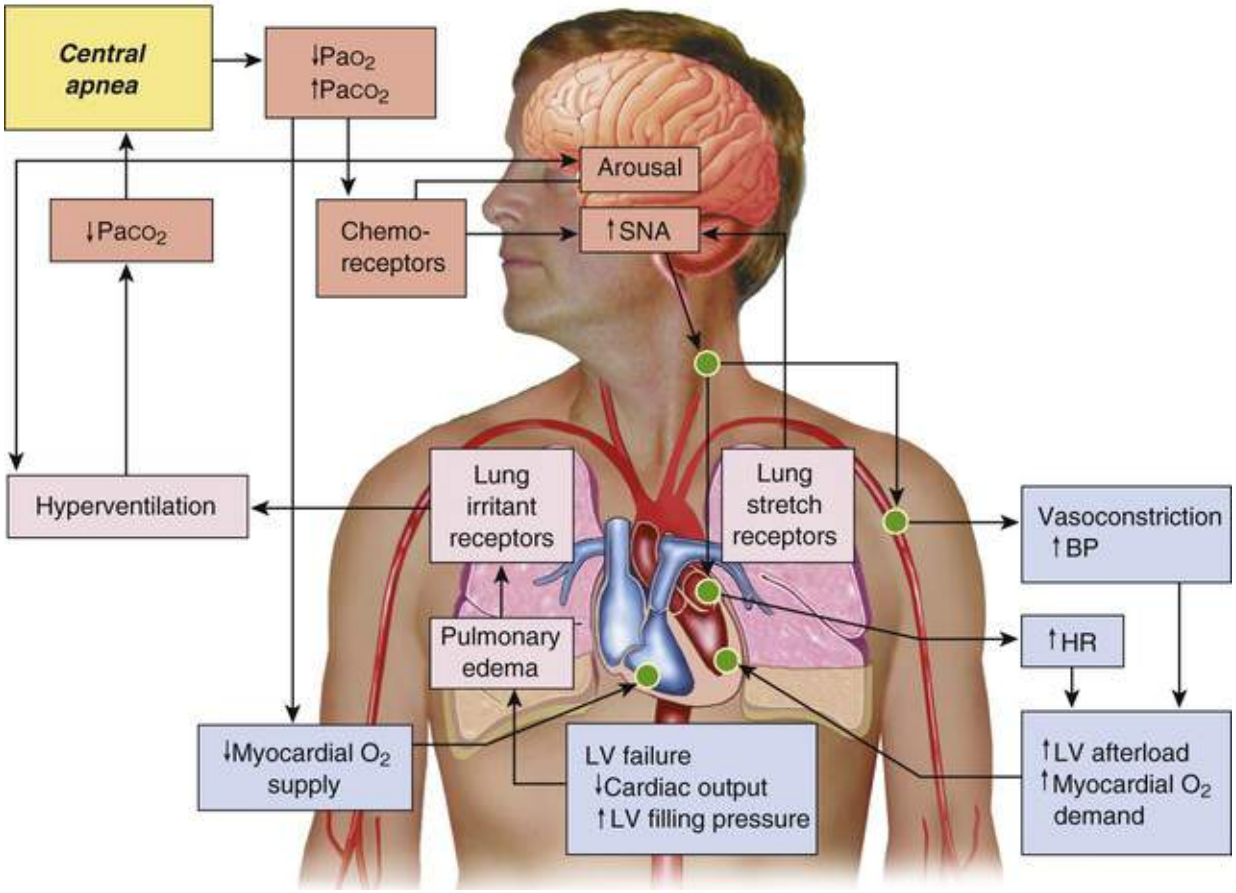

FIGURE 25. 17 Pathophysiology of central sleep apnea and Cheyne-Stokes respiration in heart failure (HF). HF leads to increased LV filling pressure. The resulting pulmonary congestion activates lung vagal irritant receptors, which stimulate hyperventilation and hypocapnia. Superimposed arousals cause further abrupt increases in ventilation and drive the partial pressure of carbon dioxide in arterial blood ($PaCO_2$) below the threshold for ventilation, triggering a central apnea. Central sleep apneas are sustained by recurrent arousal resulting from apnea-induced hypoxia and the increased effort to breathe during the ventilatory phase because of pulmonary congestion and reduced lung compliance. Increased sympathetic activity causes increases in blood pressure (*BP*) and heart rate (*HR*) and increases myocardial oxygen (O_2) demand in the presence of reduced supply. *SNA,* Sympathetic nervous system activity; PaO_2, partial pressure of oxygen in arterial blood. (Redrawn from Bradley TD, Floras JS: Sleep apnea and heart failure. Part II. Central sleep apnea. Circulation 2003;107:1822.)

Although current guidelines recommend that continuous positive airway pressure (CPAP) may be reasonable to improve sleep quality and daytime sleepiness in patients with OSA,[10] there is no consensus as to how CSA should be treated. Since CSA is to some extent a manifestation of advanced HF, the first consideration is to optimize drug therapy, including aggressive diuresis to lower cardiac filling pressure, along with the use ACEIs/ARBs, ARNIs, beta blockers, and MRAs, which may lessen the severity of

CSA. In some cases, however, metabolic alkalosis arising from diuretic use may predispose to CSA by narrowing the difference between the circulating arterial carbon dioxide partial pressure ($PaCO_2$) and the $PaCO_2$ threshold that is necessary for apnea to develop. The use of nocturnal oxygen and CPAP devices has been reported to alleviate CSA, abolish apnea-related hypoxia, and decrease nocturnal norepinephrine levels, as well as produce symptomatic and functional improvement in HF patients when used in the short term (up to 1 month). However, the effects of supplemental O_2 on CV endpoints over more prolonged periods have not been assessed. Although there is no direct evidence that treatment of sleep-disturbed breathing prevents the development HF, treatment with CPAP breathing has been shown to improve LV structure and function in patients with OSA or CSA disturbed-breathing syndrome.[54]

Despite these objective measurements of improvement with CPAP, this treatment modality did not lead to a prolongation of life in the Canadian Continuous Positive Airway Pressure for Patients with Central Sleep Apnea and Heart Failure (CANPAP) trial,[54] which was discontinued early after concerns about the early divergence of transplantation-free survival favoring the control group. There was no difference in the primary endpoint of death or transplantation ($P = 0.54$) and no significant difference in the frequency of hospitalization between groups (0.56 versus 0.61 hospitalizations per patient year; $P = 0.45$). However, a post hoc analysis of the CANPAP study suggested that adequate suppression of CSA by CPAP was associated with improved heart transplant–free survival.[54]

The role of adaptive servo-ventilation (ASV), which alleviates CSA by delivering servo-controlled inspiratory pressure support on top of expiratory positive airway pressure was evaluated in the SERVE-HF trial (Treatment of Sleep-Disordered Breathing with Predominant Central Sleep Apnea by Adaptive Servo Ventilation in Patients with Heart Failure).[55] In patients with HFrEF (LVEF ≤45%) who predominantly had CSA, ASV had no effect on the primary end point, which was a time-to-event analysis of the first event of death from any cause, lifesaving CV intervention (cardiac transplantation, implantation of ventricular assist device, resuscitation after sudden cardiac arrest, or appropriate lifesaving shock), or unplanned hospitalization for worsening HF. However, all-cause mortality (HR, 1.28; 95% CI 1.06 to 1.55; $P = 0.01$) and CV mortality (HR, 1.34; 95% CI 1.09 to 1.65; $P = 0.006$) were significantly higher in the ASV group than in the control group. Therefore, ASV is not recommended in patients with NYHA Class II to IV HFrEF and predominantly CSA (level III: harm).[10]

Thus the data remain unclear whether elimination of apnea will lead to improved clinical outcomes. Other therapies proposed for sleep-disordered breathing in HF include nocturnal O_2, CO_2 administration (by adding dead space), theophylline, and acetazolamide and diaphragmatic pacing, but have not yet been systematically studied in outcome-based, prospective randomized trials.[56]

Disease Management Approach to Heart Failure

Despite the compelling scientific evidence that ACEIs/ARBs, beta blockers, and aldosterone antagonists reduce hospitalizations and mortality in patients with HF, these life-prolonging therapies continue to be underutilized outside of the highly artificial environment of clinical trials. Indeed, numerous studies in a variety of different clinical settings have documented that a significant proportion of patients with HF are not receiving treatment with guideline-recommended, evidence-based therapies. The failure to deliver optimal medical care to HF patients is almost certainly multifactorial, as it is with other complex chronic conditions that have substantial morbidity and mortality. Further, the elderly status of many HF patients, who often have a myriad of comorbidities, also presents a special challenges to health care providers. Optimal HF care includes a trained network of health care providers involved in the delivery of HF

management and interventions, including nurses, case managers, physicians, pharmacists, caseworkers, dietitians, physical therapists, psychologists, and information systems specialists; a method for communicating this knowledge to the patient, including patient education, education of caregivers and family members, medication management, peer support, or some form of post–acute care, as well as a method of ensuring that the patient has received and understood the knowledge; and a system for encouraging adherence to the recommended regimen and patient compliance (**Fig. 25.18**). Numerous studies have shown that many of the challenges to delivering optimal care to HF patients can be met through an integrated specialized HF clinic approach that uses nurse and physician extenders to deliver and ensure the implementation of care. Technology-driven strategies that employ low-cost telemonitoring also appear promising in terms of improving HF management and outcomes[57] (**see Chapter 27**). However, the optimum approach to noninvasive remote monitoring is uncertain, and the data from randomized clinical trials have been inconsistent and are not recommended by current practice guidelines.

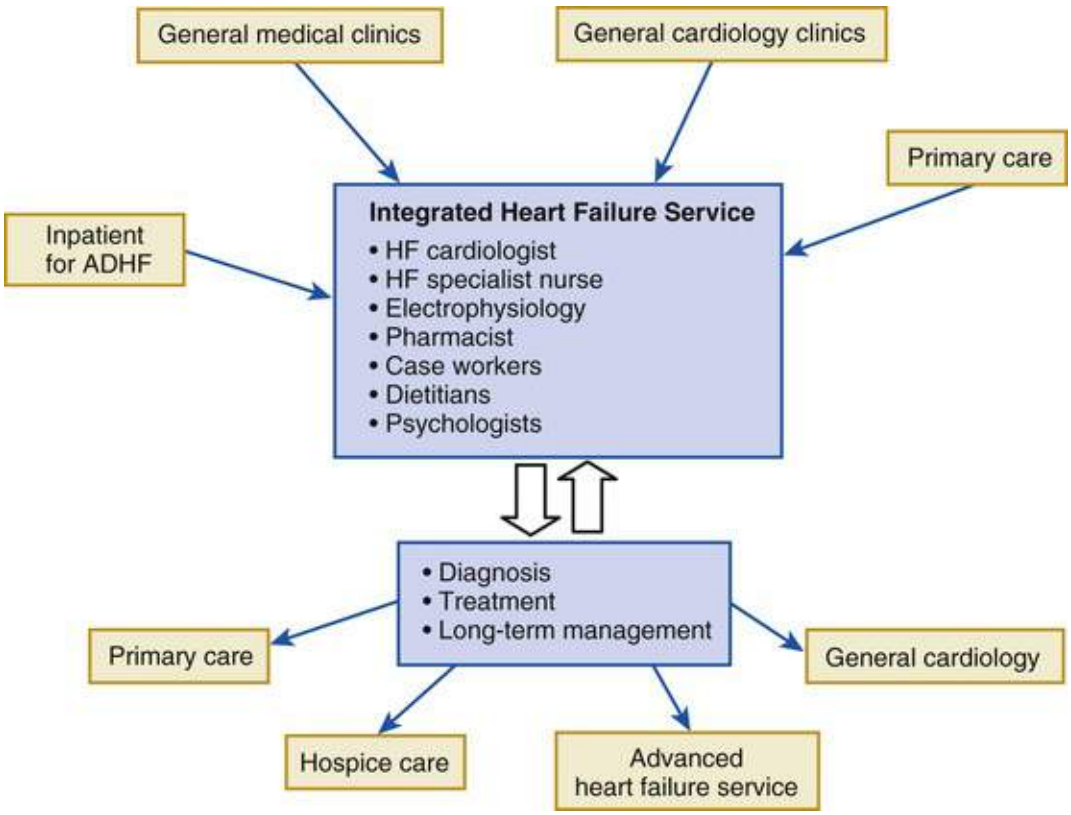

FIGURE 25.18 Integrated disease management program in heart failure. *ADHF,* Acute decompensated heart failure. (Modified from McDonagh TA. Lessons from the management of chronic heart failure. Heart 2005;91(Suppl 2):ii24-7.)

A disease management approach to HF has been shown to reduce hospitalizations and increase the percentage of patients receiving ideal, guideline-recommended therapy. Recent studies demonstrate that disease management programs need not be confined to the outpatient setting, and that hospital-based disease management systems can also improve medical care and education of hospitalized HF patients and accelerate use of evidence-based, guideline-recommended therapies by administering them before hospital discharge.[35] Although disease management strategies can lead to improved survival, it is not clear that these strategies are necessarily more cost-effective. Accordingly, the greatest challenge to disease management programs will be to determine how to support the additional personnel required in this model of care.

Patients With Refractory End-Stage Heart Failure (Stage D)

Most patients with HF caused by reduced LVEF respond well to evidenced-based pharmacologic and nonpharmacologic treatments and enjoy a good quality of life with a meaningful prolongation of life. However, for reasons that are not clear, some patients do not improve or will experience a rapid recurrence of symptoms despite optimal medical and device therapies. These individuals represent the most advanced stage of HF (stage D) and should be considered for specialized treatment strategies, such as mechanical circulatory support (**see Chapter 29**), continuous IV positive inotropic therapy, or referral for cardiac transplantation (**see Chapter 28**). However, before a patient is considered to have refractory HF, physicians should identify any contributing conditions (**see Table 25.5**) and ensure that all conventional medical strategies have been optimally employed. When no further therapies are appropriate, careful discussion of the prognosis and options for end-of-life care should be initiated (**see Chapter 31**).

Future Perspectives

Treatment with ACEIs/ARBs, beta blockers, MRAs, and cardiac devices has substantially improved quality and quantity of life for patients with HFrEF. Moreover, the recent success with the use of ARNIs offers the possibility of combining traditional neurohormonal approaches with drugs such as neprilysin inhibitors, whose mode of action is not completely understood. Ongoing approaches with small molecules that modulate contractility and gene therapy (**see Chapter 30**), accompanied by growing appreciation of the role of pharmacogenomics (**Chapter 8**), may lead to further advances in the field.

Guidelines

Management of Heart Failure with a Reduced Ejection Fraction

Douglas L. Mann

Guidelines for the initial evaluation of the heart failure patient are reviewed in **Chapter 21**, whereas this chapter reviews guidelines for the management of patients with a reduced ejection fraction (HFrEF). A joint task force of the American College of Cardiology and the American Heart Association (ACC/AHA) published updated comprehensive guidelines for the evaluation and management of heart failure (HF) in 2013.[1] These were updated in two sequential guidelines in 2016[2] that focused on changes in medical therapies but did not provide new guidelines for devices in diagnosing and treating heart failure.[2] The Heart Failure Society of America (HFSA) has partnered with the ACC and the AHA to provide coordinated recommendations about the 2016 and 2017 guidelines. The European Society of Cardiology (ESC) guidelines for the diagnosis and treatment of chronic HF were published 2016,[3] which superseded guidelines in 2012.[4] The ACC/AHA updated guidelines for management of patients with heart failure with a preserved ejection fraction (HFpEF) are reviewed in **Chapter 26**, and the use of devices for managing heart failure in **Chapter 27**.

As reviewed in this chapter and **Chapter 21**, the ACC/AHA guidelines classify patients according to four stages:

Stage A: patients at high risk for developing heart failure but without structural disorders of the heart
Stage B: patients with a structural disorder of the heart but no symptoms of heart failure
Stage C: patients with past or current symptoms of heart failure associated with underlying structural heart disease
Stage D: patients with end-stage disease who require specialized treatment strategies such as mechanical circulatory support, continuous inotropic infusions, cardiac transplantation, or hospice care

The following guidelines are organized into recommendations for each stage. As with other ACC/AHA guidelines, these recommendations classify interventions into one of three classes of recommendation (COR), including two levels of the "intermediate" group and two of the "no benefit" (NB) group. The term *guideline-directed medical therapy* (GDMT) represents optimal medical therapy as defined by the ACC/AHA guideline–recommended therapies.

Treatment of Patients at High Risk of Developing Heart Failure (Stage A)

The 2013 ACC/AHA guidelines for stage A patients are simplified from previous guidelines and continue to provide strong recommendations (class I) for treating hypertension and lipid disorders in accordance with contemporary guidelines in order to lower the risk of HF (**Table 25G.1**). The guidelines also suggest that other conditions that may lead to or contribute to HF, such as obesity, diabetes mellitus, tobacco use, and known cardiotoxic agents, should be controlled or avoided. For the first time, the updated ACC/AHA/HFSA 2017 guidelines provide a class IIa recommendation (level of evidence B-R) for the use of screening natriuretic peptide biomarker to prevent HF.

TABLE 25G.1

ACC/AHA Guidelines for Treating Patients at High Risk of Developing Heart Failure (Stage A)

CLASS	INDICATION	LEVEL OF EVIDENCE
I	Hypertension and lipid disorders should be controlled in accordance with contemporary guidelines to lower the risk of HF.	A
I	In patients at increased risk, stage A, the optimal blood pressure in those with hypertension should be less than 130/80 mm Hg.	B-R
I	Other conditions that may lead to or contribute to HF, such as obesity, diabetes mellitus, tobacco use, and known cardiotoxic agents, should be controlled or avoided.	C
II	For patients at risk of developing HF, natriuretic peptide biomarker–based screening followed by team-based care, including a cardiovascular specialist optimizing GDMT, can be useful to prevent the development of left ventricular dysfunction (systolic or diastolic) or new-onset HF.	B-R

GDMT, Guideline-directed medical therapy; *HF,* heart failure.

Treatment of Patients With Left Ventricular Dysfunction Who Have Not Developed Symptoms (Stage B)

The goal of therapy in stage B HF is to reduce the risk of further damage to the heart and to minimize the rate of progression of LV dysfunction (**Table 25G.2**). In the absence of contraindications, beta blockers

and angiotensin-converting enzyme inhibitors (ACEIs), or angiotensin receptor antagonists (ARBs) in those intolerant of ACEIs, are recommended for all patients with histories of myocardial infarction (MI), regardless of ejection fraction (EF), and for all patients with diminished EF, regardless of history of MI (class I, level of evidence A-C). In contrast, the guidelines discourage use of calcium channel blockers with negative inotropic action in this population. The guidelines also support the use of an ICD (class IIb, level of evidence B) in patients with asymptomatic ischemic cardiomyopathy who have had a recent (>40 days) MI with and EF of 30% or less, who are on appropriate medical therapy, and who have a reasonable expectation of life longer than 1 year (**see Chapter 27** for review of ICD guidelines).

TABLE 25G.2

ACC/AHA Guidelines for Treatment of Asymptomatic Left Ventricular Systolic Dysfunction (Stage B)

CLASS	INDICATION	LEVEL OF EVIDENCE
I	In all patients with a recent or remote history of MI or ACS and reduced EF, ACE inhibitors should be used to prevent symptomatic HF and reduce mortality. In patients intolerant of ACE inhibitors, ARBs are appropriate unless contraindicated.	A
	In all patients with a recent or remote history of MI or ACS and reduced EF, evidence-based beta blockers should be used to reduce mortality. Beta blockade and ACE inhibition should be used in all patients with a recent or remote history of MI regardless of EF or presence of HF.	B
	In all patients with a recent or remote history of MI or ACS, statins should be used to prevent symptomatic HF and cardiovascular events.	A
	Blood pressure should be controlled in accordance with clinical practice guidelines for hypertension to prevent symptomatic HF.	A
	ACE inhibitors should be used in all patients with a reduced EF to prevent symptomatic HF.	A
	Beta blockers should be used in all patients with a reduced EF to prevent symptomatic HF.	C
IIa	To prevent sudden death, placement of an ICD is reasonable in patients with asymptomatic ischemic cardiomyopathy who are at least 40 days post-MI, have an LVEF of 30% or less, are on appropriate medical therapy, and have reasonable expectation of survival with a good functional status for more than 1 year.	B
III: Harm	Nondihydropyridine calcium channel blockers with negative inotropic effects may be harmful in asymptomatic patients with low LVEF and no symptoms of HF after MI.	B

ACE, Angiotensin-converting enzyme; *ACS,* acute coronary syndrome; *ARB,* angiotensin receptor antagonist; *EF,* ejection fraction; *ICD,* implantable cardioverter-defibrillator; *LVEF,* left ventricular ejection fraction; *MI,* myocardial infarction.

Treatment of Patients With Left Ventricular Dysfunction and Current or Prior Symptoms (Stage C)

Fig. 25G.1 and **Table 25G.3** summarize the 2017 ACC/AHA/HFSA recommended approach to the treatment of stages C and D HFrEF.[5] Application of the same measures recommended for preventing or minimizing progression of LV dysfunction for stage A and B patients is supported for stage C patients, who have current or prior symptoms attributable to LV dysfunction (**Table 25G.3**). Physical activity and cardiac rehabilitation are recommended for stage C patients. The updated guidelines also reflect the results of the recent HF-ACTION trial (**see Chapter 25**), in which exercise training did not have a favorable impact on all-cause mortality or HF hospitalization. Maximal exercise testing with or without measurement of respiratory gas exchange to facilitate an appropriate exercise program, which was a class IIa indication in 2009, is not recommended in the 2013 ACC/AHA guidelines, although it is still recommended in the 2016 ESC guidelines.

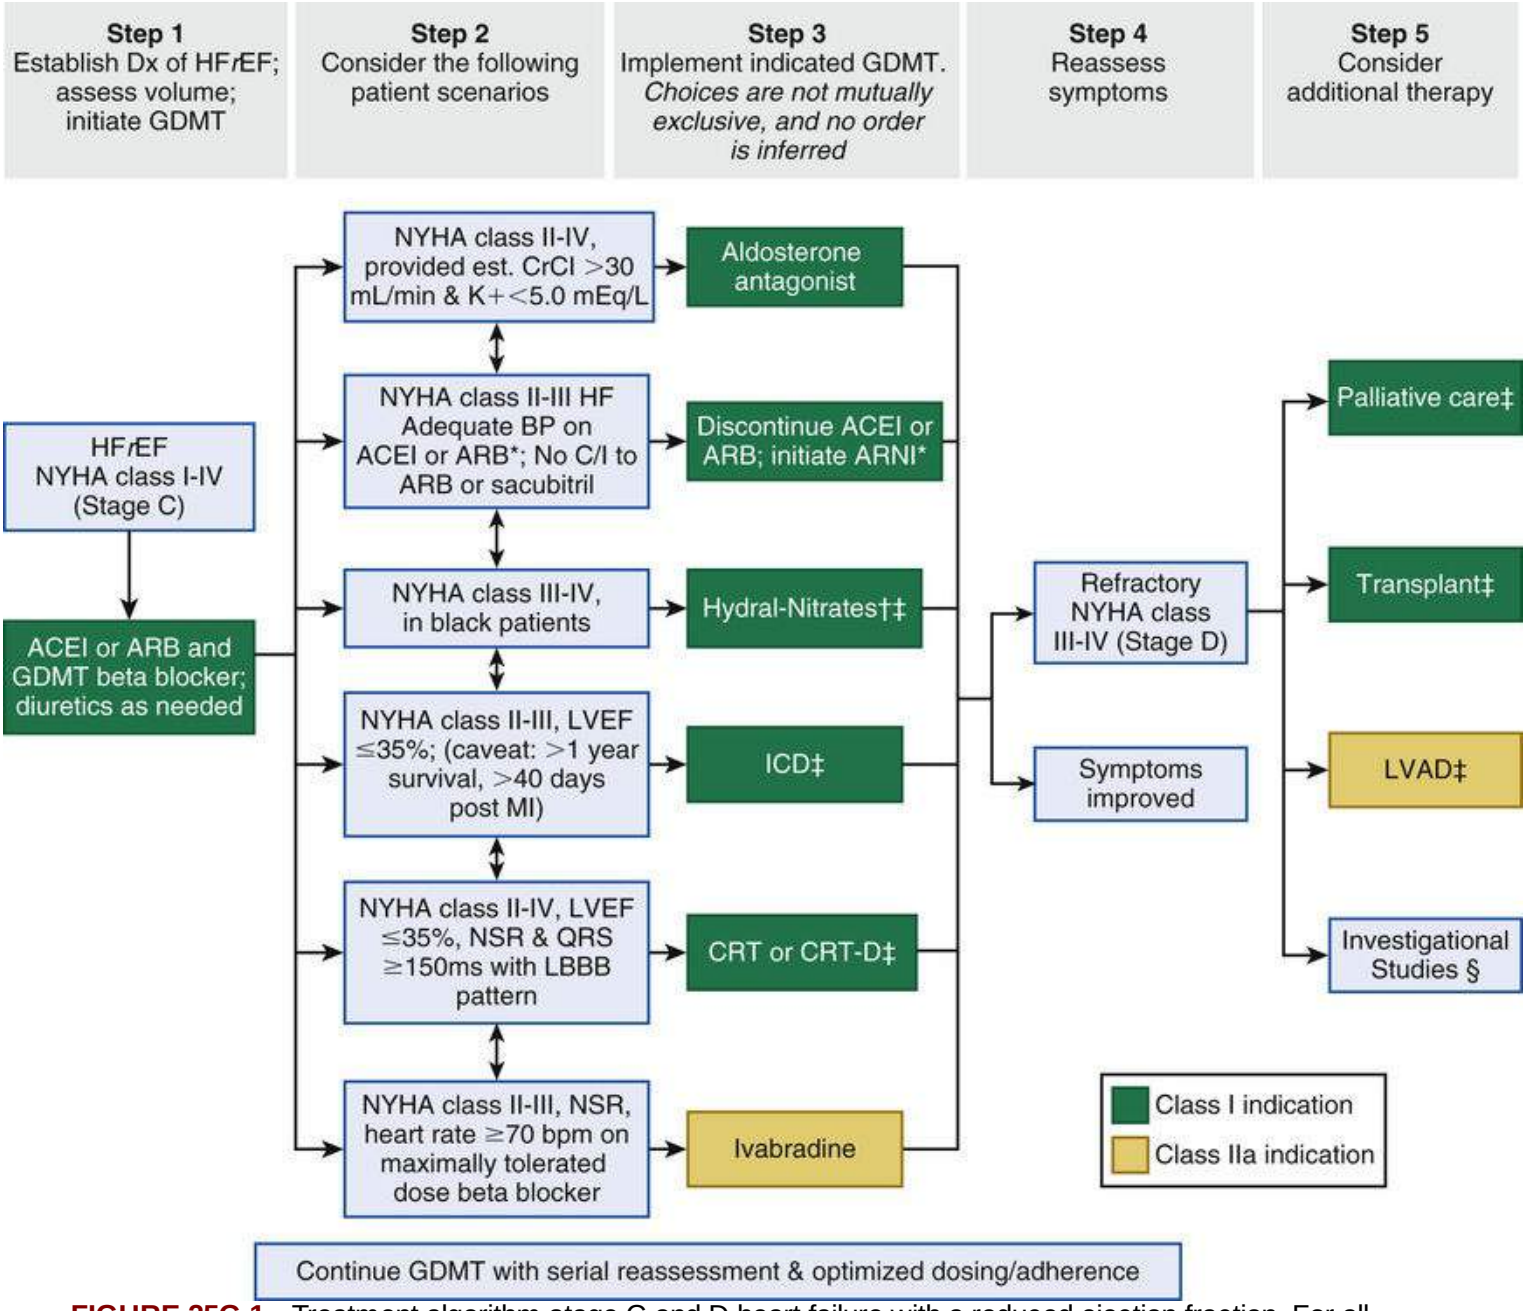

FIGURE 25G.1 Treatment algorithm stage C and D heart failure with a reduced ejection fraction. For all medical therapies, dosing should be optimized and serial assessment exercised. (See text in Chapter 25 for details.) *See text for important treatment directions. †Hydral-Nitrates *green box*: The combination of ISDN/HYD with ARNI has not been robustly tested. BP response should be carefully monitored. ‡See 2013 ACC/AHA heart failure guidelines.[1] §Participation in investigational studies is also appropriate for stage C, NYHA Class II and III HF. ACEI, Angiotensin-converting enzyme inhibitor; ARB, angiotensin receptor-blocker; ARNI, angiotensin receptor neprilysin inhibitor; BP, blood pressure; bpm, beats per minute; C/I, contraindication; CrCl, creatinine clearance; CRT-D, cardiac resynchronization therapy–device; Dx, diagnosis; GDMT, guideline-directed management and therapy; HF, heart failure; HF*r*EF, heart failure with reduced ejection fraction; ICD, implantable cardioverter-defibrillator; ISDN/HYD, isosorbide dinitrate hydral-nitrates; K^+, potassium; LBBB, left bundle-branch block; LVAD, left ventricular assist device; LVEF, left ventricular ejection fraction; MI, myocardial infarction; NSR, normal sinus rhythm; NYHA, New York Heart Association. (Modified from Yancy CW, Jessup M, Bozkurt B, et al. 2017 ACC/AHA/HFSA focused update of the 2013 ACCF/AHA Guideline for the Management of Heart Failure: a report of the American College of Cardiology/American Heart Association Task Force on Clinical Practice Guidelines and the Heart Failure Society of America. Circulation 2017 Apr 28; doi: 10.1161. [Epub ahead of print.].)

TABLE 25G.3

ACC/AHA Guidelines for Treatment of Patients with Prior or Current Symptoms of Chronic HFrEF (Stage C)

CLASS	INDICATION	LEVEL OF EVIDENCE
	Nonpharmacologic Interventions	
I	Patients with HF should receive specific education to facilitate HF self-care.	B
	Exercise training (or regular physical activity) is recommended as safe and effective for patients with HF who are able to participate to improve functional status.	A
IIa	Cardiac rehabilitation can be useful in clinically stable patients with HF to improve functional capacity, exercise duration, health-related quality of life, and mortality.	B
	Sodium restriction is reasonable for patients with symptomatic HF to reduce congestive symptoms.	C
	Continuous positive airway pressure (CPAP) can be beneficial to increase LVEF and improve functional status in patients with HF and sleep apnea.	B
	Pharmacologic Interventions	
I	Measures listed as class I recommendations for patients in stages A and B are recommended where appropriate.	A,B,C
	GDMT as depicted in should be the mainstay of pharmacologic therapy for HFrEF.	A
	Diuretics	
I	Diuretics are recommended in patients with HFrEF who have evidence of fluid retention, unless contraindicated, to improve symptoms.	C
	ACEIs/ARBs/ARNIs	
I	The use of ACE inhibitors is beneficial for patients with prior or current symptoms of chronic HFrEF, to reduce morbidity and mortality.	A
	The use of ARBs to reduce morbidity and mortality is recommended in patients with prior or current symptoms of chronic HFrEF who are intolerant of ACE inhibitors because of cough or angioedema.	A
I	ARNIs are recommended in patients with HFrEF unless contraindicated, to reduce morbidity and mortality.	B-R
I	ARNIs are recommended in patients with HFrEF NYHA Class II-III who are tolerant of an ACE inhibitor or ARB; replacement by a ARNI is recommended to further reduce morbidity and mortality.	B-R
IIa	ARBs are reasonable to reduce morbidity and mortality as alternatives to ACE inhibitors as first-line therapy for patients with HFrEF, especially for patients already taking ARBs for other indications, unless contraindicated.	A
IIb	Addition of an ARB may be considered in persistently symptomatic patients with HFrEF who are already being treated with an ACE inhibitor and a beta blocker in whom an aldosterone antagonist is not indicated or tolerated.	A
IIa	Ivabradine can be beneficial to reduce HF hospitalizations in patients with NYHA Class II-III HFrEF (LVEF <35%) who are receiving GDMT, including a beta blocker, and who are in sinus rhythm with a heart rate of ≥70 beats/min.	B-R
III: harm	Routinely combining an ACE inhibitor, an ARB, and an aldosterone antagonist is not recommended.	C
III: harm	ARNI should not be administered concomitantly with ACE inhibitors or within the last dose of an ACE inhibitor.	B-R
III: harm	ARNI should not be administered to patients with a history of angioedema.	C-EO
	Beta-Adrenergic Blockers	
I	Use of one of the three beta blockers proven to reduce mortality (i.e., bisoprolol, carvedilol, and sustained-release metoprolol succinate) is recommended for all patients with current or prior symptoms of HFrEF, unless contraindicated, to reduce morbidity and mortality.	A
	Aldosterone Receptor Antagonists	
I	Aldosterone receptor antagonists (or MRAs) are recommended in patients with NYHA Class II-IV and who have LVEF ≤35%, unless contraindicated, to reduce morbidity and mortality.	A
I	Aldosterone receptor antagonists are recommended to reduce morbidity and mortality following an acute MI in patients who have LVEF ≤40% who develop symptoms of HF or who have a history of diabetes mellitus, unless contraindicated.	B
III: harm	Inappropriate use of aldosterone receptor antagonists is potentially harmful because of life-threatening hyperkalemia or renal insufficiency when serum creatinine is >2.5 mg/dL in men or >2.0 mg/dL in women (or estimated glomerular filtration rate [eGFR] <30 mL/min/1.73 m^2), and/or potassium >5.0 mEq/L.	B
	Hydralazine and Isosorbide Dinitrate	
I	The combination of hydralazine and isosorbide dinitrate is recommended to reduce morbidity and mortality for patients self-described as African Americans with NYHA Class III-IV HFrEF receiving optimal therapy with ACE inhibitors and beta blockers, unless contraindicated.	A
IIa	A combination of hydralazine and isosorbide dinitrate can be useful to reduce morbidity or mortality in patients with current or prior symptomatic HFrEF who cannot be given an ACE inhibitor or ARB because of drug intolerance, hypotension, or renal insufficiency, unless contraindicated.	B
	Digoxin	
IIa	Digoxin can be beneficial in patients with HFrEF, unless contraindicated, to decrease hospitalizations for HF.	B
	Anticoagulation	
I	Patients with chronic HF with permanent/persistent/paroxysmal AF and an additional risk factor for cardioembolic stroke (history of hypertension, diabetes mellitus, previous stroke or transient ischemic attack, or ≥75 years of age) should receive chronic anticoagulant therapy.	A
I	The selection of an anticoagulant agent (warfarin, dabigatran, apixaban, or rivaroxaban) for permanent/persistent/paroxysmal AF should be individualized on the basis of risk factors, cost, tolerability, patient preference, potential for drug interactions, and other clinical characteristics, including time in the international normalized ratio (INR) therapeutic range if the patient has been taking warfarin.	C
IIa	Chronic anticoagulation is reasonable for patients with chronic HF who have permanent/persistent/paroxysmal AF but are without an additional risk factor for cardioembolic stroke.	B
III: no benefit	Anticoagulation is not recommended in patients with chronic HFrEF without AF, a prior thromboembolic event, or a cardioembolic source.	B
	Statins	
III: no benefit	Statins are not beneficial as adjunctive therapy when prescribed solely for HF.	A
	Omega-3 Polyunsaturated Fatty Acids	
IIa	Omega-3 polyunsaturated fatty acid (PUFA) supplementation is reasonable to use as adjunctive therapy in patients with NYHA Class II-IV symptoms and HFrEF or HFpEF, unless contraindicated, to reduce mortality and cardiovascular hospitalizations.	B
	Drugs of Unproven Value or that May Cause Harm	
III: no benefit	Nutritional supplements as treatment for HF are not recommended in patients with current or prior symptoms of HFrEF.	B
	Hormonal therapies other than to correct deficiencies are not recommended for patients with current or prior symptoms of HFrEF.	C
III: harm	Drugs known to adversely affect the clinical status of patients with current or prior symptoms of HFrEF are potentially harmful and should be avoided or withdrawn whenever possible (e.g., most antiarrhythmic drugs, most calcium channel blockers except amlodipine, NSAIDs, thiazolidinediones).	B
	Long-term use of infused positive inotropic drugs is potentially harmful for patients with HFrEF, except as palliation for patients with end-stage disease who cannot be stabilized with standard medical treatment (see recommendations for stage D).	C
	Calcium Channel Blockers	
III: no benefit	Calcium channel blocking drugs are not recommended as routine therapy for patients with HFrEF.	A

ACEIs, Angiotensin-converting enzyme inhibitors; *ARBs,* angiotensin receptor blockers; *ARNIs,* angiotensin receptor neprilysin

inhibitors; *GDMT,* guideline-directed medical therapy; *HFpEF,* heart failure with preserved ejection fraction; *HFrEF,* heart failure with a reduced ejection fraction; *LVEF,* left ventricular ejection fraction; *NYHA,* New York Heart Association.

The 2017 ACC/AHA/HFSA updated guidelines support the use of beta blockers (bisoprolol, carvedilol, sustained-release metoprolol succinate) and ACEIs (ARBs for patients who cannot tolerate ACEIs) for all stage C patients, in the absence of contraindications, and use of diuretics for patients with fluid overload. New for the 2017 guidelines is the class I recommendation (level B-R) to replace an ACE inhibitor/ARB by a ARNI to further reduce morbidity and mortality in patients with NYHA Class II-III heart failure. When stopping an ACEI and starting an ARNI, it is important to wait at least 36 hours, to avoid the risk of angioedema (class III: harm; level of evidence EO). Of note, the 2016 ESC guidelines do not recommend the routine replacement of an ACEI/ARB by an ARNI unless the patient remains symptomatic after an ACEI (equivalent to 10 mg twice daily of enalapril) or ARB, a beta blocker, and a mineralocorticoid receptor antagonist (MRA), and had elevated levels of plasma natriuretic peptides (BNP ≥150 pg/mL or plasma NT-proBNP ≥600 pg/mL), or if there was a HF hospitalization within the past 12 months with an elevated plasma level of natriuretic peptides (BNP ≥100 pg/mL or plasma NT-proBNP ≥400 pg/mL).[3] The class IIa recommendation for the use of ivabradine in symptomatic patients in sinus rhythm and a heart rate of 70 beats/min or higher (at rest) is also new for the 2017 AHA/ACC/HFSA guidelines.

Based on the results of the Eplerenone in Mild Patients Hospitalization and Survival Study in Heart Failure (EMPHASIS-HF), MRAs are now recommended for all NYHA Class II-IV HF patients with an EF of 35% or less, to reduce morbidity and mortality, unless contraindicated (class I, level of evidence A). As with the 2009 guidelines, the use of hydralazine and isosorbide remains a class I indication for self-identified African Americans who remain symptomatic in NYHA Class III-IV HF despite optimal therapy. The combination of hydralazine and isosorbide is recommended in patients who are intolerant of an ACEI or ARB. Digitalis remains a reasonable approach to decrease hospitalizations in symptomatic patients. Based on the results of the WARCEF (Warfarin versus Aspirin in Reduced Cardiac Ejection Fraction), anticoagulation is not recommended in patients with chronic HF without atrial fibrillation, a prior embolic event, or a cardioembolic source (class III: no benefit). However, anticoagulation continues to be recommended for patients with chronic HF and permanent/persistent/paroxysmal atrial fibrillation who have an additional risk factor for cardioembolic stroke (class I, level of evidence B). The guidelines explicitly discourage the routine use of a combination of an ACEI with an ARB and MRA because of the risk of hyperkalemia; use of an ACEI with an ARNI because of the risk of angioedema; calcium channel blockers, long-term infusion of positive inotropic drugs (except as palliation in patients with end-stage disease, **see Table 25G.3**), use of nutritional supplements, statins as adjunctive therapy for HF, and hormonal therapies other than those needed to replete deficiencies. The recommendations regarding the use of implantable cardioverter-defibrillators (ICDs) and cardiac resynchronization therapy (CRT) are reviewed in **Chapter 26**.

Treatment of Patients With Refractory End-Stage Heart Failure (Stage D)

The 2009 ACCF/AHA HF guidelines define stage D as patients with truly refractory HF who might be eligible for specialized advanced treatment strategies such as mechanical circulatory support (MCS; **see Chapter 29**), procedures to facilitate fluid removal, continuous inotropic infusions, or cardiac transplantation (**Chapter 28**) or other innovative or experimental surgical procedures, or for end-of-life care, such as hospice (**Chapter 31**). The guidelines provide clear indications for the use of inotropic

agents and MCS in stage D patients (**Table 25G.4**). The guidelines endorse the use of continuous IV inotropic support until definitive therapy can be performed (e.g., MCS, heart transplantation) and/or to maintain systemic perfusion and preserve end-organ performance until the acute precipitating problem is resolved (class I, level of evidence C). The guidelines also support inotropic support as "bridge therapy" to guideline-directed medical therapy (GDMT) and/or device therapy (class IIa, level of evidence B), as well as short-term continuous IV inotropic in hospitalized patients with documented severe systolic dysfunction who present with low blood pressure and significantly depressed cardiac output, in order to maintain systemic perfusion and preserve end-organ performance, or as palliative therapy for symptom control (class IIb, level of evidence B). The guidelines regard long-term use of either continuous or intermittent, IV parenteral positive inotropic agents, in the absence of specific indications or for reasons other than palliative care, as potentially harmful (class III: harm, level of evidence B)

TABLE 25G.4

ACC/AHA Guidelines for Treatment of Patients with End-Stage Heart Failure (Stage D)

CLASS	INDICATION	LEVEL OF EVIDENCE
	Nonpharmacologic Interventions	
IIa	Fluid restriction (1.5-2 L/day) is reasonable in stage D, especially in patients with hyponatremia.	B
	Inotropic Support	
I	Until definitive therapy (e.g., coronary revascularization, MCS, heart transplantation) or resolution of the acute precipitating problem, patients with cardiogenic shock should receive temporary IV inotropic support to maintain systemic perfusion and preserve end-organ performance.	C
IIa	Continuous IV inotropic support is reasonable as "bridge therapy" in patients with stage D refractory to GDMT and device therapy who are eligible for and awaiting MCS or cardiac transplantation.	B
IIb	Short-term, continuous IV inotropic support may be reasonable in those hospitalized patients presenting with documented severe systolic dysfunction who present with low blood pressure and significantly depressed cardiac output, to maintain systemic perfusion and preserve end-organ performance.	B
	Long-term, continuous IV inotropic support may be considered as palliative therapy for symptom control in select patients with stage D despite optimal GDMT and device therapy who are not eligible for either MCS or cardiac transplantation.	B
III: Harm	Long-term use of either continuous or intermittent, IV parenteral positive inotropic agents, in the absence of specific indications or for reasons other than palliative care, is potentially harmful in the patient with HF.	B
	Use of parenteral inotropic agents in hospitalized patients without documented severe systolic dysfunction, low blood pressure, or impaired perfusion, and evidence of significantly depressed cardiac output, with or without congestion, is potentially harmful.	B
	Mechanical Circulatory Support (MCS)	
IIa	MCS is beneficial in carefully selected patients with stage D HFrEF in whom definitive management (e.g., cardiac transplantation) or cardiac recovery is anticipated or planned.	B
	Nondurable MCS, including the use of percutaneous and extracorporeal ventricular assist devices (VADs), is reasonable as a "bridge to recovery" or "bridge to decision" for carefully selected patients with HFrEF with acute, profound hemodynamic compromise.	B
	Durable MCS is reasonable to prolong survival for carefully selected patients with stage D HFrEF.	B
	Cardiac Transplantation	
I	Evaluation for cardiac transplantation is indicated for carefully selected patients with stage D HF despite GDMT, device, and surgical management	C

GDMT, Guideline-directed medical therapy; *HFrEF,* heart failure with reduced ejection fraction; *IV,* intravenous; *MCS,* mechanical circulatory support.

The 2013 ACC/AHA guidelines provide qualified support for MCS in carefully selected patients with stage D HF with a reduced ejection fraction (HFrEF), in whom definitive management (e.g., cardiac transplantation) or cardiac recovery is anticipated or planned, and also indicate that percutaneous and extracorporeal ventricular assist devices (VADs) are reasonable as a "bridge to recovery" or "bridge to decision" for carefully selected patients with HFrEF with acute profound hemodynamic compromise (class IIb, level of evidence B). The guidelines also provide qualified support for the use of durable VADs to prolong survival in carefully selected patients with stage D HFrEF. As in previous guidelines, cardiac transplantation remains a class I indication (level of evidence C) for carefully selected patients with stage D HFrEF despite GDMT, device, and surgical management.

Comorbidities in Heart Failure Patients

The 2013 ACC/AHA practice guidelines recognize the importance of comorbidities in the heart failure

patient, including hypertension, anemia, diabetes, arthritis, chronic kidney disease, and depression, but did not provide specific recommendations. However, the 2017 ACC/AHA/HFSA focused guideline update did provide specific recommendations for the treatment of hypertension, anemia, and sleep-disordered breath (**Table 25G.5**).

TABLE 25G.5

ACC/AHA/HFSA Guidelines for Treatment of Comorbidities in Heart Failure

CLASS	INDICATION	LEVEL OF EVIDENCE
	Hypertension	
I	Patients with HFrEF and hypertension should be prescribed GDMT titrated to attain systolic blood pressure less than 130 mm Hg.	C-EO
	Anemia	
IIb	In patients with NYHA Class II and III HF and iron deficiency (ferritin <100 ng/mL or 100-300 ng/mL if transferrin saturation is <20%), intravenous iron replacement might be reasonable to improve functional status and quality of life.	B-R
III: No Benefit	In patients with HF and anemia, erythropoietin-stimulating agents should not be used to improve morbidity and mortality.	B-R
	Sleep-Disordered Breathing	
IIa	In patients with NYHA Class II-IV HF and suspicion of sleep-disordered breathing or excessive daytime sleepiness, a formal sleep assessment is reasonable.	C-LD
IIb	In patients with cardiovascular disease and obstructive sleep apnea, CPAP may be reasonable to improve sleep quality and daytime sleepiness.	B-R
III: Harm	In patients with NYHA Class II-IV HFrEF and central sleep apnea, adaptive servo-ventilation causes harm.	B-R

CPAP, Continuous positive airway pressure; *NYHA,* New York Heart Association.

The Hospitalized Patient

The updated 2010 HFSA, 2012 ESC, and 2013 ACC/AHA guidelines included specific recommendations regarding the hospitalized patient and are reviewed in **Chapter 24** (**Table 24G.1**).

Heart Failure With Preserved Ejection Fraction

The updated 2010 HFSA, 2012 ESC, and 2013 ACC/AHA guidelines included specific recommendations regarding management of patients with HFpEF and are reviewed in **Chapter 26** (**Table 26G.1**).

Surgical/Percutaneous/Transcatheter Interventional Treatment of Heart Failure

The 2013 ACC/AHA guidelines reviewed surgical therapies and percutaneous interventions that are commonly integrated in the management of HF patients, including coronary revascularization (e.g., CABG, angioplasty, stenting); aortic valve replacement, mitral valve replacement, and LV surgical reconstruction (**Table 25G.6**). The revised guidelines recommend coronary artery revascularization via CABG or percutaneous intervention for patients on GDMT with angina and suitable coronary anatomy, especially for a left main stenosis (>50%) or left main equivalent disease (class I, level of evidence C). CABG was also recommended to improve survival in mild to moderate LV dysfunction (EF 35% to 50%) and significant (≥70% diameter stenosis) multivessel CAD or proximal left anterior descending coronary artery stenosis when viable myocardium is present, as well as to improve morbidity and cardiovascular mortality for patients with severe LV dysfunction (EF <35%), HF, and significant CAD (class IIa, level of evidence B). Qualified support was provided for a survival benefit for CABG (class IIb, level of evidence B) in patients with ischemic heart disease with severe LV systolic dysfunction (EF <35%) and operable coronary anatomy irrespective of whether viable myocardium was present. The new guidelines

provided a class IIa (level of evidence B) recommendation for surgical aortic valve replacement in patients with a predicted surgical mortality of less than 10% and a class IIa (level of evidence B) recommendation for transcatheter aortic valve replacement in inoperable patients with critical aortic valve disease. The guidelines offer qualified support for transcatheter mitral valve repair or mitral valve surgery for functional mitral insufficiency and recommend that this approach should be considered after careful candidate selection and in addition to GDMT (class IIb, level of evidence B). A similar level of qualified support was given for surgical reverse remodeling or LV aneurysmectomy for intractable HF and ventricular arrhythmias.

TABLE 25G.6

ACC/AHA Guidelines for Surgical/Percutaneous/Transcatheter Interventional Treatments for Heart Failure

CLASS	INDICATION	LEVEL OF EVIDENCE
I	Coronary artery revascularization via CABG or percutaneous intervention is indicated for patients (HFpEF and HFrEF) on GDMT with angina and suitable coronary anatomy, especially for a left main stenosis (>50%) or left main equivalent disease.	C
IIa	CABG to improve survival is reasonable in patients with mild to moderate LV systolic dysfunction (EF 35%-50%) and significant (≥70% diameter stenosis) multivessel CAD or proximal left anterior descending coronary artery stenosis when viable myocardium is present in the region of intended revascularization.	B
	CABG or medical therapy is reasonable to improve morbidity and cardiovascular mortality for patients with severe LV dysfunction (EF <35%), HF, and significant CAD.	B
	Surgical aortic valve replacement is reasonable for patients with critical aortic stenosis and a predicted surgical mortality of no greater than 10%.	B
	Transcatheter aortic valve replacement after careful candidate consideration is reasonable for patients with critical aortic stenosis who are deemed inoperable.	B
IIb	CABG may be considered with the intent of improving survival in patients with ischemic heart disease with severe LV systolic dysfunction (EF <35%) and operable coronary anatomy whether or not viable myocardium is present.	B
	Transcatheter mitral valve repair or mitral valve surgery for functional mitral insufficiency is of uncertain benefit and should only be considered after careful candidate selection and with a background of GDMT.	B
	Surgical reverse remodeling or LV aneurysmectomy may be considered in carefully selected patients with HFrEF for specific indications, including intractable HF and ventricular arrhythmias.	B

CABG, Coronary artery bypass grafting; *CAD,* coronary artery disease; *EF,* ejection fraction; *GDMT,* guideline-directed medical therapy; *HFpEF,* heart failure with preserved ejection fraction; *HFrEF,* heart failure with reduced ejection fraction; *LV,* left ventricular.

Coordinating Care for Patients With Chronic Heart Failure

The guidelines recognize that systems of care designed to support patients with HF and other cardiac diseases can produce significant improvement in outcomes, but indicate that the quality of evidence is mixed for specific components of HF clinical management interventions, such as home-based care, disease management, and remote telemonitoring programs. Thus the guidelines recommend that interventions should focus on improving adherence to GDMT (**Table 25G.7**). The updated guidelines advocate patient education and involvement of patients with HF and their families, especially during transitions of care, to ensure effective care that is designed to achieve GDMT and prevent hospitalizations (class I, level of evidence B). The guidelines also recommend that every patient with HF should have a clear, detailed, and evidence-based plan of care that ensures the achievement of GDMT goals, effective management of comorbid conditions, timely follow-up with the health care team, appropriate dietary and physical activities, and compliance with secondary prevention guidelines for cardiovascular disease (class I, level of evidence C). The guidelines recommend that the HF and palliative care teams are best suited to help patients and families decide when end-of-life care (including hospice) is appropriate (class I, level of evidence C). The core elements of comprehensive palliative care for HF include expert symptom assessment and management, including symptom control, psychosocial distress, health-related quality of life, preferences about end-of-life care, caregiver support,

and assurance of access to evidence-based disease-modifying interventions.

TABLE 25G.7

Coordinating Care for Patients with Chronic Heart Failure

CLASS	INDICATION	LEVEL OF EVIDENCE
I	Effective systems of care coordination with special attention to care transitions should be deployed for every patient with chronic HF, to facilitate and ensure effective care designed to achieve GDMT and prevent hospitalization.	B
	Every patient with HF should have a clear, detailed, and evidence-based plan of care that ensures the achievement of GDMT goals, effective management of comorbid conditions, timely follow-up with the health care team, appropriate dietary and physical activities, and compliance with secondary prevention guidelines for cardiovascular disease. This plan of care should be updated regularly and made readily available to all members of each patient's health care team.	C
	Palliative and supportive care is effective for patients with symptomatic advanced HF to improve quality of life.	B

GDMT, Guideline-directed medical therapy.

Pharmacogenomics in Heart Failure

Current heart failure (HF) practice guidelines (**see Chapter 25** heart failure guidelines) recommend titrating angiotensin-converting enzyme inhibitors (ACEIs), angiotensin receptor blockers (ARBs), angiotensin receptor neprilysin inhibitors (ARNIs), aldosterone antagonists, and beta blockers to doses that have been shown to be beneficial in clinical trials. Although this approach tends to work well for most patients, it has two major shortcomings. Most importantly, basing drug dosing on the doses selected in clinical trials does not allow for dose optimization in patients who may metabolize and/or distribute drugs differently. The second problem is that clinical trials are generally designed to yield "binary" results. That is, a drug under investigation is either deemed beneficial or not beneficial because the patients in the treatment arm have, or have not, reached a prespecified endpoint (e.g., death or hospitalization). A beneficial effect in a positive clinical trial implies that all patients will receive the same degree of benefit from the drug that is given. However, a more likely outcome is that a given therapy will have a markedly positive impact for some patients, a more modest effect in others, and may be completely ineffective or perhaps even harmful in a smaller group of treated patients. Thus, even though a drug is deemed beneficial in a clinical trial, there is no guarantee that an individual patient will benefit from the treatment. For example, beta blockers have been shown consistently to reduce the risk of death in HF patients by approximately 35% (**see Fig. 25.14**); however, clinical trials have also shown that beta blockers will need to be discontinued in 8% to 25% of HF patients because of significant adverse effects, including worsening HF.[1] Recent advances in the field of pharmacogenetics suggest that a careful analysis of underlying gene polymorphisms within a given patient may enable clinicians to develop personalized therapeutic regimens for HF patients. Given the central role of the renin-angiotensin-aldosterone system (RAAS) and adrenergic systems in the pathophysiology (**see Chapter 23**) and treatment of HF, it is perhaps not surprising that polymorphisms in the genes that regulate these pathways appear to influence the therapeutic efficacy of ACEIs and beta blockers.

Genetic Variations in the Renin-Angiotensin Aldosterone System

One of the most widely studied genetic variants is the ACE insertion/deletion polymorphism (I/D) that involves a 287–base pair insertion or deletion within intron 16 of the ACE gene. Although the clinical significance of this polymorphism remains controversial, the physiologic association with ACE enzymatic activity has consistently been demonstrated. Studies have shown that individuals with the DD genotype have the highest ACE activity and angiotensin II levels, heterozygotes (I/D) have intermediate levels, and individuals who are homozygous for the I allele (I/I) have the lowest levels of ACE activity. The relationship of ACE I/D has been explored with respect to numerous conditions, including atherosclerosis, myocardial infarction, left ventricular hypertrophy, hypertrophic cardiomyopathy, and HF. Although the current weight of evidence does not allow for definitive conclusions to be made with respect to the overall contribution of the ACE I/D polymorphism to the clinical outcome in these conditions, there is growing evidence that the ACE I/D polymorphism may predict drug responsiveness to both beta blockers and ACEIs in HF patients. In one study of patients with chronic HF, the ACE DD polymorphism was significantly associated with death or the need for transplantation compared to patients with II or ID genotypes. Within the ACE DD group, patients treated with beta blockers had significantly improved transplant-free survival compared to patients not receiving beta-blocker therapy, whereas beta-blocker treatment had no effect in clinical outcomes in the II or ID groups.[2] In a similar study, patients with the DD genotype had better clinical outcomes when receiving high-dose ACEI therapy compared to low-dose ACEI therapy, whereas the ACE dose had no effect on clinical outcomes in patients with the II or ID

genotype. In this study the regimen of high-dose ACE inhibitors and beta blockers had the greatest impact on transplant-free survival in patients with the DD variant.[2] Taken together, these studies suggest a differential clinical response to standard HF therapy based on the ACE I/D polymorphism.

While the impact of genetic heterogeneity on HF outcomes has been extensively studied in predominantly white cohorts, few studies have investigated the impact of genomic variation in blacks. In a genetic substudy of the African Americans in Heart Failure (A-HeFT) trial (**see Chapter 25**), a single-nucleotide polymorphism within the promoter region of the aldosterone synthase gene (C-to-T transition at position −344) was shown to predict responsiveness to the fixed combination of hydralazine and isosorbide dinitrate.[3] In A-HeFT treatment with the fixed combination of hydralazine/isosorbide was associated with a markedly improved clinical outcome (mortality, HF hospitalization, and change in quality of life at 6 months) in the TT homozygotes, but had no significant impact among subjects with the −344C allele, suggesting that genetic variations in aldosterone production may play an important role in disease progression in blacks with HF.

Genetic Variations in Beta-Adrenergic Receptor System

Beta-adrenergic blockers have been a mainstay of HF pharmacotherapy; however, there is great variation in response to beta-blocker therapy, including certain subsets of the HF population who do not receive the same mortality and morbidity benefit.[4] Single-nucleotide polymorphisms (SNPs) have been identified in the β_1-AR (*ADRB1)*, β_2-AR (*ADRB2)*, α_{2c} AR (*ADRA2C)*, and G-protein receptor kinase 5 (*GRK5)* genes of the adrenergic system and may partially explain the variable effects received from beta blockade. Patients with a common polymorphism of the beta$_1$-adrenergic receptor (AR) that results in either an arginine (Arg) or glycine (Gly) substitution at amino acid position 389 have different clinical responses to beta blockers. In the Bucindolol Evaluation of Survival trial (BEST), bucindolol-treated patients who were homozygous for the Arg 389 polymorphism (Arg389Arg) had improved clinical outcomes compared to “glycine carriers” (Arg389Gly and Gly389Gly) who were treated with bucindolol, suggesting that the therapeutic response to beta blockers differs by genotype.[5] The Arg389Arg genotype was also associated with significantly greater reductions in LV end-diastolic and end-systolic diameters following treatment with beta blockers compared to identically treated Gly389 carriers. In a substudy of the BEST trial that evaluated the effects of bucindolol in patients with atrial fibrillation, AF patients and sinus rhythm patients who achieved a resting heart rate of 80 beats/min or less on bucindolol showed beneficial treatment effect on cardiovascular (CV) mortality/CV hospitalization. The patients who were homozygous for the Arg389Arg genoty had nominally significant reductions in all-cause mortality/HF hospitalization and CV mortality/hospitalization, whereas the Gly389 carriers did not.[6]

The alpha$_{2c}$-adrenergic receptor inhibits norepinephrine release at cardiac presynaptic nerve endings through a negative feedback mechanism. The deletion of four consecutive amino acids in (aa 322-325) in the alpha$_{2c}$-adrenergic receptor results in loss of normal synaptic autoinhibitory feedback mechanism and thus enhanced presynaptic release of norepinephrine. There appears to be an increased risk of developing HF when the alpha$_{2c}$Del322-325 and the Arg389 beta$_1$-AR polymorphism are both present (i.e., a diplotype).[7] Although the impact of the alpha$_{2c}$Del322-325 and Arg389 beta$_1$-AR synergism on beta-blocker responsiveness is not known, it is likely that patients with this diplotype may have increased responsiveness to beta blockers, based on what has been reported thus far for the Arg389 polymorphism. Recently, a nonsynonymous polymorphism in which leucine (Leu) is substituted for glutamine (Gln) at amino acid position 49 of G-protein receptor kinase 5 (GRK5-Leu41), which desensitizes beta-AR

signaling, was shown to uncouple beta-AR signaling more effectively than the GRK5-Gln41 polymorphism. Human association studies showed a pharmacogenomic interaction between GRK5-Leu41 and beta-blocker treatment, in which the presence of the GRK5-Leu41 polymorphism was associated with decreased mortality in African Americans (in whom this polymorphism is more prevalent) with HF or cardiac ischemia. Subsequent studies showed that among patients not taking beta blockers, GRK5-Leu41 was associated with improved survival in African Americans, suggesting that GRK5-Leu41 provides a "genetic beta blockade" that improves survival in African Americans with HF.[8] In addition to contributing to the functional response to beta-blockers, genetic polymorphisms that affect drug metabolism may also influence the therapeutic response to beta blockers. For example, genetic variants in the cytochrome P-450 (CYP) 2D6 gene have a marked effect on plasma concentrations of metoprolol and carvedilol. In subjects with a nonfunctional CYP2D6 enzyme (poor metabolizers), the peak plasma concentration of metoprolol is sixfold higher than in subjects with a normally functioning enzyme.[1]

Genetic Variations in Response to Hydralazine and Isosorbide Dinitrate

The combination of hydralazine and isosorbide dinitrate is recommended for African Americans with NYHA Class III-IV HFrEF who remain symptomatic despite concomitant use of ACE inhibitors, beta blockers, and aldosterone antagonists. Polymorphisms in the G-protein $beta_3$ subunit (GNB3) influence $alpha_2$-adrenergic signaling. Specifically, the GNB3 C825T polymorphism is associated with enhanced adrenergic signaling. In the GRAHF (Genetic Risk Assessment of Heart Failure in African Americans) patients who were homozygous for the GNB3 TT allele had a greater therapeutic effect of fixed-dose hydralazine/isosorbide dinitrate with respect to the composite endpoint of death, hospital stay for heart failure, event-free survival, and change in quality of life (QoL).[9]

Genetic Variations in Response to Digoxin

Digoxin is recommended for patients with symptomatic HF, but only at doses that correlate with relatively low serum levels, due to increased mortality at higher levels. Given this narrow therapeutic range, factors that impact digoxin concentration may have important clinical implications. The P-glycoprotein encoded by the *ABCB1* gene plays a role in the elimination of digoxin.[10] Three SNPs in *ABCB1(*substitution of thymine at positions 1236, 2677, and 3435 [referred to as the TTT haplotype]) have been associated with increased digoxin serum levels in some, but not all studies.[11] Validation in a larger independent population will be necessary to establish if there is a genetic link between the TTT haplotype to digoxin levels and in HF patients who are receiving digoxin.

Genetic Variations in Response to Loop Diuretics

As noted, loop diuretics act by inhibiting sodium-potassium-chloride luminal transporters in the loop of Henle (**see Fig. 25.7**). Pharmacogenomic research has shown that changes in the response to diuretics is based, at least in part, on genetic variations in the solute carrier genes. In a pharmacogenomic study on furosemide, bumetanide, and torsemide, a polymorphism in *SLC12A3* (Ala26) gene, which encodes the renal thiazide-sensitive NaCl cotransporter and mediates Na^+ and Cl^- reabsorption in the distal nephron, was associated with increased excretion of Cl^- and K^+ compared to the SLC12A3 Gly264 polymorphism.[11] In a post hoc analysis of clinical trials from the NIH Heart Failure Network, a set of rare

variants in the *APOL1* gene, which codes for apolipoprotein L1, was associated with an increase in net fluid loss after 72 hours of loop diuretic treatment. Additionally, a common variant in the multidrug-resistant protein-4 coding gene (*ABCC4*) was associated with increased weight loss with furosemide use.[12] Further confirmatory work in HF patients will be necessary to understand the clinical utility of these studies.

Digoxin

Cardiac glycosides are used to treat chronic HF in patients in sinus rhythm and to control the response of the ventricular rate to supraventricular arrhythmias, including atrial fibrillation.[1] Digoxin is the most

commonly prescribed cardiac glycoside because of its convenient pharmacokinetics, alternative routes of administration, and widespread availability of serum drug level measurements.

Mechanisms of Action

Digoxin is a complex agent in that its mode of action, inhibition of Na^+,K^+-ATPase, affects multiple cellular processes, including several critical to cardiac myocyte function.[1] Digoxin is also extremely toxic, not surprising in view of its apparent role in nature as a toxin evolved by plants to kill mammals. Cardiac glycosides bind to a specific high-affinity site on the extracytoplasmic face of the alpha subunit of Na^+,K^+-ATPase, the enzymatic equivalent of the cellular "sodium pump." The affinity of the subunit for cardiac glycosides varies among species and among the three known mammalian subunit isoforms, each of which is encoded by a separate gene.[1]

Cardiac glycoside binding to and inhibition of the Na^+,K^+-ATPase sodium pump are reversible and entropically driven. Under physiologic conditions, these drugs preferentially bind to the enzyme after phosphorylation of a beta-aspartate on the cytoplasmic face of the alpha subunit, thus stabilizing what is known as the E2P conformation.[1,2] Extracellular K^+ promotes dephosphorylation at this site, resulting in a decrease in the cardiac glycoside–binding affinity for the enzyme.[2] This action presumably explains why increased extracellular K^+ tends to reverse some manifestations of digitalis toxicity.

Positive Inotropic Effect

Cardiac glycosides increase the velocity and extent of shortening of cardiac muscle, thereby resulting in an upward and leftward shift of the ventricular function curve (Frank-Starling) relating cardiac performance to filling volume or pressure. This process occurs in normal as well as failing myocardium and in atrial as well as ventricular muscle. The effect appears to be sustained for weeks or months without evidence of desensitization or tolerance.[3]

The positive inotropic effect is caused by an increase in the availability of cytosolic Ca^{2+} during systole, thus increasing the velocity and extent of sarcomere shortening. The increase in intracellular $[Ca^{2+}]$ is a consequence of cardiac glycoside–induced inhibition of sarcolemmal Na^+,K^+-ATPase.[1,2] Inhibition of Na^+,K^+-ATPase causes an increase in intracellular Na^+, which is then exchanged for extracellular Ca^{2+} through the Na^+/Ca^{2+} exchanger. The net effect of these adjustments is to increase intracellular Ca^{2+} during systole, which increases systolic function.

In part because cardiac glycosides produce an increase in contractile function without increasing the heart rate, the positive inotropic effects are more energetically efficient than the effects of beta-adrenergic agonists and higher doses of phosphodiesterase inhibitors.[4] This difference may be one of the reasons why low-dose digoxin does not increase mortality in patients with HF.[5]

Sympatholytic Effects

Na^+,K^+-ATPase is involved in baroreflex afferent signaling and may be upregulated in the carotid sinus in HF.[6] Decreased baroreflex control is one of the mechanisms responsible for an increase in generalized and cardiac adrenergic activity in HF.[6] Inhibition of Na^+,K^+-ATPase by ouabain modulates baroreflex function toward normal in animal models of HF,[6] which is likely to be the mechanism by which cardiac glycosides inhibit adrenergic activity in HF.

Electrophysiologic Effects

Cardiac glycosides have complex electrophysiologic effects that are a combination of indirect, parasympathetic, and direct effects on specialized cardiac pacemaker and conduction tissues. At low to moderate therapeutic serum concentrations (0.5 to1.9 ng/mL), digoxin usually decreases automaticity and increases maximal diastolic resting membrane potential in atrial and atrioventricular (AV) nodal cells as a result of augmented vagal tone and decreased sympathetic nervous system activity. These effects are accompanied by prolongation of the effective refractory period and decreased AV nodal conduction velocity. At higher, toxic digoxin levels or in the presence of underlying disease, patients are susceptible to sinus bradycardia or arrest, prolongation of AV conduction, or heart block. At toxic levels, cardiac glycosides can also increase sympathetic nervous system activity, potentially contributing to the generation of arrhythmias.

Increased intracellular Ca^{2+} loading and increased sympathetic tone both contribute to an increased rate of spontaneous (phase 4) diastolic depolarization and also to delayed afterdepolarizations that may reach threshold and generate propagated action potentials. The combination of increased automaticity and depressed conduction in the His-Purkinje network predisposes to arrhythmias, including ventricular tachycardia and fibrillation. Data from the Digitalis Investigation Group (DIG) Trial[7] suggest that the increase in ventricular arrhythmia manifested in chronic HF as an increase in sudden death extends down to digoxin serum levels of 1.0 ng/mL, because higher concentrations were associated with an increase in mortality.

Pharmacokinetics and Dosing

Orally administered digoxin is variably absorbed, depending on the preparation, but Lanoxin is 60% to 80% absorbed. Digoxin is approximately 25% protein bound in plasma, has a large volume of distribution (4 to 7 L/kg), and crosses both the blood-brain barrier and the placenta. Digoxin is eliminated primarily by renal mechanisms, both glomerular filtration and tubular secretion. Tubular excretion is through the energy-dependent membrane-bound efflux pump/transport enzyme, P-glycoprotein, which is modulated by many other drugs. Digoxin is largely excreted in the urine unchanged, with a clearance rate proportional to the GFR, which results in the excretion of approximately one third of body stores daily. The half-life for digoxin elimination of 36 to 48 hours in patients with normal or near-normal renal function permits once-daily or every-other-day dosing.[8] In the presence of an elevated blood urea nitrogen/creatinine ratio (“prerenal azotemia”), digoxin clearance more closely parallels urea clearance, indicating that under these circumstances, some of the drug filtered through the glomerulus undergoes tubular reabsorption.[8] In patients with HF, increased cardiac output and renal blood flow in response to treatment with vasodilators or sympathomimetic agents may increase renal digoxin clearance and necessitate dosage adjustment.

Digoxin can be loaded at a dose of 0.75 to 1.25 mg orally (or intravenously at doses 25% lower) over a 24-hour period in three to four divided doses and then given at a maintenance dose, or a daily oral maintenance dose of 0.0625 to 0.25 mg can be started, depending on renal function, body size, and the presence or absence of co-administered drugs causing pharmacokinetic interactions. In the absence of loading doses, nearly steady-state blood levels are achieved in four to five half-lives, or about 1 week after initiation of maintenance therapy if normal renal function is present. If given intravenously, administration should be carried out over at least 15 minutes to avoid vasoconstrictor responses to a more rapid injection. Intramuscular digoxin is absorbed unpredictably, causes local pain, and is not recommended.

Patients with HF usually have a reduced volume of distribution and reduced renal function, and both

may be influenced by other treatment and by the ebb and flow of HF. Although nomograms on digoxin dosing have been published, these nomograms should not be used in patients with HF because of the narrow therapeutic index and the unpredictability of the numerous factors that can alter digoxin pharmacokinetics. Instead, patients should be started on a dose as just described and trough levels (see later) measured 1 to 2 weeks later and at frequent intervals (every 1 to 3 months) thereafter.

Drug Interactions with Digoxin

Multiple drugs interact with digoxin at multiple levels, including reduced renal tubular excretion by drugs inhibiting P-glycoprotein renal tubular transport,[9] induction of gut P-glycoprotein, alterations in gut flora by antibiotics causing less gut metabolism of digoxin before absorption, displacement from plasma protein-binding sites, or reduction in renal function. The accompanying table provides a partial list of these interactions. Among these interactions are drugs that are routinely used in patients with HF, including carvedilol and amiodarone, in whose presence digoxin doses should be lowered.

Partial List of Drugs Interacting with Digoxin

Drug	Effect on Serum Level	Mechanism
Amiodarone	Increases	?Renal clearance
Verapamil	Increases	?Renal clearance
Nifedipine	Increases	?Renal clearance
Diltiazem	Increases	?Renal clearance
Quinidine	Increases	Displacement of protein binding ?Renal clearance
Propafenone	Increases	?Renal clearance
Captopril	Increases	? Renal clearance
Carvedilol	Increases	?Oral bioavailability
Spironolactone	Increases	?Renal clearance
Amiloride	Increases	?Renal clearance
Triamterene	Increases	?Renal clearance
Salbutamol (albuterol)	Decreases	Unknown
Macrolide antibiotics	Increases	Altered gut flora ?Renal clearance
Tetracycline	Increases	Altered gut flora
Indomethacin	Increases	?Renal clearance
Alprazolam	Increases	?Renal clearance
Itraconazole	Increases	?Renal clearance
Rifampin	Decreases	Induction of gut P-glycoprotein
Sucralfate	Decreases	Decreased gut absorption
Cholestyramine	Decreases	Decreased gut absorption
Cyclosporine	Increases	?Renal clearance
St. John's wort	Increases	?Renal clearance

Therapeutic Drug Monitoring

Digoxin has an extremely low therapeutic index, and its use should be carefully monitored by serum blood levels. The various clinical conditions and drug interactions that can alter digoxin's pharmacokinetics are also reflected in the serum digoxin level. As discussed earlier, on the basis of the dose range of the positive inotropic effects,[10] the neurohormonal inhibition effects,[11] and the DIG trial mortality data,[7] the optimal trough digoxin serum level is 0.5 to 1.0 ng/mL. This concentration range also should be used to control the ventricular rate response to atrial fibrillation in patients with HF, particularly because digoxin is not a very effective agent in this regard in the setting of high amounts of adrenergic activity.[12] Blood samples for measurement of serum digoxin levels should be taken at least 6 to 8 hours following the last digoxin dose, and patients should be instructed to take their digoxin in the evening so that any level determined during the day is a trough measurement.

Digitalis Toxicity

In patients with HF, overt clinical toxicity tends to emerge at serum concentrations greater than 2.0 ng/mL, but substantial overlap in serum levels exists among patients exhibiting symptoms and signs of toxicity and those with no clinical evidence of intoxication. Disturbances in cardiac impulse formation, conduction, or both are the hallmarks of digitalis toxicity. Among the common electrocardiographic manifestations are ectopic beats of AV junctional or ventricular origin, first-degree AV block, an excessively slow ventricular rate response to atrial fibrillation, or an accelerated AV junctional pacemaker. These manifestations may require only dosage adjustment and monitoring. Sinus bradycardia, sinoatrial arrest or exit block, and second- or third-degree AV conduction delay often respond to atropine, but temporary ventricular pacing is sometimes necessary and should be available.

Management

Oral potassium administration is often useful for atrial, AV junctional, or ventricular ectopic rhythms, even when the serum potassium is in the normal range, unless high-grade AV block is also present. However, [K^+] must be monitored carefully to avoid hyperkalemia, especially in patients with renal failure. Magnesium may be useful in patients with atrial fibrillation in an accessory pathway in whom digoxin administration has facilitated a rapid accessory pathway–mediated ventricular response; again, careful monitoring is required to avoid hypermagnesemia.[13] Neurologic or gastrointestinal complaints can also be manifestations of digitalis toxicity. Occasionally, gynecomastia results from digoxin administration, apparently because of the similarity of the glycoside structure to that of estrogens.

Antidigoxin Immunotherapy

Potentially life-threatening digoxin or digitoxin toxicity can be reversed by antidigoxin immunotherapy. Purified Fab fragments from digoxin-specific antisera are available at most poison control centers and larger hospitals in North America and Europe. Clinical experience in adults and children has established the effectiveness and safety of antidigoxin Fab in treating life threatening digoxin toxicity, including cases of massive ingestion with suicidal intent.[14] Doses of Fab are calculated by using a simple formula based on either the estimated dose of drug ingested or the total body digoxin burden and are administered intravenously in saline over 30 to 60 minutes.

Heart Failure with a Preserved Ejection Fraction

Michael R. Zile, Sheldon E. Litwin

Overview

Patients with heart failure can be divided into those with (1) heart failure with a *reduced* ejection fraction

(HFrEF) and (2) heart failure with a *preserved* ejection fraction (HFpEF). All these patients, regardless of ejection fraction status (EF value), have the clinical syndrome of heart failure (HF). In addition, many features are similar across the EF spectrum, including abnormal left ventricular (LV) filling dynamics, elevated LV diastolic pressure, LV systolic and diastolic dysfunction, neurohormonal activation, impaired exercise tolerance, frequent hospitalization, and reduced survival.[1-4] Patients with HFpEF have a devastating 5-year mortality rate (approaching 60%), costly morbidity (6-month hospitalization rate of 50%), and debilitating symptoms (reduced exercise capacity and maximum myocardial oxygen consumption [MVO_2; averaging 12 to 14 mL/g/min]).[5-9] Clear differences also are recognized between HFpEF and HFrEF. Compared to HF patients with a reduced EF, those with preserved EF are older and more likely to be female, although HFpEF occurs in both men and women throughout the fifth to ninth decades of life.[10] The most common antecedent disease leading to HFpEF is systolic hypertension, which is present in more than 85% of patients, whereas ischemic heart disease is less common than in HFrEF.[10] Differences in cardiovascular (CV) structure and function between HFpEF and HFrEF also are well recognized.[4,11-15] Patients with HFpEF have normal LV end-diastolic volume and normal (or near-normal) EF and stroke volume (at rest) and usually exhibit concentric remodeling of LV chamber and/or cardiomyocytes. Differences also are evident in the effects of pharmacologic treatment in patients with HFrEF versus HFpEF. Standard HF therapy shown to be effective in HFrEF has not been found to reduce morbidity or mortality associated with HFpEF, leaving a substantial area of unmet need (**Table 26.1**). This chapter summarizes the current understanding of the clinical, prognostic, pathophysiologic, and therapeutic information about patients with HFpEF and suggests where future advances are likely to occur.

Terminology

A variety of terms have been used to describe patients with the condition currently called *heart failure with a preserved ejection fraction* (HFpEF), including heart failure with a normal EF, heart failure with normal systolic function, diastolic heart failure, and diastolic dysfunction heart failure. Heart failure

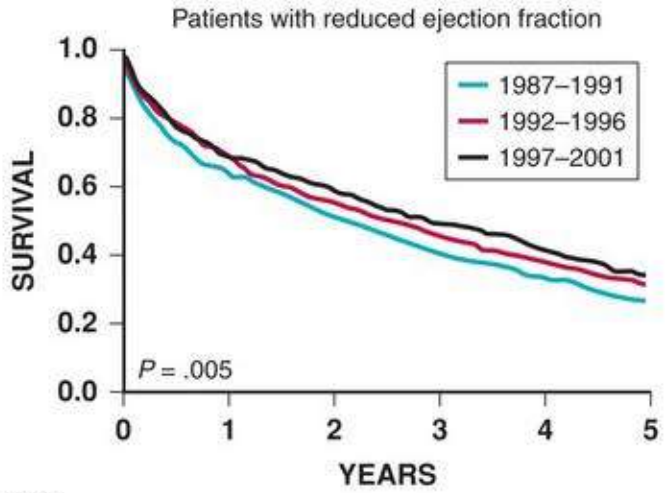
guidelines, recent publications, and this chapter use the term HFpEF. The rationale for this choice includes the following. The mean EF in normal populations depends somewhat on the method used to measure it, but this is generally agreed to be above 60%. The lower 95% confidence interval (CI) for EF is approximately 55%, whereas an EF greater than 50% often is used as a diagnostic criterion for HFpEF; the term HFpEF also has been applied to HF in some patients with EF in lower than normal range. For example, some randomized controlled trials (RCTs) have included patients with EF greater than 35%, 40%, or 45%. Therefore, because the term HFpEF has been applied to this broader spectrum of patients with HF, the term "heart failure with a normal EF" is less frequently used. Although patients with an EF below 50% clearly have significant abnormalities in systolic function, recent studies have shown that even patients with an EF above 50% may have midwall and/or longitudinal systolic dysfunction at rest and global systolic dysfunction during exercise. Therefore the term "heart failure with normal systolic function" is not an accurate description, even for patients with heart failure and EF above 50%.

Because patients with the clinical syndrome of HFpEF have abnormalities in LV diastolic function, systolic function, and vascular properties, the terms "diastolic heart failure" and "diastolic dysfunction heart failure," which single out the abnormalities in diastole, are now used less often. The term *diastolic dysfunction* refers to abnormalities in LV filling secondary to altered compliance, relaxation, and recoil. Abnormalities in diastolic function can occur in the presence or absence of a clinical syndrome of HF and with normal or abnormal systolic function. Whereas diastolic dysfunction describes abnormal LV performance, HFpEF describes a clinical syndrome of heart failure. The epidemiology of HFpEF is reviewed in **Chapter 21**.

Natural History

Mortality

The 5-year survival rate for all patients with heart failure, regardless of EF, is less than 50%. Although survival has improved over time for patients with HFrEF, it has not changed for patients with HFpEF[16] (**Fig. 26.1A, B**). Some epidemiologic studies have found that all-cause mortality for HFpEF is similar to that for HFrEF; other epidemiologic studies and RCTs suggest that all-cause mortality is somewhat lower in HFpEF than in HFrEF (**see Chapter 25**). For example, three RCTs have enrolled both patients with HFpEF and those with HFrEF, allowed direct comparisons, and demonstrated a lower mortality rate in HFpEF versus HFrEF.[17] Taken together, data from epidemiologic studies of HFpEF find that the annual mortality is approximately 10%, but RCTs in patients with HFpEF suggest that the annual mortality is about 5%. This apparent difference may be caused by the exclusion of patients with the comorbid conditions from the RCTs. However, the mortality rates found in patients with HFpEF are not caused solely by the comorbid diseases. In the RCTs, patients with HFpEF, who have antecedent and comorbid factors such as hypertension, coronary artery disease (CAD), and diabetes mellitus (DM), were found to have more than twice the mortality rate of patients with hypertension, CAD, or DM who do not have HFpEF[17] (**Fig. 26.1C, D**).



No. at risk

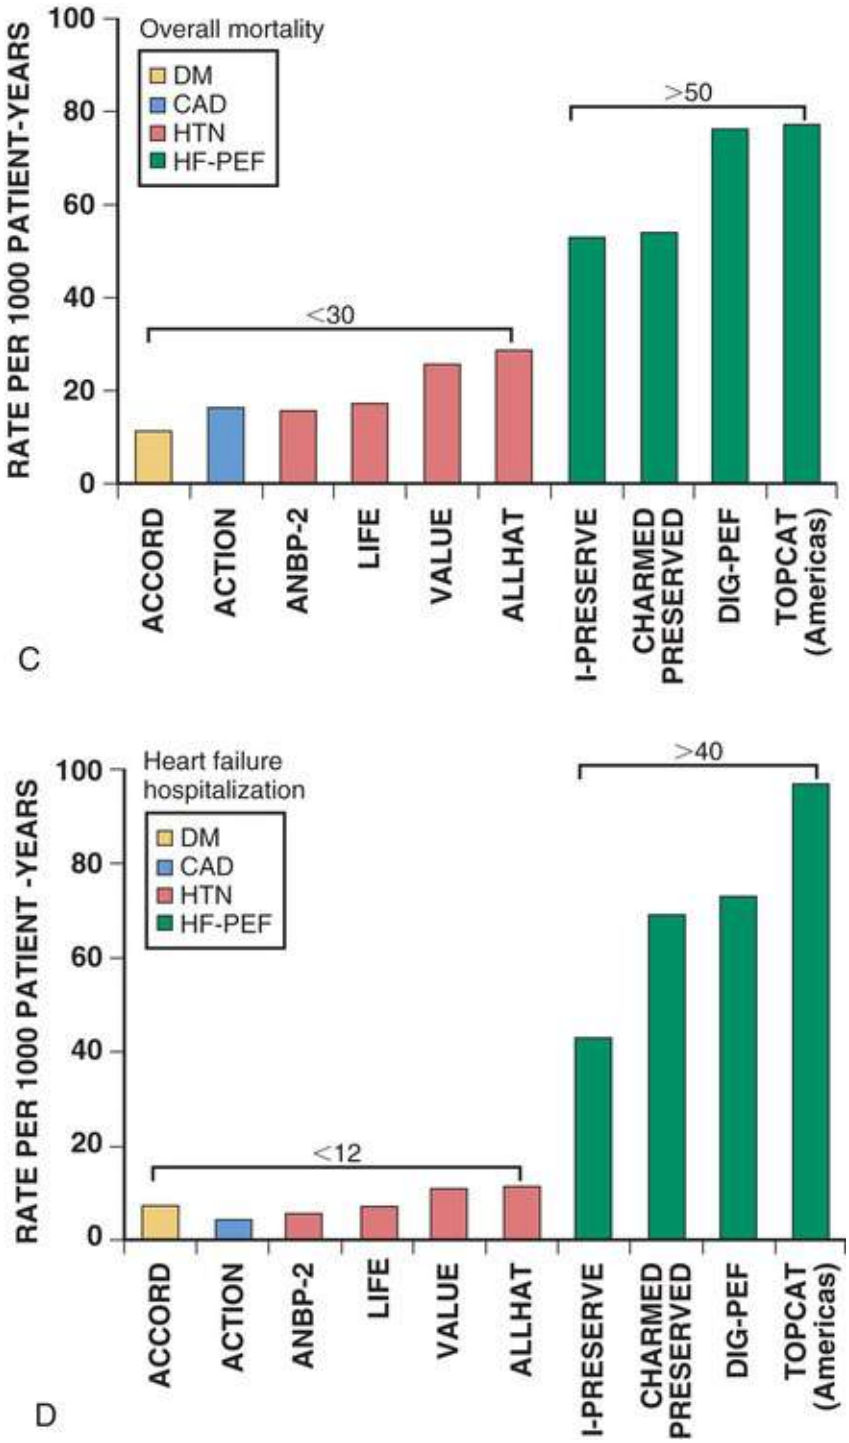

FIGURE 26.1 Mortality and morbidity in patients with HFrEF or HFpEF in epidemiologic studies versus randomized controlled trials (RCTs). **A, B,** In epidemiologic studies, 5-year survival rate for all patients with heart failure, regardless of EF, is less than 50%; survival has improved over time in HFrEF but has not changed in HFpEF. RCTs suggest that mortality is somewhat lower in HFpEF than in HFrEF. **C, D,** Mortality and morbidity in patients with HFpEF do not arise solely from the comorbid conditions. In the RCTs, among patients with HFpEF, who have antecedent and comorbid factors such as hypertension (HTN), coronary artery disease (CAD), and diabetes mellitus (DM), mortality rate and heart failure–related hospitalization rate are more than twice those in patients with HTN, CAD, or DM who do not have congestive heart failure. (**A, B,** From Owan TE et al: Trends in prevalence and outcomes of heart failure with preserved ejection fraction. N Engl J Med 2006;355:251; **C, D,** from Campbell R et al. What have we learnt about patients with heart failure and preserved ejection fraction (HF-PEF) from DIG-PEF, CHARM-Preserved, and I-Preserve? J Am Coll Cardiol 2012;60:2349.)

Mode of Death

Most of the deaths (50% to 70%) in patients with HFpEF are cardiovascular in nature, with 20%

resulting from heart failure and 35% from sudden death[18] (**eTable 26.1**). This distribution of modes of CV death is similar to that for HFrEF. The incidence of noncardiovascular deaths is significantly higher for HFpEF (30% to 40%) than for HFrEF (15%), reflecting the higher age and increased comorbidity in patients with HFpEF.[19] Additional content on the morbidity of HFrEF and conversion from HFpEF to HFrEF are presented in an online supplement for this chapter (Morbidity of HFpEF).

Pathophysiology

The pathophysiologic mechanisms that cause the development of HFpEF are reflected in changes in LV relaxation and filling, LV and left atrial (LA) structural remodeling and altered geometry, changes in LV and systemic and pulmonary vascular compliance, skeletal muscle and endothelial function, and proinflammatory and profibrotic signaling (**Table 26.2 and Figs. 26.2 and 26.3**).

Concentric remodeling
Left ventricular hypertrophy
Left Ventricular Function
Diastolic dysfunction: abnormal relaxation, decreased recoil, abnormal filling, decreased distensibility, increased diastolic pressure
Systolic dysfunction: abnormal midwall and long-axis shortening, decreased twist
Hemodynamic load
Increased afterload and filling load
Heterogeneity
Dyssynergy, dyssynchrony
Left atrial structure and function
Increased LA volume and stiffness, decreased LA reservoir function, passive conduit function, and active booster pump function
Ischemia
Subendocardial and microvascular disease, impaired coronary, pulmonary, and peripheral flow reserve
Rate and rhythm abnormalities
Chronotropic incompetence, atrial fibrillation, supraventricular tachycardia
Vascular dysfunction
Arterial stiffening, endothelial dysfunction
Cardiomyocyte
Abnormal calcium homeostasis (↑ diastolic calcium or ↓ rate of calcium reuptake → incomplete or impaired relaxation)
Sarcolemmal calcium channels (Na^+/Ca^{2+} exchanger and calcium pump)
Sarcoendoplasmic reticulum Ca^{2+}-ATPase (SERCA) abundance and function
Proteins modifying SERCA activity: phospholamban, calmodulin, calsequestrin abundance, and phosphorylation state
Sarcoplasmic reticulum calcium release channels
Energetics (↓ ATP or ↑ ADP slows actin-myosin cross-bridge release)
ADP/ATP ratio, ADP and P_i concentration, phosphocreatine shuttle function
Proteins regulating cross-bridge formation and calcium sensitivity
Troponin C: calcium binding
Troponin I: phosphorylation state
Cytoskeletal proteins
Microtubules (increased density) → ↑ diastolic stiffness
Titin isoforms (↑ noncompliant isoform and phosphorylation state) → ↑ diastolic stiffness
Extracellular Matrix
Collagen structure, geometry, content, collagen I/III ratio
Collagen homeostasis, synthesis, postsynthetic processing, post-translational cross-linking, degradation
Basement membrane proteins
Bioactive proteins and peptides: MMP/TIMP, SPARC, TGF-β
Fibroblast structure, function, phenotype
Myofibroblast transdifferentiation
Extracardiac
Extrinsic forces (RV-LV interaction and pericardial constraint)
Peripheral muscle and ergoreflex dysfunction
Pulmonary hypertension (secondary to chronic pulmonary venous hypertension)
Neurohormonal activation
Comorbid conditions (renal dysfunction, anemia, chronic lung disease)

ADP, Adenosine diphosphate; *ATP,* adenosine triphosphate; *MMP,* matrix metalloproteinase; *RV-LV,* right ventricle–left ventricle; *SPARC,* secreted protein, acidic and rich in cysteine [osteonectin]; *TGF,* transforming growth factor; *TIMP,* tissue inhibitor of metalloproteinase.

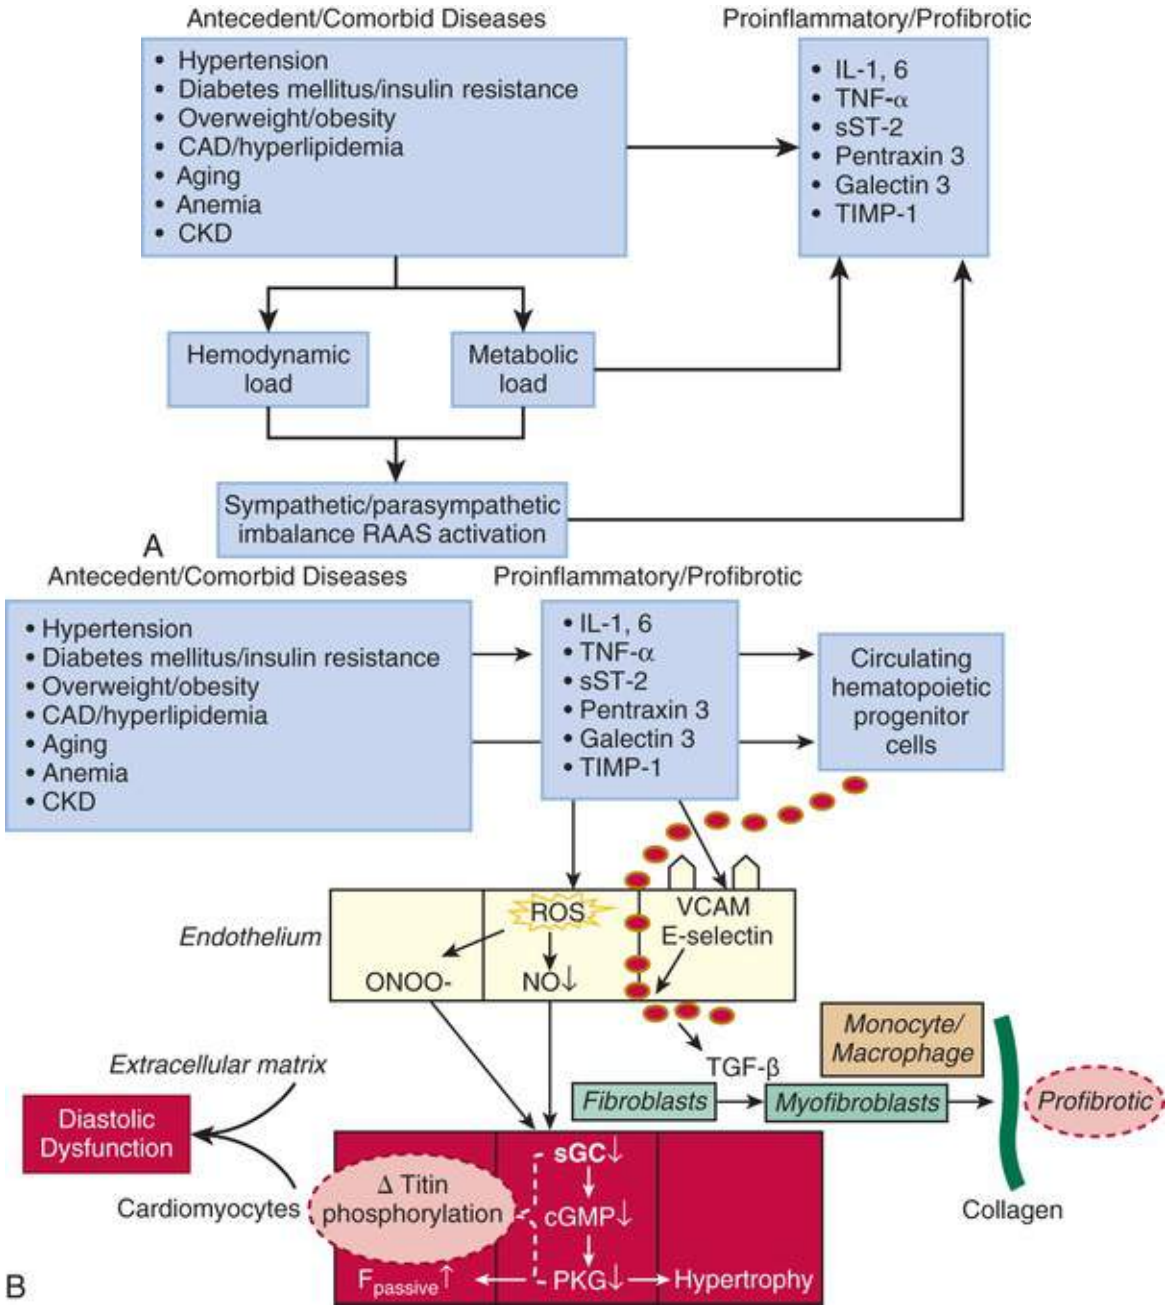

FIGURE 26.2 Pathophysiologic mechanisms underlying the development of HFpEF. **A,** Antecedent and comorbid diseases create both a hemodynamic and metabolic load that causes sympathetic and RAAS activation and parasympathetic suppression. These factors create a pro-inflammatory and profibrotic milieu as evidenced by changes in typical plasma biomarkers. CAD, Coronary artery disease; CKD, chronic kidney disease; TIMP, tissue inhibitor of metalloproteinase. **B,** Proinflammatory and profibrotic signaling effects recruitment of circulating hematopoietic progenitor cells, alters endothelial function, and increases reactive oxygen species, all of which in turn alters extracellular matrix (ECM) homeostasis that favors fibrosis and cardiomyocyte mechanisms including calcium and energetic regulation, myofilament structure and function, and intracellular signaling. In aggregate these changes in the ECM and cardiomyocyte result in abnormal diastolic function and promote the development of HFpEF. ROS, Reactive oxygen species; VCAM, vascular cell adhesion molecule. (Modified from Paulus WJ, Tschöpe C. A novel paradigm for heart failure with preserved ejection fraction: comorbidities drive myocardial dysfunction and remodeling through coronary microvascular endothelial inflammation. J Am Coll Cardiol 2013;62:263-71.)

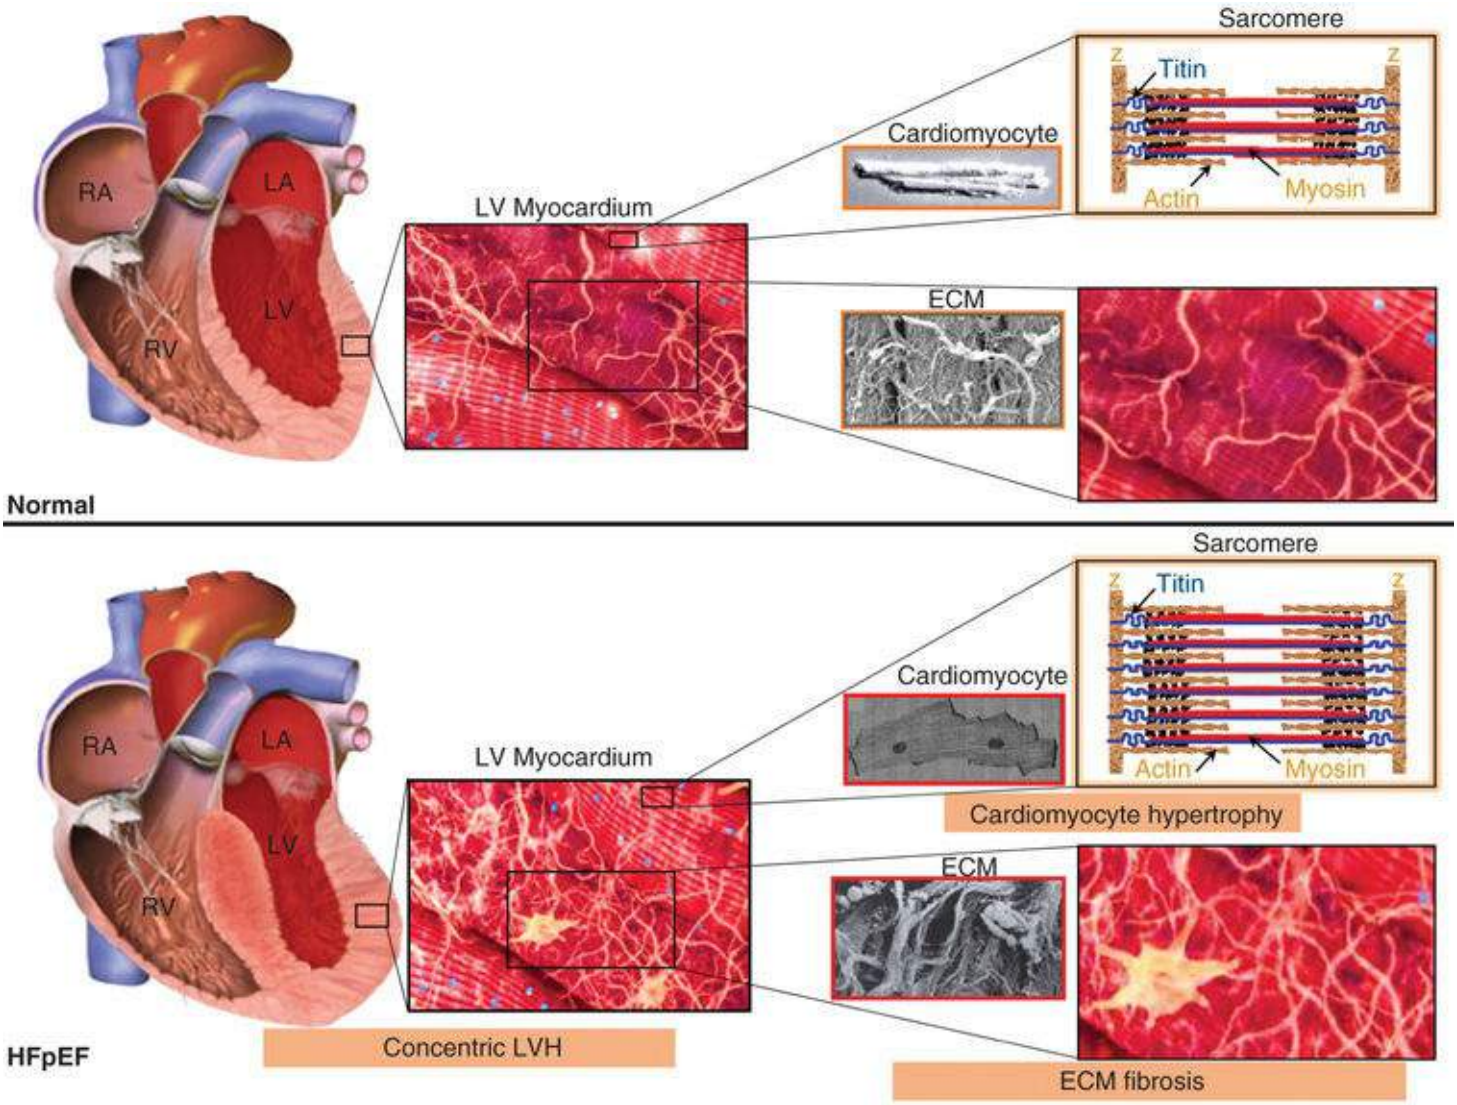

FIGURE 26.3 Ventricular, cellular, extracellular matrix (ECM), and molecular structural changes in patients with HFpEF. Compared with age- and gender-matched normal controls **(upper panel),** HFpEF patients **(lower panel)** are characterized frequently by concentric hypertrophy or remodeling at the LV and cardiomyocyte level. The left ventricle is increased in wall thickness with no change in volume; cardiomyocytes have increased diameter but no change in length. These structural cellular changes are accompanied by alterations in titin phosphorylation. In addition, there are structural changes in the ECM, including increased fibrillar collagen content, thickness, and number. These ECM structural changes are associated with alterations in fibroblast function that lead to interstitial fibrosis. *LVH,* Left ventricular hypertrophy. (Modified from Aurigemma GP, Zile MR, Gaasch WH. Contractile behavior in the left ventricle in diastolic heart failure: with emphasis on regional systolic function. Circulation 2006;113:296; and Zile MR et al. Myocardial stiffness in patients with heart failure and a preserved ejection fraction: contributions of collagen and titin. Circulation 2015;131:1247-59.)

Normal Diastolic Properties

Normal diastolic function allows the ventricle to fill adequately during rest and exercise, without an abnormal increase in LA pressure (**see Chapter 21**). The phases of diastole are *isovolumic pressure decline* and *filling*. The filling phase is divided into early rapid filling, diastasis, and atrial systole. *Early rapid filling* contributes 70% to 80% of LV filling in normal individuals. This contribution diminishes with age and various disease states. Early diastolic filling is driven by the LA-to-LV pressure gradient, which depends on a complex interplay of factors: myocardial relaxation, LV elastic recoil, LV diastolic stiffness, LA pressures, ventricular interaction, pericardial constraint, pulmonary vein properties, and mitral orifice area. *Diastasis* occurs in mid-diastole, when the LA and LV pressures usually are almost

equal. It contributes less than 5% of the LV filling, and its duration shortens with tachycardia. In normal individuals, *atrial systole* contributes 15% to 25% of LV diastolic filling without raising the mean LA pressure. This contribution depends on the PR interval, atrial inotropic state, atrial preload, atrial afterload, autonomic tone, and heart rate.

Left Ventricular Relaxation

LV relaxation is an active, energy-dependent process that begins with the decay of force-generating capacity, follows the completion of the ejection phase of systole, and continues through isovolumic pressure decline and the rapid filling phase. LV filling depends both on active relaxation and on the recoil/suction that results from the release of potential energy stored during systole by contraction. Thus, blood is effectively "pulled" into the left ventricle.[20] In normal hearts, over a range of normal heart rates, relaxation and recoil are adequate to allow LA pressures to remain normal. In addition, catecholamine-induced enhancement of relaxation and recoil during exercise lowers LV pressures in early diastole, thereby increasing the LA-to-LV pressure gradient without increasing LA pressures, as well as enhancing filling during exercise. By contrast, in patients with HFpEF, relaxation and recoil are abnormal at rest and are not enhanced during increased HR or exercise. As a result, filling can be maintained only by increased LA pressure; blood must be "pushed" into the left ventricle.

Isovolumic Pressure Decline.

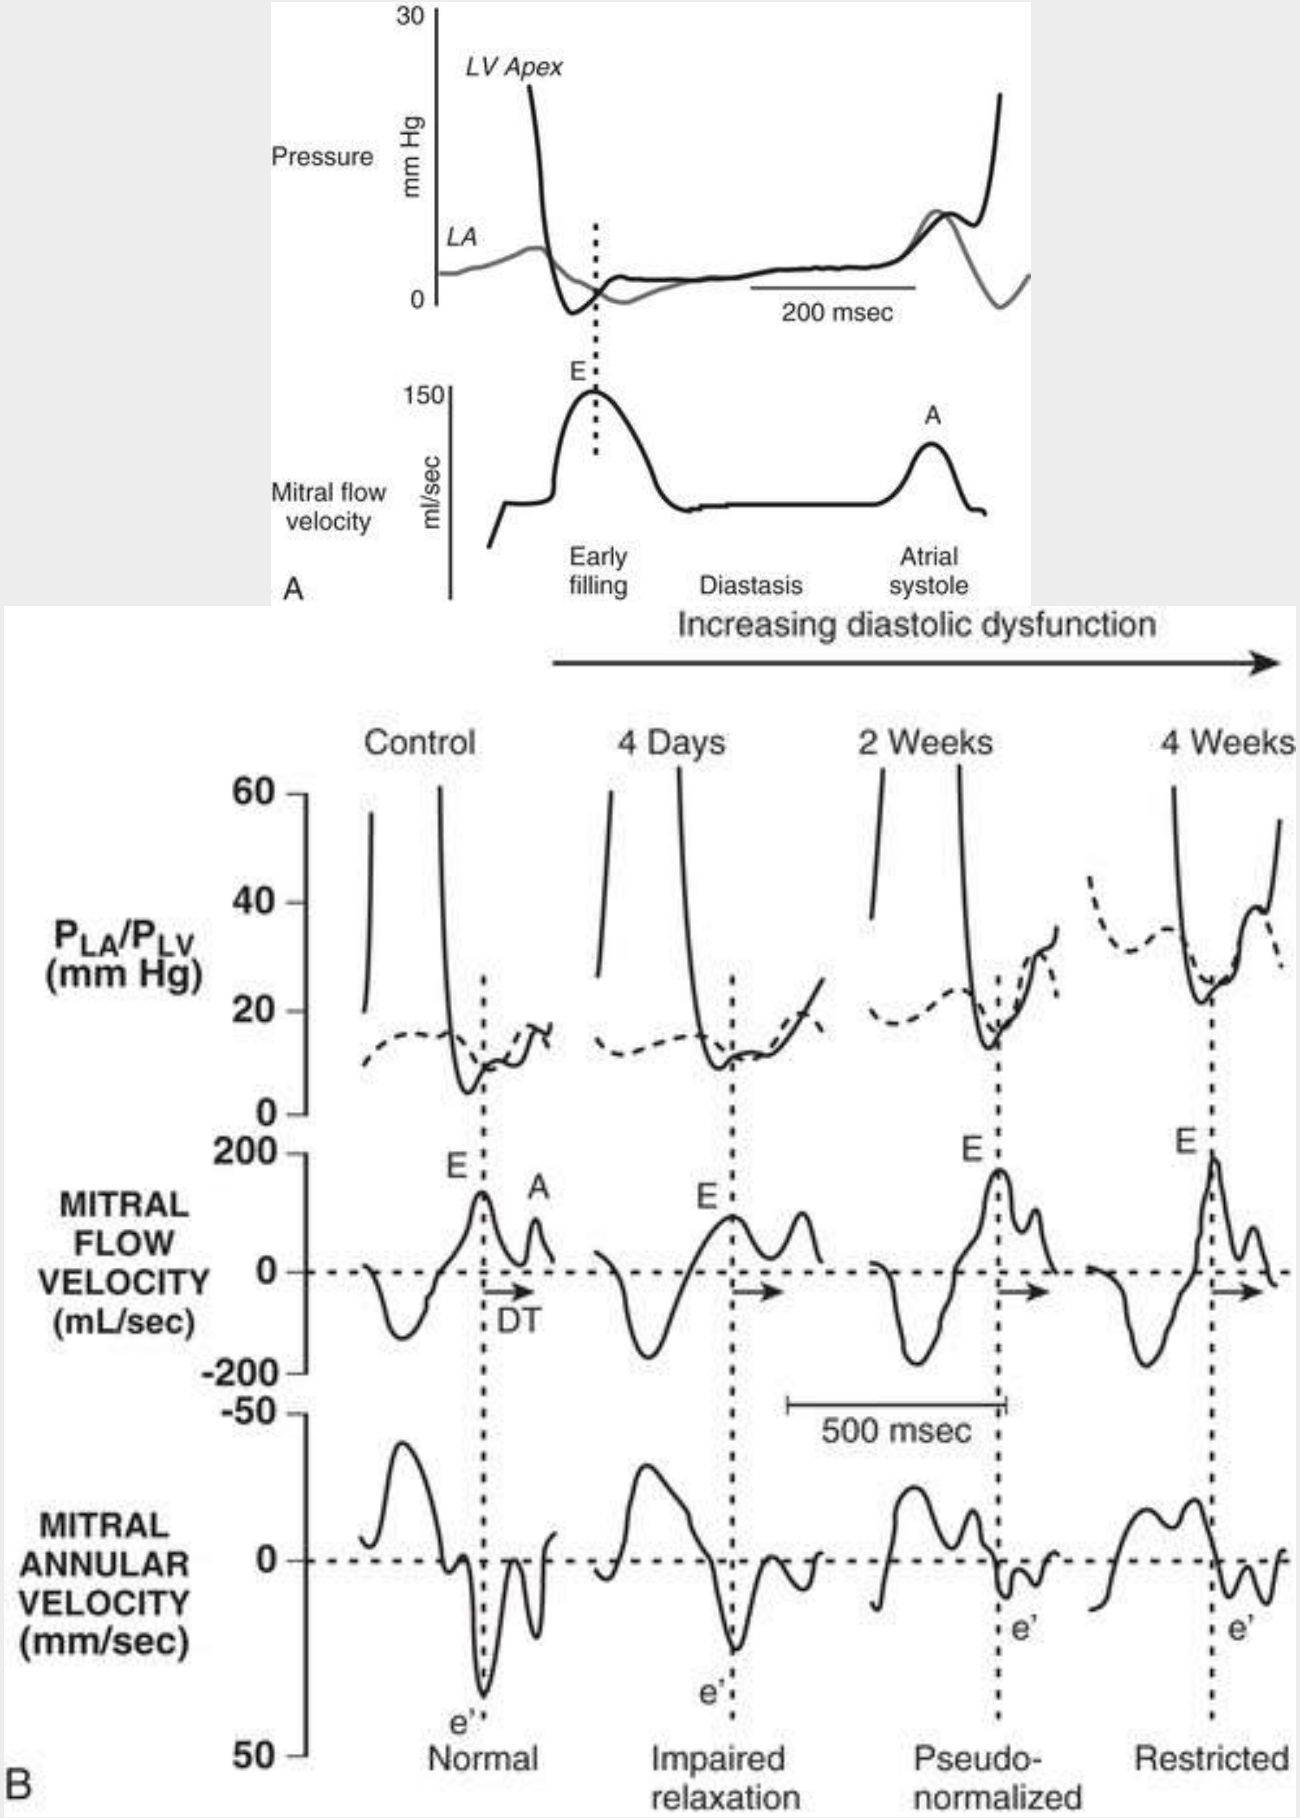
The time course of isovolumetric pressure decline has been quantitatively described by the peak rate of pressure fall (dP/dt_{min}) and the time constant τ (tau) of the exponential fall in LV isovolumetric pressure. Each of these requires that LV pressure be measured using a micromanometer-tipped catheter. dP/dt_{min} measures the rate of pressure decline at a single point in time, is strongly influenced by the LV pressure at the time of aortic valve closure, and therefore, as with all indices of diastolic function, is afterload dependent. Patients with HFpEF have a larger dP/dt_{min}, signifying that relaxation rate is decreased.

The time constant τ describes the rate of LV pressure decline throughout isovolumic relaxation. Pressure (P) and time (t) data during the period from end-systole (aortic valve closure) to the onset of LV filling (mitral valve opening) are fit to an exponential equation such as the following: LV pressure = $P_0 e^{-t/\tau}$, where P_0 is LV pressure at end-ejection and τ is the exponential time constant. The larger the value of τ, the longer it takes for the LV pressure to fall and the more impaired is relaxation. A normal value for τ is less than 40 milliseconds in most age-groups, suggesting that relaxation is nearly complete by 3.5 × τ (<140 milliseconds).

The *isovolumic relaxation time* (IVRT) also can be estimated by echo techniques as the time between aortic valve closure and mitral valve opening. Although less precise than τ, IVRT is useful in the noninvasive assessment of diastolic properties. However, IVRT depends not only on the rate of LV relaxation but also on the aortic pressure at the time of aortic valve closure and the LA pressure at mitral valve opening. Thus, IVRT can be increased by an elevation of aortic pressure or decreased by an increase in LA pressure. The time course of LV pressure decline during isovolumetric relaxation can also be characterized using noninvasive Doppler measurement of the velocity of a regurgitant jet across the mitral valve. In this method the modified Bernoulli equation is used to approximate LV pressure during isovolumetric relaxation, allowing calculation of the maximum rate of LV pressure decline and the exponential time constant.

Recoil and Left Ventricular Filling.

During systole, potential energy is stored in the elastic elements of the cardiomyocytes and extracellular matrix (ECM).[20] The elastic elements are compressed and twisted during systolic contraction. During relaxation, this potential energy is released as the elastic elements recoil and return to their original length and orientation. Recoil causes LV pressure to fall rapidly during isovolumetric relaxation. Furthermore, for the first 30 to 40 milliseconds after mitral valve opening, the relaxation of LV wall tension normally is rapid enough to cause LV pressure to continue to decline despite an increase in LV volume. This fall in LV pressure produces an early diastolic pressure gradient from the left atrium that extends to the LV apex (**eFig. 26.1A**). This accelerates blood out of the left atrium and produces rapid early diastolic flow that quickly propagates to the apex. Because the diastolic intraventricular pressure gradient pulls blood to the apex, it can be considered a measure of LV suction. It is reduced in both experimental models and in patients with ischemia, hypertrophic cardiomyopathy,[21] and heart failure, including HFpEF.[22-24] The intraventricular pressure gradient can be measured noninvasively from the diastolic spatial-temporal velocity map obtained using apical color M-mode echocardiography.



EFIGURE 26.1 **A,** LV filling dynamics recorded in a conscious animal. **B,** Recordings in a conscious animal of pressures in the apex of the left ventricle (P_{LV}) and left atrium (P_{LA}) and the mitral valve flow velocity. The late diastolic mitral flow velocity (A), peak early diastolic flow velocity (E), peak early mitral annular velocity (e'), and E deceleration time (DT) are shown. (From Little WC, Oh JK. Echocardiographic evaluation of diastolic function can be used to guide clinical care. Circulation 2009;120:802.)

Because the LV apex remains fixed during the cardiac cycle, the *mitral annular velocity* provides a measure of long-axis lengthening rate.[25] Under normal conditions, peak early diastolic mitral annular velocity (e′) occurs coincidentally with or before the mitral peak early diastolic flow velocity (E)[26,27] (**eFig. 26.1B**). This is a manifestation of the symmetric expansion of the left ventricle in early diastole as blood moves rapidly to the LV apex in response to a progressive pressure gradient from the left atrium to the LV apex. In addition, the rapid recoil of the mitral annulus and valve into the left atrium early in diastole relocates blood from the left atrium into the left ventricle. Under normal circumstances, both E and e′ respond to changes in the LA-to-LV pressure gradient. For example, both E and e′ normally increase in response to increased volume load and exercise.[27-29]

Determinants of Left Ventricular Relaxation

LV relaxation is under the control of multiple factors that include hemodynamic load (early diastolic load and afterload), myofiber inactivation (see later discussion of cellular determinants), and the uniformity of the distribution of load and inactivation in space and time (dyssynchrony, dyssynergy, treppe). Each of these determinants may affect indices of diastolic relaxation, recoil, and filling.

Hemodynamic Load

Both isovolumic pressure decline and early filling are affected by afterload (LV systolic stress). An increase in LV systolic stress results in a delay in and slowed rate of pressure decline and early filling. Increases in systolic load may have different effects, depending on when the load is imposed during systole. Increases in LV pressure late in systole hasten the onset of LV relaxation, but relaxation occurs at a slower rate (increased τ). Increases in LV pressure late in systole occur with aging because of age-related vascular stiffening, which alters the timing of reflected pressure wave in the vascular tree so that the reflected wave arrives in late systole rather than diastole. In clinical practice an acute increase in blood pressure either at rest or during exercise will impair ejection, slow pressure decline, prolong time to complete relaxation, and reduce recoil. These changes in relaxation decrease the LA-to-LV gradient, decrease early filling, and result in increased LV diastolic and LA pressure. In addition, the load present at mitral valve opening (LA-to-LV gradient, i.e., early diastolic load) affects early LV filling.

Heterogeneity

Synchrony (timing of relaxation of the different myocardial segments) and *synergy* (extent to which myocardial segments relax) will enhance LV relaxation, whereas *dyssynchrony* or *dyssynergy* (e.g., caused by infarction, ischemia, asymmetry of hypertrophy, or conduction abnormalities) will impair global LV relaxation. Dyssynchrony, measured using a variety of echocardiographic measurements, may be present in patients with HFpEF, particularly those with left bundle branch block (LBBB) or right ventricular (RV) pacing. Whether or not treatment aimed at resynchronization (i.e., cardiac resynchronization therapy [CRT]) will effect clinical improvement in patients with HFpEF has not been fully investigated.

Cellular Mechanisms

Myofiber inactivation refers to the many cellular processes that ultimately influence the process by which the left ventricle, its constitutive cardiomyocytes, and individual sarcomeres return to a normal end-diastolic length with minimum cross-bridge cycling and low force generation. To accomplish this state of

complete relaxation requires (1) calcium (Ca^{2+}) resequestration into the sarcoplasmic reticulum, followed by calcium extrusion into the extracellular space; (2) availability of sufficient adenosine triphosphate (ATP); (3) normal myofilament function; and (4) normal elastic properties of the cardiomyocyte and the ECM. Additional material on this topic is presented in an online supplement for this chapter (Cellular Mechanisms of Myocardial Relaxation).

Prevalence and Prognosis for Abnormal Relaxation

Impaired relaxation is present in HFpEF and contributes to the development of elevated LA pressure at rest. The rate of relaxation is further impaired during exercise and hemodynamic stress. Any factor that shortens the diastolic filling period (prolonged contraction or long PR interval) will worsen the effect of impaired relaxation on LV diastolic pressures during filling and thus affect the mean LA pressure needed to fill the left ventricle. Whether therapies to enhance relaxation directly and specifically can be developed, and whether such therapies will relieve symptoms, remains an area of active investigation.

Left Ventricular Diastolic Stiffness, Compliance, and Distensibility

Methods of Measurement

The passive characteristics of the left ventricle during diastole can be described by the passive *diastolic pressure-volume relationship* (DPVR).[20] Optimally, this relationship should be constructed from points that are obtained after relaxation is complete and at slow filling rates so that viscous effects are not present. In practice, this can be approximated using points obtained late in diastole, when relaxation is assumed to be complete, by correcting pressure data affected by incomplete relaxation or by using data from variably loaded beats at end-diastole. The resultant DPVR is nonlinear and can be approximated by an exponential function. *Left ventricular stiffness* is defined as the ratio of LV diastolic pressure and LV diastolic volume (LV dP/dV) at any given LV diastolic volume. *Left ventricular compliance* is the reciprocal of stiffness (LV dV/dP). Because the DPVR can be approximated as an exponential, stiffness will increase as the left ventricle fills to higher LV diastolic volumes; thus, as the left ventricle fills, it becomes stiffer. *Left ventricular diastolic distensibility* is defined as the end-diastolic pressure required to distend the left ventricle to an end-diastolic volume. Patients with HFpEF have reduced distensibility, indicated by a normal or reduced end-diastolic volume and an elevated end-diastolic pressure.[2,30] Because the DPVR can be approximated by an exponential function, its position and shape can be described by the constants within an equation such as $P = \alpha \times e^{\beta V}$, where α and β represent the "stiffness constants." It should be recognized that β does not indicate stiffness but instead describes how rapidly stiffness increased with increases in volume ($\beta = [dP/dV]/V$). The "stiffness constants" derived in this fashion can be used to compare passive diastolic properties in different patients or patient groups. The end-diastolic pressure-versus-volume ratio (instantaneous operative distensibility) also can be used in comparing patients or patient groups. Patients with HFpEF have abnormal DPVR with elevated β and abnormal distensibility (**Fig. 26.4**).

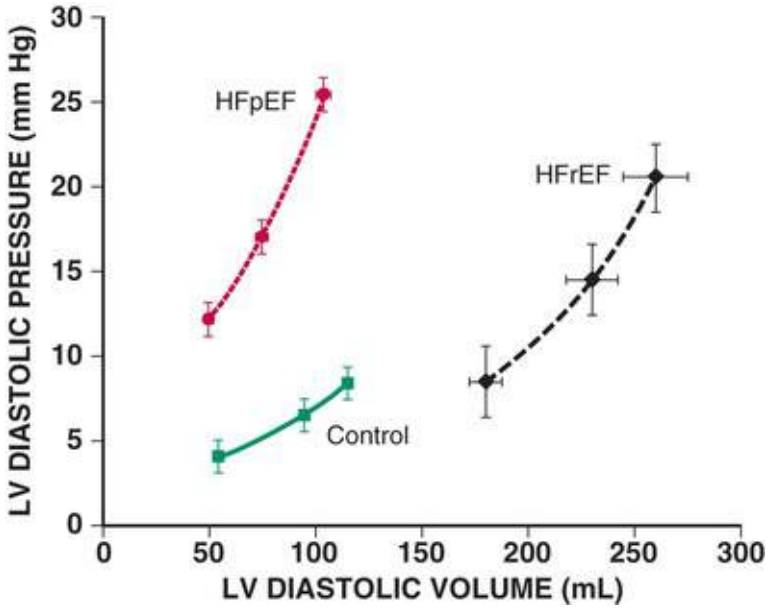


FIGURE 26.4 Difference in diastolic chamber distensibility in patients with HFpEF (in *red*) versus HFrEF (in *black*) versus age- and gender-matched referent controls (in *green*). Compared with that in the controls, the diastolic pressure-volume relationship (DPVR) in patients with HFpEF is shifted upward and to the left, such that for any given LV volume, pressure is higher in HFpEF, indicating decreased distensibility (increased stiffness). By contrast, in patients with HFrEF, the DPVR is shifted to the right, indicating increased distensibility. (From Zile MR, Baicu CF, Gaasch WH. Diastolic heart failure—abnormalities in active relaxation and passive stiffness of the left ventricle. N Engl J Med 2004;350:1953; and Aurigemma GP, Zile MR, Gaasch WH. Contractile behavior in the left ventricle in diastolic heart failure: With emphasis on regional systolic function. Circulation 2006;113:296.)

Patients with HF and an increased LV diastolic pressure can be divided into four groups defined by patterns of DPVR (**Fig. 26.5**). DPVR in patients with HFrEF typically is characterized by the graphed curve D in the figure, in which eccentric remodeling results in a shift of the DPVR to the right, representing an increase in distensibility. It should be recognized that although the ventricle is more distensible, the LV end-diastolic volume in these patients typically is very large, and the end-diastolic stiffness in the operating region is high. DPVR in patients with HFpEF may be characterized by graphed curves A to C. In **Fig. 26.5C**, pericardial constraint causes a parallel upward shift in DPVR. In patients with HFpEF, when relaxation is markedly prolonged and diastole is abbreviated (**Fig. 26.5A**), LV diastolic pressure falls throughout diastole but remains increased. In the most prevalent pattern in HFpEF (**Fig. 26.5B**), DPVR is shifted upward and to the left, indicating reduced distensibility, where LV pressure is increased at any LV volume.

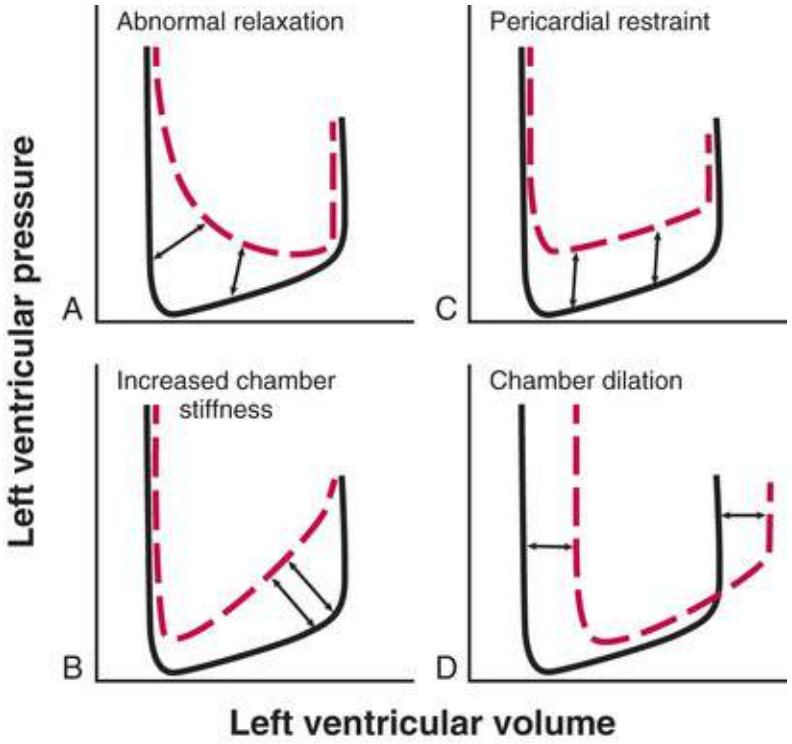

FIGURE 26.5 Mechanisms that result in increased LV diastolic pressure. Among patients with heart failure and an increased LV diastolic pressure, four patterns of diastolic pressure-volume relationship (DPVR) can be discerned. DPVR in patients with HFpEF may be characterized by graphed curves **A** and **B.** In the most prevalent pattern in HFpEF, represented by curve **B,** the DPVR is shifted upward and to the left, indicating reduced distensibility, where LV pressure is increased at any LV volume. In patients with HFpEF, when relaxation is markedly prolonged and diastole is abbreviated, as shown in curve **A,** LV diastolic pressure falls throughout diastole but remains increased. In curve **C,** pericardial constraint causes a parallel upward shift in the DPVR. DPVR in patients with HFrEF typically is characterized by curve **D,** in which eccentric remodeling results in a shift of the DPVR to the right, representing an increase in distensibility. It should be recognized that although the ventricle is more distensible, the end-diastolic volume in these patients typically is very large and the end-diastolic stiffness in the operating region is high. (From Carroll JD, Lang RM, Neumann AL, et al. The differential effects of positive inotropic and vasodilator therapy on diastolic properties in patients with congestive cardiomyopathy. Circulation 1986;74:815.)

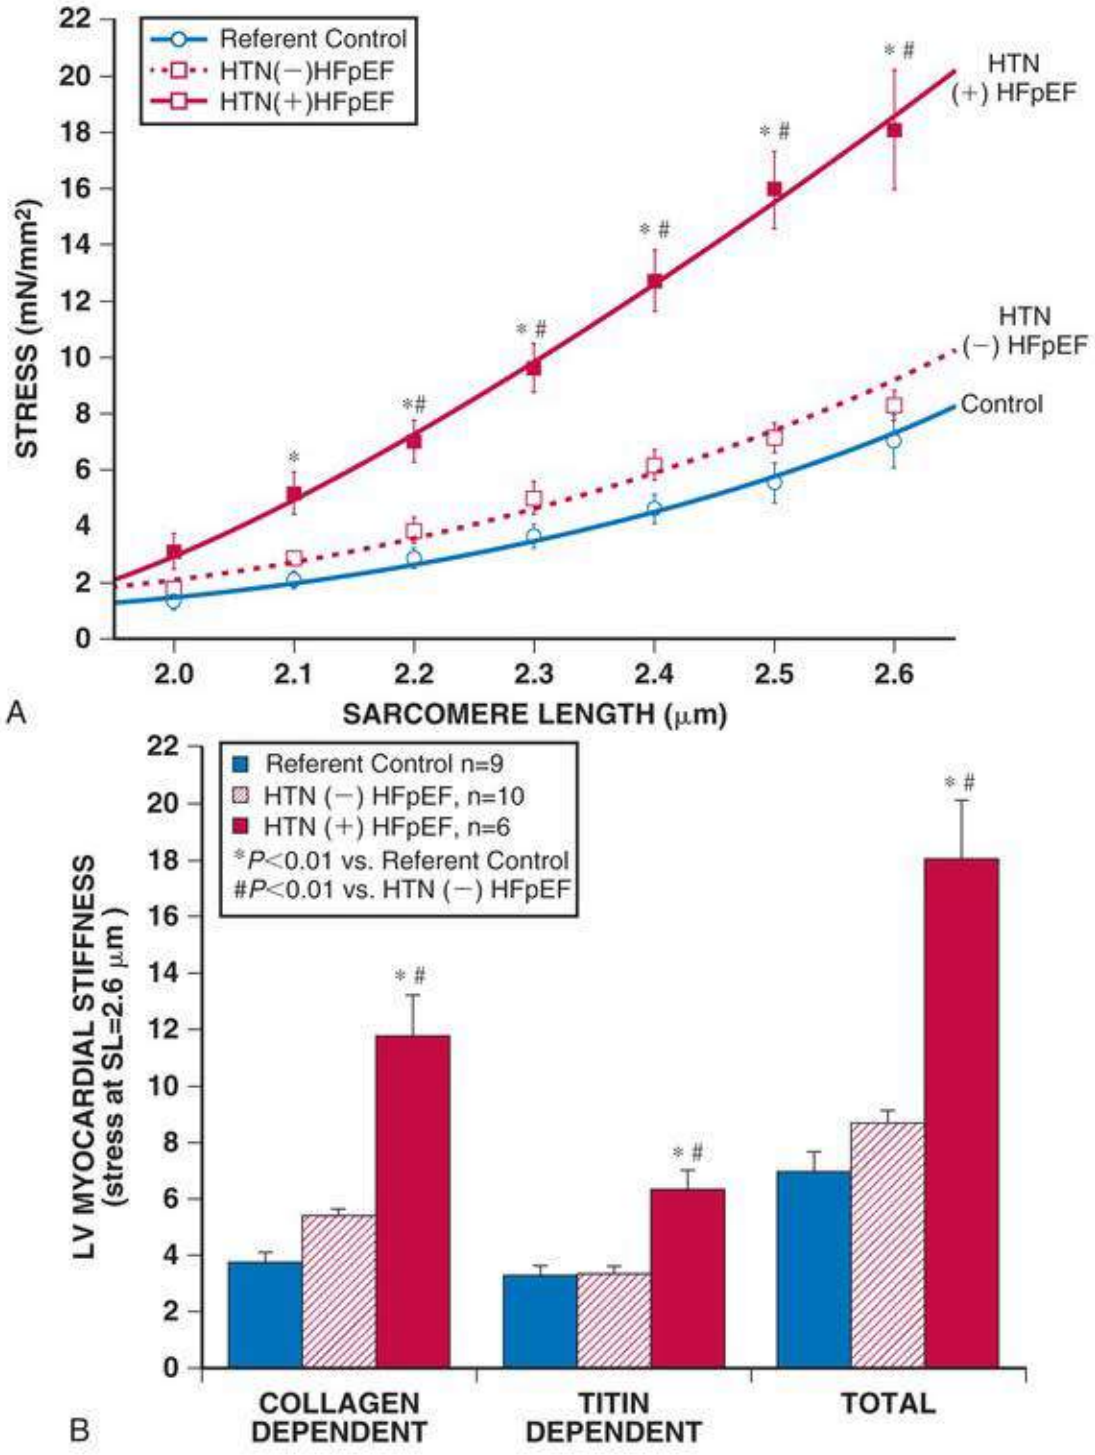
Determinants of Left Ventricular Pressure-versus-Volume Relationship

Two of the determinants associated with an upward and leftward shift of the DPRV in patients with HFpEF are (1) the presence of LV and cardiomyocyte concentric remodeling and hypertrophy and (2) changes in the material properties of myocardial muscle itself (i.e., myocardial stiffness). *Myocardial diastolic stiffness* can be determined by assessing the myocardial diastolic LV stress-versus-strain relationship. The stress-strain relationship represents the resistance of the myocardium to *stretch* (increase in length) when subjected to *stress* (distending force). Calculation of stress requires the use of a geometric model of the left ventricle, and the calculation of strain requires assumption of the unstressed LV volume, which cannot be directly measured in the intact circulation. In addition to these potential theoretical limitations, these calculations require accurate measurements over a wide range of LV pressures, volumes, dimensions, and wall thicknesses. These challenges in determining myocardial stress-strain relationships have limited their clinical application, but they remain important to basic and translational research efforts.

Recently, techniques have been developed that allow assessment of myocardial stiffness and determination of the mechanisms that alter myocardial stiffness to be examined using LV myocardial biopsies in patients with clinical heart disease and patients with HFpEF. These translational studies examined the contribution that changes in the cardiac ECM such as fibrillar collagen, cardiomyocyte

cellular structure and processes such as calcium homeostasis and energetics, and myofilament and cytoskeletal proteins such as titin and microtubules make to the abnormalities in myocardial stiffness present in patients with HFpEF[31-33] (**Fig. 26.6**).



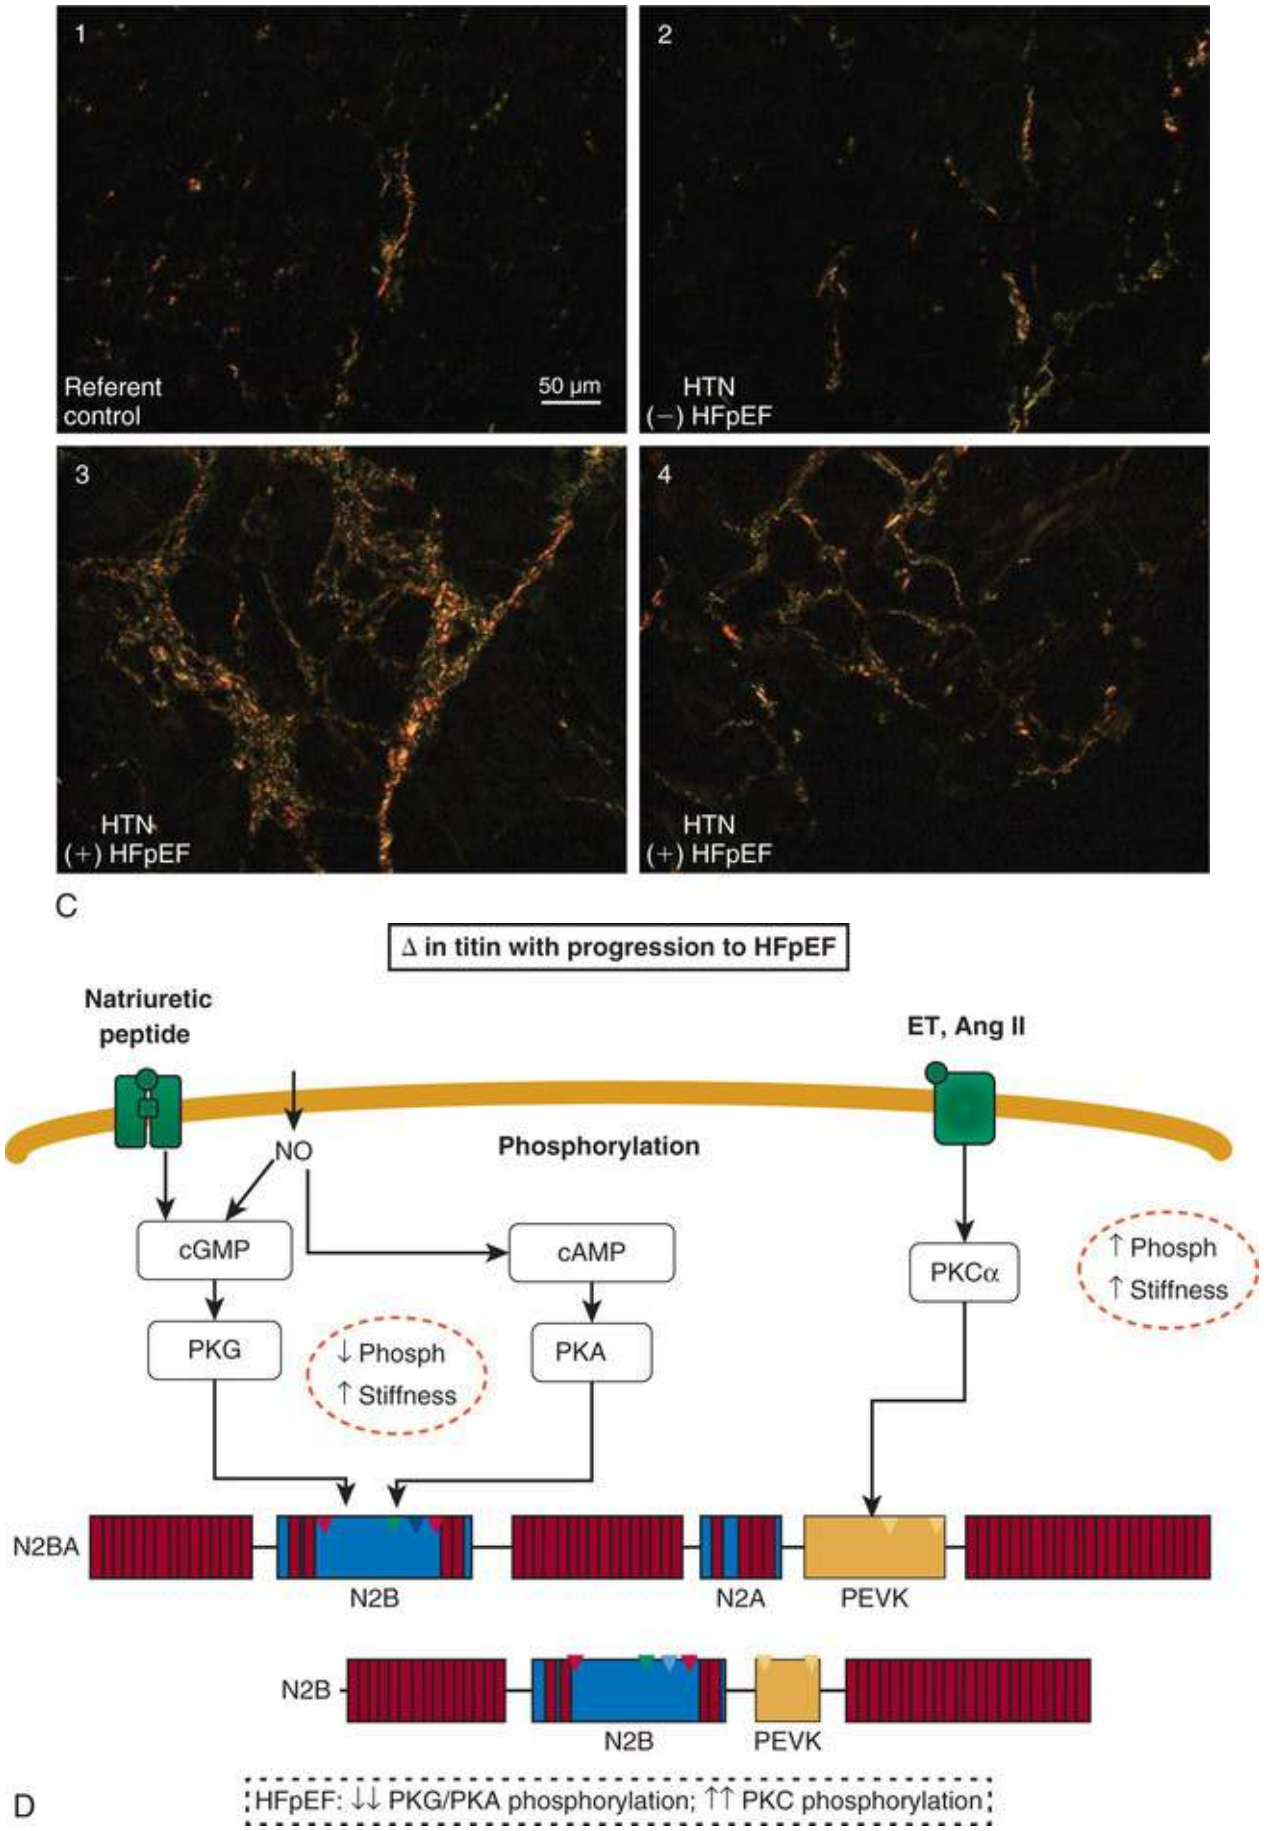


FIGURE 26.6 Contributions of changes in collagen and titin to the increased myocardial stiffness in HFpEF patients. **A,** Total myocardial stiffness expressed as the relationship between myocardial stress versus cardiomyocyte sarcomere length for referent control patients (*open circle, solid blue line*), patients with hypertension but without heart failure and a preserved ejection fraction (HTN(−)HFpEF, *closed circle, dashed red line*), and patients with hypertension and HFpEF (HTN(+)HFpEF, *closed squares, solid red line*). As sarcomere length increases, the slope increases most rapidly in the HTN(+)HFpEF group. Patients with HTN(+)HFpEF had an increase in total myocardial stiffness as indicated by a leftward shift in the stress vs. sarcomere length relationship. There were no significant differences between

HTN(−)HFpEF vs. referent control patients; hypertension in the absence of HFpEF, did not alter passive myocardial stiffness. *, # = $P < 0.01$ vs. referent control and HTN(−)HFpEF. **B,** Myocardial stiffness: Contribution of cellular vs. extracellular matrix (ECM) mechanism. Patients with HTN(+)HFpEF (*solid red bar*) had an increase in collagen-dependent myocardial stiffness and titin-dependent myocardial stiffness. There were no significant differences in HTN(−)HFpEF (*cross-hatched red bar*) or referent control patients (*solid blue bar*). *, # = $P < 0.01$ vs. referent control and HTN(−)HFpEF. **C,** Myocardial collagen content in patients with HTN(+)HFpEF **(panels 3 and 4)** vs. HTN(−)HFpEF **(panel 2)** and referent control **(panel 1).** Picrosirius-stained myocardial sections showed that P HTN(+)HFpEF had an increase in collagen; there were no significant differences between HTN(−)HFpEF or referent control patients. **D,** Change in titin phosphorylation with progression to HFpEF. Compared with referent control patients and patients with HTN(−)HFpEF, patients with HTN(+)HFpEF S11878(S26) and S12022(S170), sites known to be phosphorylated by protein kinase C (*PKC*) and S4185(S469), a site known to be phosphorylated by protein kinase A (*PKA*). Patients with HTN(+)HFpEF had an decreased phosphorylation on the PKG/PKA related N2B S4185(S469) site and increased titin phosphorylation on the PKCα-related PEVK S11878(S26); both of which lead to increased myocardial stiffness. *ET,* Endothelin. (**A-C,** from Zile MR, Baicu CF, Ikonomidis JS, et al. Myocardial stiffness in patients with heart failure and a preserved ejection fraction: contributions of collagen and titin. Circulation 2015;131:1247-59; **D,** from American Heart Association; LeWinter MM, Granzier HL. Titin is a major human disease gene. Circulation 2013;127:938-944.)

Extracellular Matrix

The ECM consists of fibrillar proteins such as collagen types I and III, elastin, and proteoglycans; basement membrane proteins such as collagen type IV, laminin, and fibronectin; and a large number of bioactive peptides and proteins such as matrix metalloproteinases (MMPs), tissue inhibitors of metalloproteinases (TIMPs), signaling proteins such as transforming growth factor-β (TGF-β), and cytokines (**see Chapter 22**). The myocardial collagen network is composed of endomysial fibers surrounding individual myocytes and capillaries; perimysial fibers, which interweave muscle bundles; and epimysial fibers, which form a matrix adjacent to the epicardial and endocardial surfaces. ECM structure is dynamic and regulated by physical, neurohormonal, and inflammatory mediators. These modulate the four steps in collagen homeostasis: collagen synthesis, postsynthetic processing, posttranslational cross-linking, and degradation.[34-37] The ECM fibrillar collagen content is increased in patients with HFpEF. These changes in fibrillar collagen are not present in patients with antecedent disease processes such as hypertensive heart disease alone but develop only after patients make the transition to HFpEF[37] (**see Fig. 26.6**). Experimental studies have shown that acute degradation of collagen fibers by collagenase perfusion or activation of MMPs results in decreased LV stiffness. Animal models have demonstrated that interventions associated with increases or decreases in myocardial fibrosis are associated with increased or decreased LV diastolic stiffness. Thus, evidence that the ECM can contribute to diastolic dysfunction by increasing diastolic stiffness or contribute to impairment in relaxation by altering regional loading or uniformity is strong and supports the potential therapeutic strategy of preventing or reducing fibrosis in the therapy of HFpEF.

Myofilament and Extramyofilament Proteins

The giant myocardial protein *titin* spans the Z-lines and serves as a molecular spring that resists distention, thereby contributing to LV stiffness (**see Chapter 21**). A number of factors, including titin isoform switches (to a less compliant N2B isoform) and titin phosphorylation state, affect diastolic stiffness. Such alterations in titin phosphorylation are present in HFpEF contributing to increased LV diastolic stiffness.[38,39] These changes in titin phosphorylation are not present in patients with antecedent disease processes such as hypertensive heart disease alone, but develop only after patients make the transition to HFpEF[37] (**see Fig. 26.6**). Interaction of titin with other signaling molecules and with ion

channels also may contribute to diastolic stiffness. The role of alterations in titin and the interactions of titin with the ECM in patients with HFpEF constitute an important area of investigation. In addition to titin, other cardiomyocyte structural proteins and changes in their phosphorylation state may affect diastolic stiffness. These include changes in myosin-binding proteins, microtubules, and others.

Prevalence and Prognosis for Decreased Diastolic Distensibility

Measuring the DPVR in large series of patients with HFpEF, particularly in RCTs, is impractical. However, several studies using both invasive measurements and noninvasive estimates of LV stiffness have shown that LV diastolic stiffness is increased in patients with HFpEF compared with both age-matched control cohorts and patients with hypertensive LV hypertrophy but without HF.[2,30,40,41] The exact prevalence in either epidemiologic or pathophysiologic studies is not completely defined, but studies to date suggest that the prevalence of increased diastolic stiffness is high in HFpEF. Several studies using implantable hemodynamic monitors (IHMs) have shown that increased LV diastolic pressures (or their equivalents in pulmonary artery diastolic pressure, left atrial pressures, and thoracic impedance) in patients with HFpEF predict an increase in the frequency of subsequent acute decompensated heart failure and mortality.

Clinical Features

Diagnostic Criteria

The diagnosis of HFpEF can be made and confirmed using a combination of clinical and laboratory assessments (**Fig. 26.7**). Diagnostic criteria for HFpEF have been proposed by the AHA, ACC, HFSA, ESC, and other groups and share the following findings. First, the diagnosis of HFpEF requires the presence of signs and symptoms of HF. This clinical evaluation can be supported by objective measures of exercise intolerance and increased pulmonary extravascular fluid (**Fig. 26.7A**). Second, an EF greater than 50% and a normal LVEDV should be present (**Fig. 26.7B**). Third, expected antecedent or comorbid conditions should be present and all noncardiac causes of symptoms and signs excluded (**Fig. 26.7C**). The presence of these findings is sufficient to make the diagnosis of HFpEF. However, if these lead to ambiguous, borderline, or nonconcordant findings, further diagnostic clarification can be obtained with a fourth set of data (**Fig. 26.7D, E**). This objective noninvasive and invasive evidence of cardiac dysfunction should be used to further support, clarify, and provide specificity to the diagnosis of HFpEF.[42]

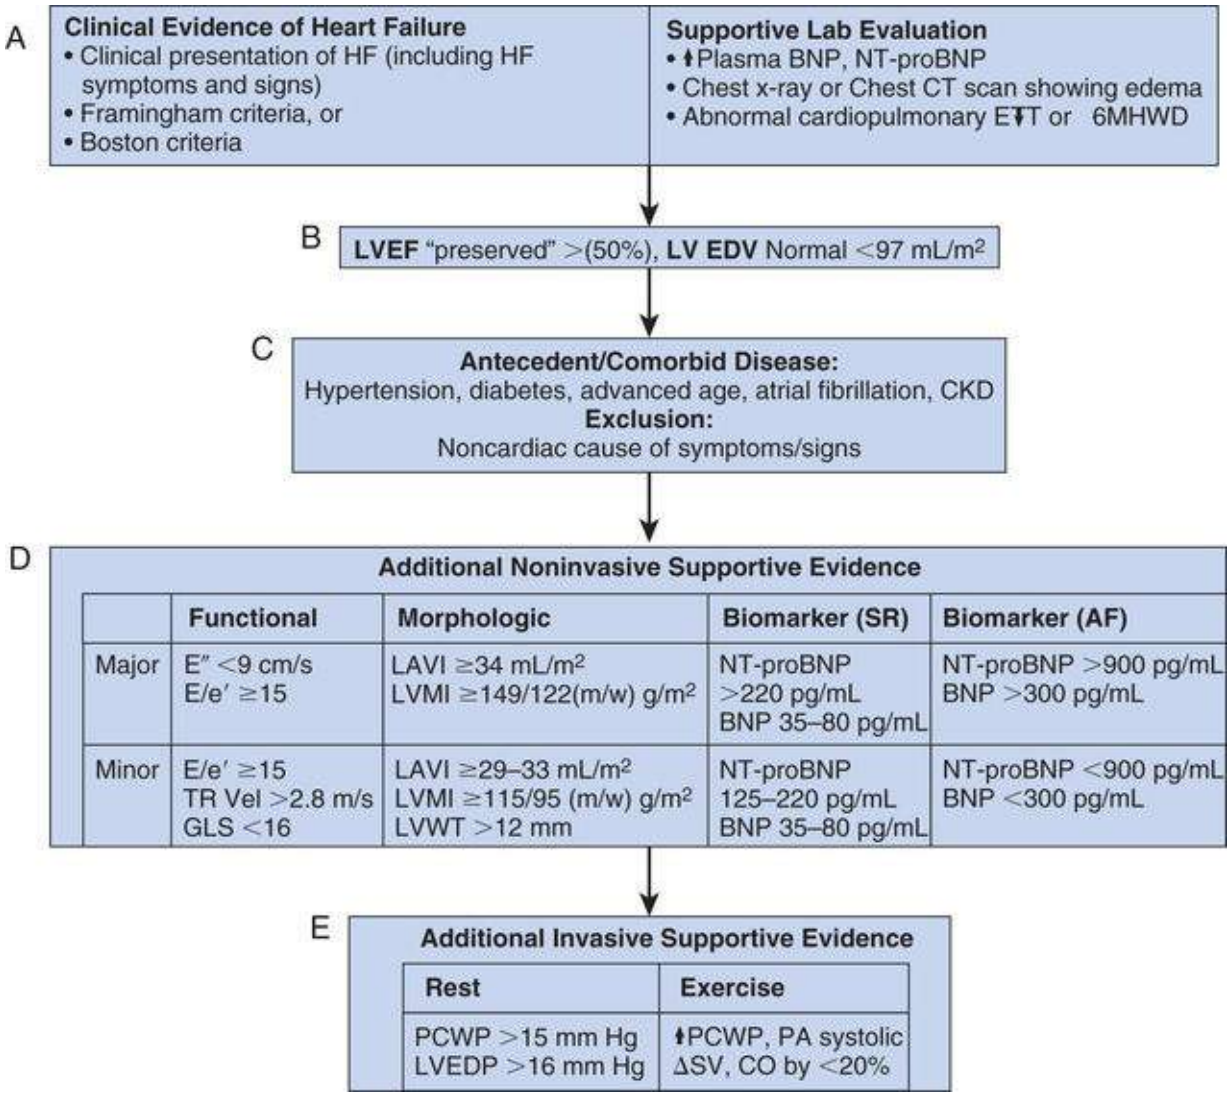

FIGURE 26.7 Diagnostic criteria for HFpEF. See text for discussion. 6MHW, 6-minute hall walk; BNP, B-type natriuretic peptide; CKD, chronic kidney disease; LAVI, left atrial volume index; LVEDP, left ventricular end-diastolic volume; LVEF, left ventricular ejection fraction; LVMI, left ventricular mass index; PCWP, pulmonary capillary wedge pressure. (Modified from Ponikowski P, Voors AA, Anker SD, et al. 2016 ESC guidelines for the diagnosis and treatment of acute and chronic heart failure: the Task Force for the Diagnosis and Treatment of Acute and Chronic Heart Failure of the European Society of Cardiology (ESC). Developed with the special contribution of the Heart Failure Association (HFA) of the ESC. Eur Heart J 2016;37:2129-200.)

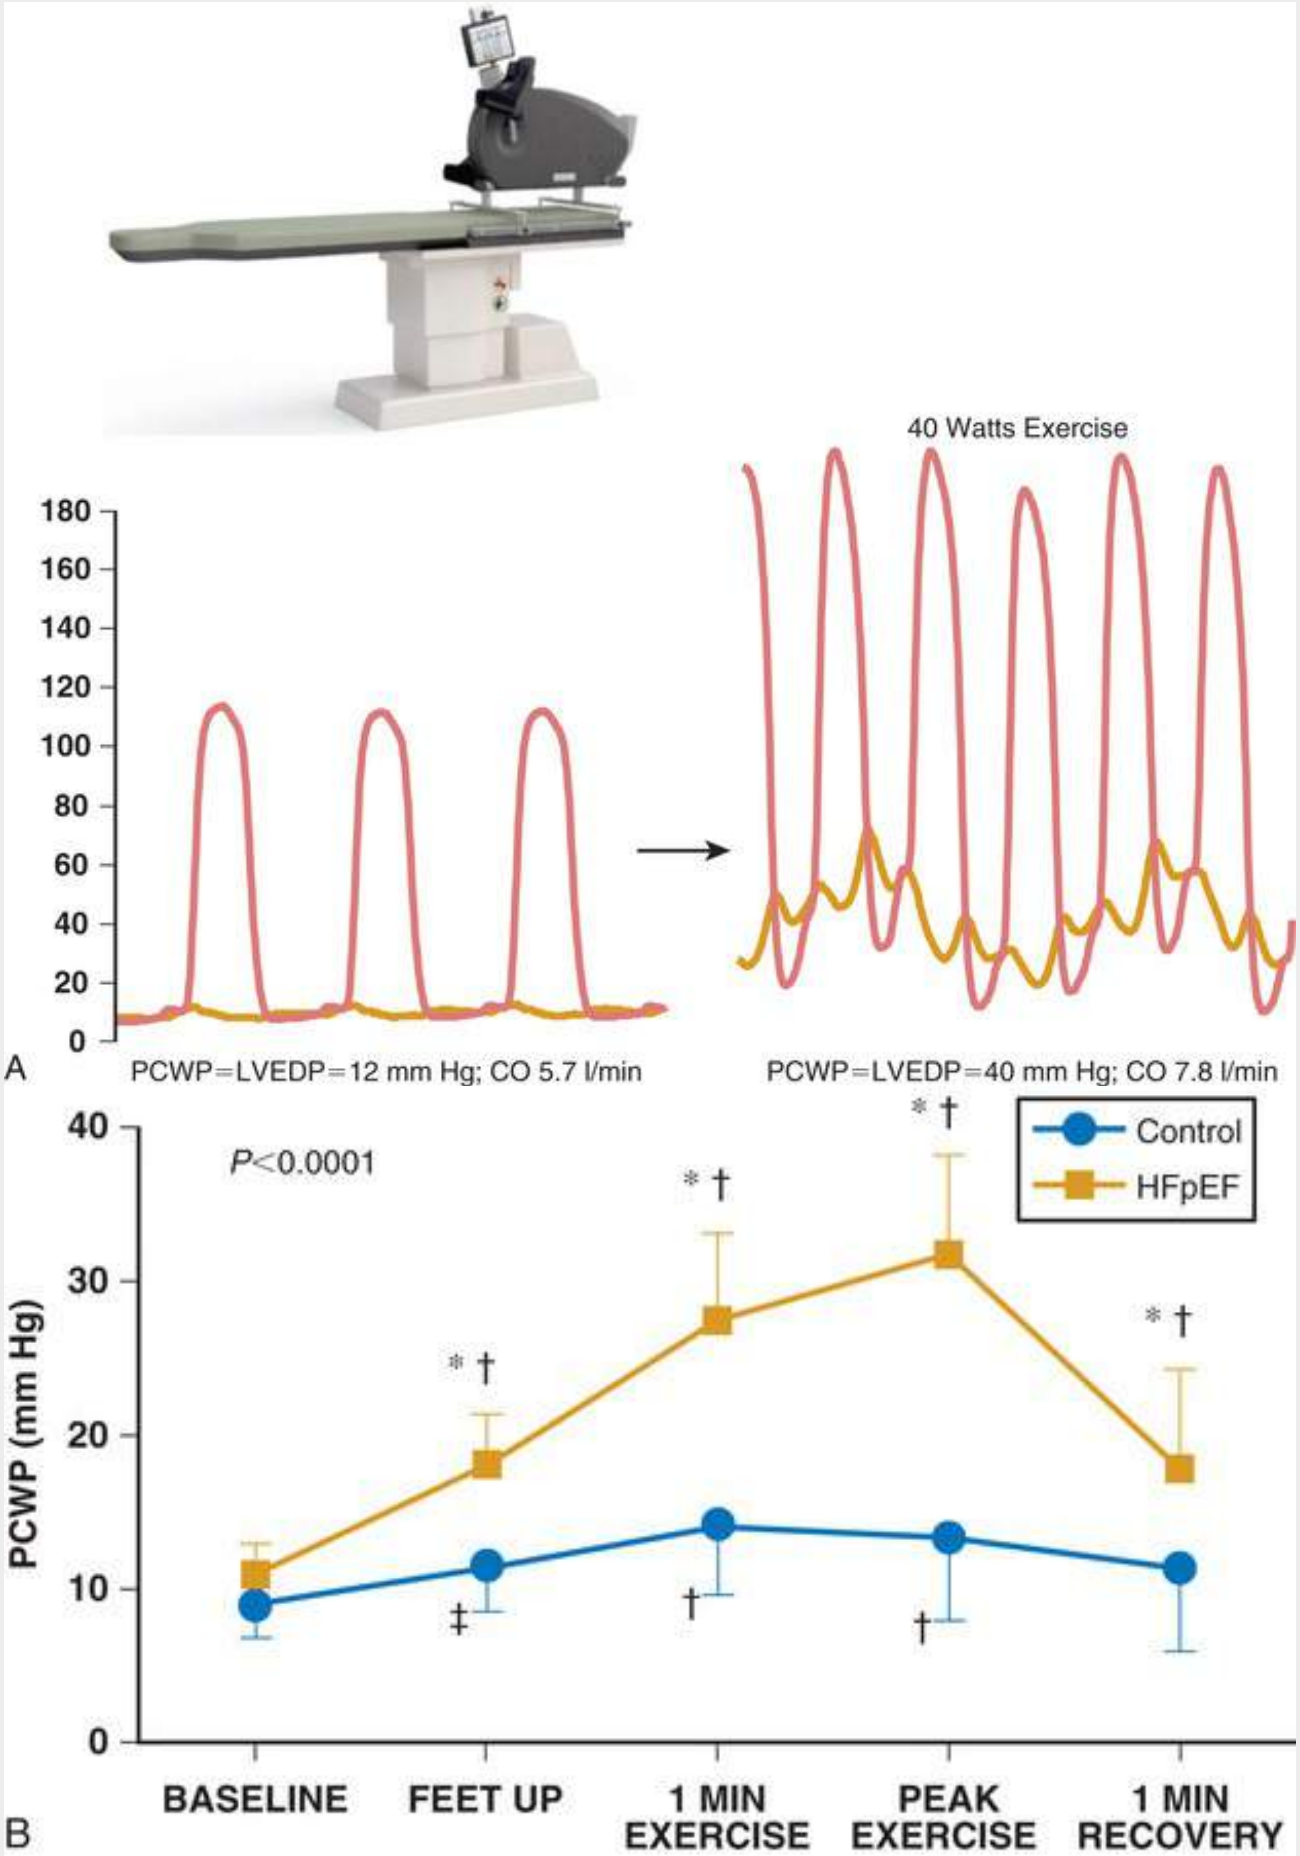
The clinical manifestations of HF are similar regardless of the EF. These include reduced exercise tolerance, dyspnea on exertion, orthopnea, paroxysmal nocturnal dyspnea, peripheral edema, and pulmonary congestion apparent on chest radiographs or computed tomography (CT) scans (**see Chapter 21**). Although a displaced LV apical impulse and pulsus alternans are presumed to be present only in HFrEF, no clinical features (symptoms, signs, or chest radiograph findings) can be used to reliably distinguish between HFpEF and HFrEF. Thus, determination of the EF and LV end-diastolic volume (usually by echocardiography) is required in patients being evaluated for HF. Furthermore, symptoms and signs common in HF can have other causes not related to HF. The diagnosis of HFpEF requires the exclusion of noncardiac causes of symptoms and signs. For example, exercise intolerance and dyspnea may be caused by obesity, pulmonary disease, anemia, or deconditioning. Edema may result from obesity or venous insufficiency. For these reasons, objective demonstration of CV dysfunction or remodeling is necessary to confirm the diagnosis of HF. A reduced EF provides this evidence in patients with HFrEF, but in HFpEF the EF is not abnormal (i.e., EF >50%) and the end-diastolic volume is not increased, so an elevation of the biomarker B-type natriuretic peptide (BNP) (or N-terminal pro-BNP), abnormal LV diastolic function (determined noninvasively or by direct measurement of LV diastolic pressure), or

elevated LA volume is required to support the diagnosis of HFpEF.

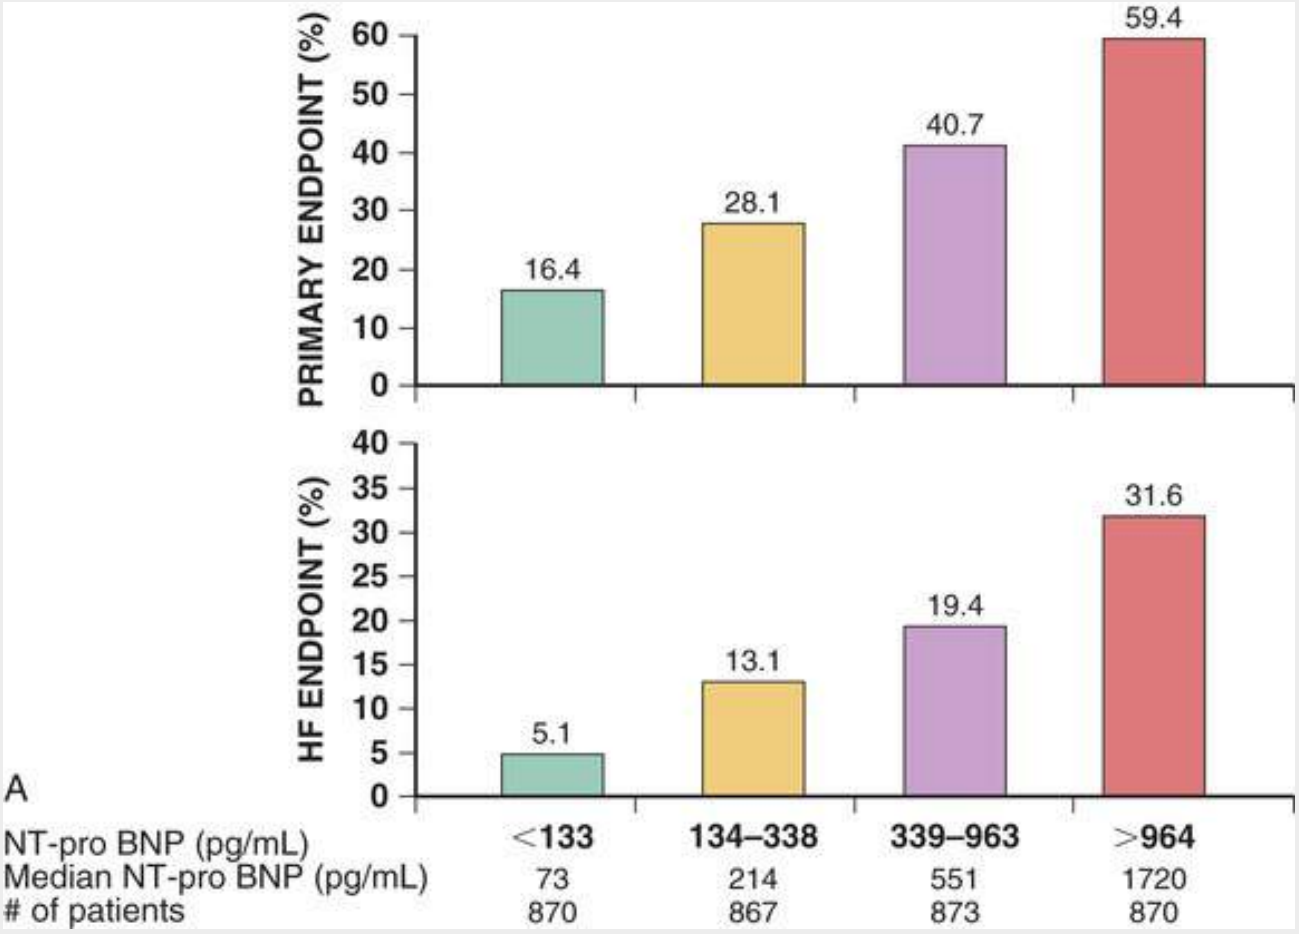
Biomarkers.
The best-characterized biomarkers in patients with HFpEF are the natriuretic peptides (NPs) BNP and NT-proBNP. The utility of NPs and other plasma/serum biomarkers in HFpEF have recently been reviewed in an AHA guideline document.[43] Circulating levels of these proteins are elevated in patients with HFpEF compared with persons without HF but are lower than in patients with HFrEF (**see Chapter 21**). In patients with HFpEF, increased BNP is directly related to LV diastolic filling pressure and end-diastolic wall stress. For any given LV diastolic filling pressure in patients with HFpEF, BNP levels are lower in obese patients and higher in women, older persons, and patients with concomitant pulmonary disease (chronic obstructive disease, pulmonary hypertension, pulmonary embolus) and renal dysfunction. Several methods have been suggested to allow "adjustment" of NP levels for these concomitant states, such as the adjustment for BMI: for every 1 kg/m^2 increase in BMI above 25, NP levels fall 4%.[44] Because patients with HFpEF have a smaller LV cavity and thicker LV walls, their end-diastolic wall stress is much lower than in HFrEF, even in the setting of high systolic and diastolic pressures, thus producing a lower stimulus for BNP production. On average, patients with HFpEF presenting with acute decompensation have a BNP value of 100 to 500 pg/mL, versus 500 to 1500 pg/mL in patients with HFrEF. The standard partition values for BNP of 100 pg/mL and for NT-proBNP of 400 pg/mL have been suggested to support the diagnosis of HFpEF. However, in a subset of patients with normal NPs but all the other characteristics typical of HFpEF, confirmation of the diagnosis should include invasive measures of diastolic function and assessment of response to exercise (**eFig. 26.2**).

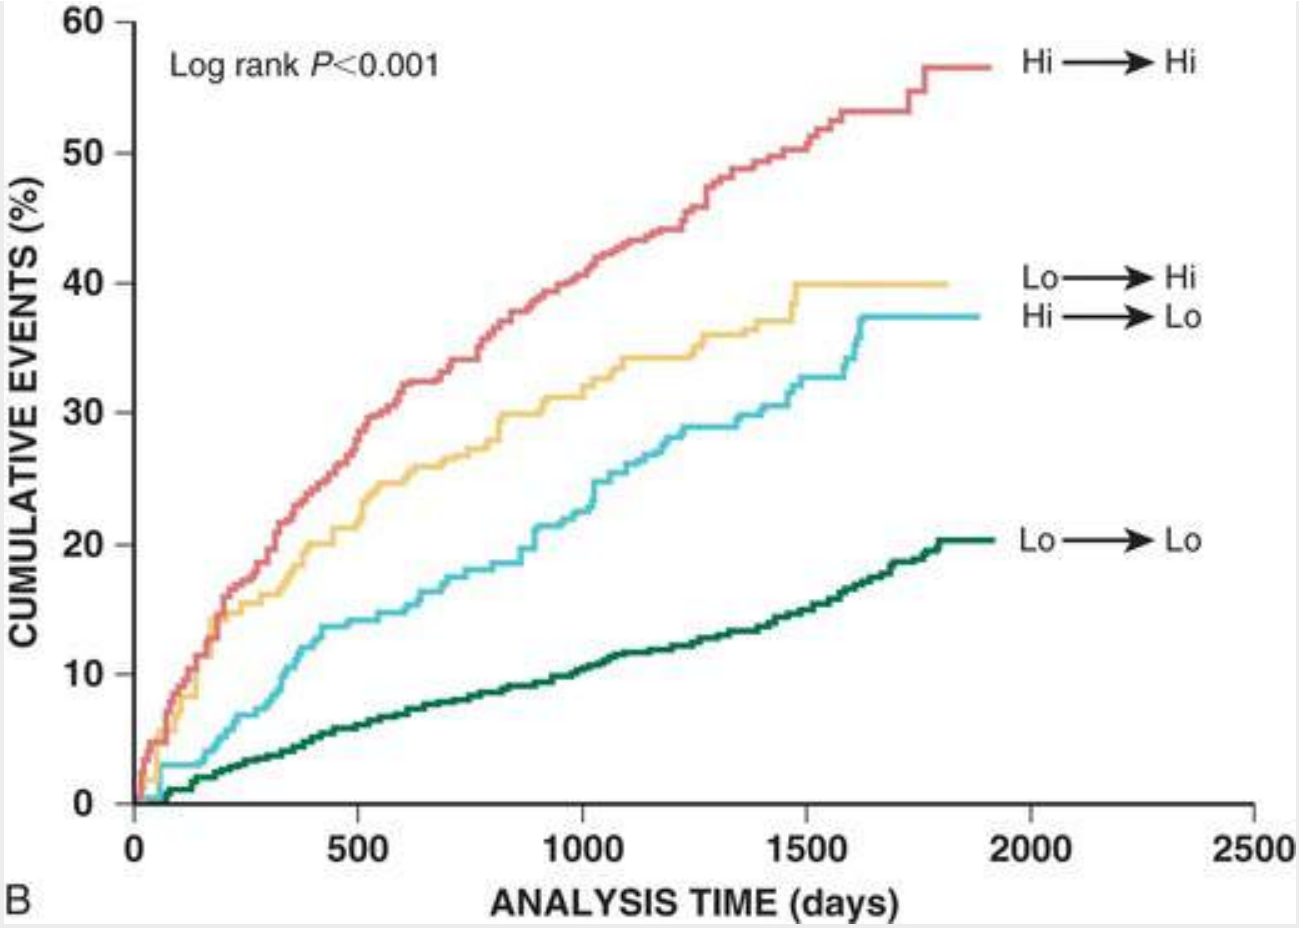


EFIGURE 26.2 Exercise-induced diastolic dysfunction in HFpEF patients using invasive measurement of diastolic function (bicycle ergometry in catheterization lab with right heart catheter in place). **A,** Example of 70-year-old patient with NYHA III symptoms of heart failure and clear decrease in 6MHWD and MVO_2 but BNP <60 pg/mL. At rest the PCWP and LVEDP were normal; however, with exercise both rose dramatically. **B,** Exercise response of PCWP in HFpEF patients (*yellow squares*) versus referent controls (*blue circles*). (**A,** Examples courtesy Barry Borlaug; **B,** From American Heart Association; Borlaug BA et al. Exercise

hemodynamics enhance diagnosis of early heart failure with preserved ejection fraction. Circ Heart Fail 2010;3:588-95.)

Both baseline values and change from baseline predict CV outcomes in patients with HFpEF (**eFig. 26.3**). Elevation of BNP also indicates increased risk for subsequent events, even in asymptomatic persons. Frequent measurement of BNP and NT-proBNP may be useful in the medical management of HFpEF. Other biomarkers to aid in the diagnosis, prognosis, and management of HFpEF include U.S. Food and Drug Administration (FDA)–approved biomarkers (e.g. soluble ST2, galectin 3), as well as others still under development (e.g., TIMP-1).[43]





EFIGURE 26.3 Baseline and change from baseline values of NT-proBNP have prognostic value in HFpEF patients. **A,** Baseline values of NT-proBNP have significant prognostic value and predict morbidity and mortality outcomes. The higher the baseline value of NT-proBNP, the higher the rate of the primary and heart failure endpoints in the I-Preserve study. **B,** Prognosis: NT-proBNP change from baseline. Change from baseline values of NT-proBNP have significant prognostic value and predict morbidity and mortality outcomes. Data from the I-Preserve study indicated that the directional change in NT-proBNP predicted primary and heart failure outcome rates. (**A,** From McKelvie RS et al. Baseline plasma NT-proBNP and clinical characteristics: results from the Irbesartan in Heart Failure with Preserved Ejection Fraction trial. J Card Fail 2010;16:128; **B,** from Jhund PS et al. Changes in N-terminal pro-B-type natriuretic peptide levels and outcomes in heart failure with preserved ejection fraction: an analysis of the I-Preserve study. Eur J Heart Fail 2015;17:809-17.)

Demographic Features

The incidence of HFpEF increases with age, and the condition is more prevalent in women (**see Chapter 21**). These demographic features may differ in specific populations and are associated with differences in race, ethnicity, and geographic region. For example, African Americans may develop HFpEF at a younger age. This predilection may be a consequence of more severe comorbid disease, including hypertension, obesity, and diabetes. In addition, HFpEF is increased in Asians with a lean body mass and diabetes. The antecedent and comorbid conditions are different in HFrEF than HFpEF. A history of hypertension is present in a majority of patients with HFpEF (80% to 90%), and the disorder may have developed only later in life. Obesity is seen in 30% to 50%, diabetes in 20% to 30%, current atrial fibrillation (AF) in up to 20% to 30%, and a history of AF in about 50% of patients. There is a high prevalence of renal disease, which may be progressive. The prevalence of CAD is 20% to 40%. The presence of each of these comorbidities predicts higher morbidity and mortality.[45] Because medical therapy is aimed at these comorbid conditions both to treat existing HFpEF and prevent the development of HFpEF, the medications used by patients with HFpEF and those with HFrEF are similar. They include diuretics, digoxin, angiotensin-converting enzyme (ACE) inhibitors, angiotensin receptor blockers (ARBs), beta

blockers, calcium channel blockers, and various other vasodilators and antihypertensive and antiarrhythmic drugs. Although these agents are not being prescribed as part of a guidelines-based therapeutic approach, they do target the comorbid conditions and the congestive state present in HFpEF.

Comorbid Conditions

Patients with HFpEF and those with HFrEF both frequently have important comorbid diseases (**see Fig. 26.2**). Some of these conditions are antecedent diseases that contribute to the structural and functional changes underlying the pathophysiology of HFpEF or precipitate the development of acute decompensation and contribute to morbidity and mortality.[45] The frequency and severity of comorbid states appear to be higher in HFpEF, at least in part because of the older age of the patients. Because no treatment approaches specific to HFpEF have been proved to reduce morbidity and mortality, treatment suggestions have focused on comorbid states. Although comorbidity plays a pivotal role in both HFrEF and HFpEF, some investigators have raised the question of whether HFpEF represents a primary cardiac condition or just a collection of comorbid conditions with a secondary phenotype of HF.

A number of recent studies have provided data supporting the conclusion that HFpEF is an important, unique clinical syndrome of heart failure.[1] For example, the role of comorbidity in 386 patients with HFpEF was examined in a recent report.[46] Hypertension, obesity, diabetes, anemia, and renal dysfunction were present in many of these patients. However, even after accounting for age, sex, body size, and comorbidity, patients with HFpEF as a group showed larger LV mass, greater degree of systolic and diastolic dysfunction, more LA enlargement, and increased arterial stiffness. These observations indicate that the comorbid conditions contribute to the development of CV abnormalities of HFpEF, but the cardiac abnormalities are more than what might be expected with these conditions alone.[1] In addition, other recent analyses of data from RCTs indicated that the prognosis with HFpEF is much worse than that expected with a specific comorbidity alone. Thus, treating the comorbid diseases (especially hypertension) can be expected to delay or prevent the development of HFpEF but may not be adequate therapy for HFpEF once it develops. Therefore, although comorbid conditions are frequent and important, HFpEF is more than just a collection of such conditions.

The distribution and frequency of comorbid conditions have led some to characterize HFpEF as a “heterogeneous” clinical syndrome. However, all patients with HF, regardless of their EF or how they are grouped, can be characterized as heterogeneous. Using any metric of heterogeneity, HFrEF patients are just as heterogeneous as HFpEF patients. There are significant variabilities in demographics, comorbidities, CV structure and function, and other metrics in both HFrEF and HFpEF populations, and these measures of heterogeneity are equally pronounced in both groups of HF patients. Therefore the presence of heterogeneity alone should not prevent or impede studies in patients with HFpEF. One potential approach to overcoming the challenges intrinsic to the presence of heterogeneity in HF populations is to characterize HFpEF using phenotypic mapping.[47]

Aging.
The incidence of HFpEF increases with age, probably because of increased comorbidity in elderly patients and the adverse effects of normal aging on the cardiovascular system. LV diastolic function becomes abnormal with normal aging. This decrement is apparent as slower rates of LV relaxation, changes in the pattern of LV filling, and reduction in the early diastolic annular velocity that slowly

progress with age. Thus age correction is used for the normal values of these parameters. In addition, arterial, LV systolic, and LV diastolic stiffness increase with aging. Structural cardiac changes with aging (e.g., increased cardiomyocyte size, increased apoptosis with decreased cardiomyocyte number, altered growth factor regulation, focal collagen deposition) and functional changes at the cellular level involving blunted beta-adrenergic responsiveness, excitation-contraction coupling, and altered calcium-handling proteins also may contribute to diastolic dysfunction with normal aging.[12] Some evidence suggests that prolonged, sustained endurance training may slow or prevent some of the age-related changes.

Sex.

Female sex is a potent risk factor for HFpEF.[48] The reasons for the female prominence in HFpEF are not entirely clear, but women have more arterial and LV systolic and diastolic stiffness compared with men, and arterial and ventricular stiffness increases more dramatically with age in women. Women are shorter in stature than men, which may enhance the impact of reflected arterial waves on systolic pressure. These differences also may result from reproductive hormone effects on LV structure and function and response to alterations in load.[49]

Hypertension.

Hypertension is the most commonly associated cardiac condition in patients with HFpEF (**see Chapters 45 and 46**). Chronically increased systolic blood pressure is an important stimulus for cardiac structural remodeling and functional changes. The resultant hypertensive heart disease is characterized by concentric remodeling or overt LV hypertrophy, increasing arterial and ventricular systolic stiffness, impaired relaxation, and increased diastolic stiffness—all factors linked to the pathogenesis of HFpEF. In the presence of hypertensive heart disease, ischemia produces exaggerated increases in filling pressures, and hypertensive and ischemic heart disease often are present in combination in patients with HFpEF. Determining which factors mediate the transition from hypertensive heart disease to clinical HFpEF is an area of active investigation; however, recent studies have demonstrated that proinflammatory and profibrotic signaling lead to both fibroblast/monocyte-macrophage mediated changes in ECM collagen homeostasis and changes in cardiomyocyte myofilament phosphorylation states. These changes lead to increased myocardial fibrosis and alterations in titin phosphorylation, which in turn increase myocardial stiffness and play a causal role in the transition to HFpEF (**see Figs. 26.2 and 26.3**).

Coronary Artery Disease.

The reported prevalence of CAD or myocardial ischemia in patients with HFpEF varies widely (**see Chapter 61**). Although acute ischemia is known to cause diastolic dysfunction, the role of coronary artery disease and ischemia in contributing to chronic diastolic dysfunction and symptoms in patients with HFpEF remains speculative. In addition, even in the absence of atherosclerosis, changes in vascular endothelial function may contribute to the development of HFpEF (**see Fig. 26.2**). Despite uncertainty regarding the role of ischemia in the pathophysiology of HFpEF and a lack of data documenting that revascularization improves outcomes in patients with HFpEF, heart failure management guidelines recommend revascularization in those patients with HFpEF in whom “ischemia is felt to contribute to diastolic dysfunction.”[50]

Atrial Fibrillation and Other Rhythm Disturbances.

AF is recognized as a frequent precipitant of acute decompensation in patients with HFpEF. This is caused by both the loss of atrial contraction and the resulting tachycardia. Whereas AF may cause acute decompensation of HF in patients with diastolic dysfunction, diastolic dysfunction (even in the absence of HF) results in left atrial enlargement and increases the risk of AF. Thus, aging, diastolic dysfunction,

AF, and HFpEF are related conditions. (**See also Chapter 38**.)

Obesity.

Obesity is associated with an increased risk for HF regardless of EF. In general, patients with HFpEF are more often obese than patients with HFrEF, and the prevalence of diastolic dysfunction is increased in obese persons. Increased adiposity not only imposes an adverse hemodynamic and metabolic load on the heart, but also is a source of a large number of biologically active peptide and nonpeptide mediators, many linked to chronic inflammation. Increased body mass index (BMI) is a risk factor for hypertension, DM, CAD, and AF, all of which are associated with HFpEF. Studies using tissue Doppler imaging or invasive LV pressure measurement have reported an association among diastolic dysfunction, elevated filling pressures, and obesity, even in the absence of an HF diagnosis.[51] Dramatic weight loss with caloric restriction or bariatric surgery is associated with improved LV diastolic function.[52]

Diabetes Mellitus.

DM is a potent risk factor for HF, and the prevalence of diabetes is similar in patients with HFrEF and in those with HFpEF, suggesting that diabetes contributes to the pathophysiology of both forms of HF (**see Chapter 51**). DM predisposes to CAD, renal dysfunction, and hypertension. In addition, direct effects of diabetes and hyperglycemia on myocardial structure and function have been described. The morphologic changes in the diabetic heart include myocyte hypertrophy, increased ECM (fibrosis), and intramyocardial microangiopathy. Functional changes include impaired endothelium-dependent and endothelium-independent vasodilation, impaired LV relaxation, increased passive diastolic stiffness, and contractile dysfunction. Mechanisms contributing to structural and functional coronary vascular and myocardial changes include metabolic disturbances, activation of proinflammatory and profibrotic mediators, cardiac autonomic neuropathy, and increases in advanced glycation end products (AGEs), which promote increased collagen accumulation and stiffness. AGE accumulation may play a role in age-related CV stiffening. It appears that better control of blood glucose is associated with an improvement in LV diastolic function, as measured by noninvasive methods.[41]

Chronic Kidney Disease.

The critical impact of renal function on morbidity and mortality in HF is well established.[53] There is no clear difference in severity of renal dysfunction between patients with HFrEF and those with HFpEF.[14,54] Furthermore, the incidence of worsening renal function during HF therapy is similar in patients with HFrEF and in those with HFpEF. However, the presence of chronic kidney disease (CKD) in HFpEF makes the regulation of volume status with diuretics and nitrates more difficult. Although the prevalence of renal vascular disease in HF has been poorly delineated, evaluation of the renal arteries should be considered in patients presenting with the triad of hypertension, renal dysfunction, and HFpEF.

Sleep Apnea.

Obstructive sleep apnea is common in patients with HFpEF, can contribute to symptom severity, and is likely to promote progression of HF. Central sleep apnea can occur in association with severe HFpEF. (**See also Chapter 87**.)

Pulmonary Hypertension.

Most patients with HFpEF have at least some degree of pulmonary hypertension, with pulmonary artery systolic pressures typically greater than 40 mm Hg.[55] This is at least partly because of the elevated LV filling pressures, with resulting increased pulmonary venous pressure.[23] In addition, the pulmonary vascular resistance may be increased by reactive pulmonary arterial vasoconstriction. This reactive process may be most apparent during exercise. In some patients, chronic pulmonary venous hypertension causes pulmonary vascular remodeling (congestive pulmonary vasculopathy), leading to irreversible

pulmonary hypertension. The presence of increased pulmonary artery pressures has prognostic implications and is associated with higher morbidity and mortality rates.

Rarer Causes of Heart Failure with Preserved Ejection Fraction

Hypertrophic cardiomyopathy (**see Chapter 78**), infiltrative cardiomyopathies such as amyloidosis (**Chapter 77**), valvular disease (**Chapters 68 to 70**), and constrictive pericarditis (**Chapter 83**) should always be considered in patients with HFpEF. However, these diseases account for a small minority of cases of HFpEF. The clinical presentation and echocardiographic appearance in older persons with HFpEF may be identical to those in patients previously diagnosed with restrictive cardiomyopathy. An important consideration in patients with previous malignancy treated with mediastinal irradiation is radiation-induced heart disease (**see Chapter 81**). Radiation can cause pericardial and concomitant myocardial damage, and persistent HF after pericardiectomy is common because of concomitant myocardial disease. Concomitant valvular disease and premature CAD also are common in patients with previous mediastinal irradiation and may contribute to the pathophysiology of HFpEF in patients with radiation-induced HF.

Acute Decompensated Heart Failure in Patients with HFpEF

Acute decompensated heart failure (ADHF) is a frequent outcome in patients with HF and may require urgent treatment in the hospital, emergency department (ED), or outpatient office setting (**see Chapter 24**). A majority of patients hospitalized for ADHF have preexisting HF; at least 50% of these patients have HFpEF. Rehospitalizations are frequent, but some patients with HFpEF may be minimally symptomatic between episodes of ADHF. In the vast majority, ADHF is caused by pulmonary congestion that accompanies increases in LV diastolic filling pressure[56] (**Fig. 26.8A**). Both baseline LV diastolic filling pressure and changes in filling pressure are sensitive predictors of future ADHF events (**Fig. 26.8B**); treatment and prevention of increased diastolic filling pressures have been shown to reduce HF hospitalization and CV mortality (**Fig. 26.8C, D**; see later discussion). ADHF in patients with HFpEF can result from increased filling pressure with or without significant changes in body weight, total blood volume, or LV diastolic volume.[57] In contrast, increased LV diastolic pressure and volume can result from increases in total intravascular volume or shifts of intravascular volume due to splanchnic vasoconstriction. The mechanisms responsible for these changes include worsening diastolic dysfunction, increased neurohormonal activation, and poorly controlled comorbid disease. In patients with HFpEF, arterial hypertension, myocardial ischemia, and DM can act on preexisting structural and functional abnormalities to cause deterioration in LV diastolic function and precipitate ADHF. Atrial arrhythmias can result in loss of atrial function and can stimulate compensatory increases in diastolic filling pressure to maintain LV filling and cardiac output. Decreased LV diastolic function and abnormal LA function can result in neurohormonal activation, which plays an important role in ADHF by increasing sodium and water retention, venous return, splanchnic tone, and arterial vasoconstriction. Even after normal volume status is restored and neurohormonal activation suppressed, the inciting comorbidity may remain and can influence the subsequent clinical course. This ongoing process may contribute to a high rate of non-HF–related rehospitalizations after an HF episode.[19,58]

Assessment of LV structure and function is an essential step in the clinical evaluation of patients with suspected HFpEF to establish diagnosis, assess prognosis, and monitor effectiveness of treatment.[25] In addition, changes in structure and function contribute to the pathophysiologic mechanisms that underlie the development of HFpEF. Although echocardiography remains the most widely used noninvasive clinical imaging technique, evaluation may be supplemented or enhanced by magnetic resonance imaging (MRI) and computed tomography (CT). As in patients with HFrEF, the structural and functional characteristics of patients with HFpEF have some features that all (or nearly all) patients share and others that demonstrate some variability in prevalence.

Left Ventricular Structure

Left Ventricular Volume

Most (>90%) patients with HFpEF have normal LV chamber dimension, area, and volume; up to 5% of patients have a mild increase in LV volume above the upper normal partition value of 75 mL/m^2.[10,59,60] In addition, in many patients with HFpEF, LV volumes are small, contributing to a limitation in stroke volume and cardiac output response to exercise. An LV volume less than 75 mL/m^2 is one of the guidelines-based diagnostic criteria for HFpEF.

Left Ventricular Mass

LV mass is increased and reaches criteria for LV hypertrophy in 30% to 50% of patients with HFpEF.[8] Some evidence suggests that the prevalence of LV hypertrophy may be higher among African American patients and women with HFpEF.[61,62] When present, LV hypertrophy is associated with significantly worse prognosis. Even in those patients who do not meet criteria for LV hypertrophy, structural remodeling may have developed, evidenced as concentric remodeling and cardiomyocyte hypertrophy (**see Fig. 26.3**).

Left Ventricular Geometry

The ratio of LV mass to volume (M/V), or of LV wall thickness to LV internal dimension (relative wall thickness [RWT]), describes the geometry of the left ventricle.[9] When mass or thickness is increased relative to (or out of proportion with) volume or dimension, the resultant changes are termed *concentric remodeling*. Concentric remodeling can occur even in the absence of frank LV hypertrophy in approximately 20% to 30% of patients with HFpEF and is associated with a 25% to 35% higher risk of HF events.[19]

Left Ventricular Function

Diastolic Properties

Patients with HFpEF may have abnormalities in all aspects of diastolic function, including a delayed and slow relaxation, decreased recoil, slow and incomplete early filling, increased filling during atrial contraction, and decreased distensibility. The methods necessary to quantify these abnormalities and the causative mechanisms are described earlier (see Pathophysiology). However, echocardiographic techniques can be used to assess these properties in a combinatorial fashion in order to characterize a diastolic function grade of 0 (normal), 1 (abnormal relaxation), 2 (pseudonormalized), 3a (reversible restrictive), or 3b (irreversible restrictive)[25] (**Fig. 26.9**). This echocardiographic and Doppler echo–based grading scale is the most common clinical method of assessing severity of diastolic dysfunction.

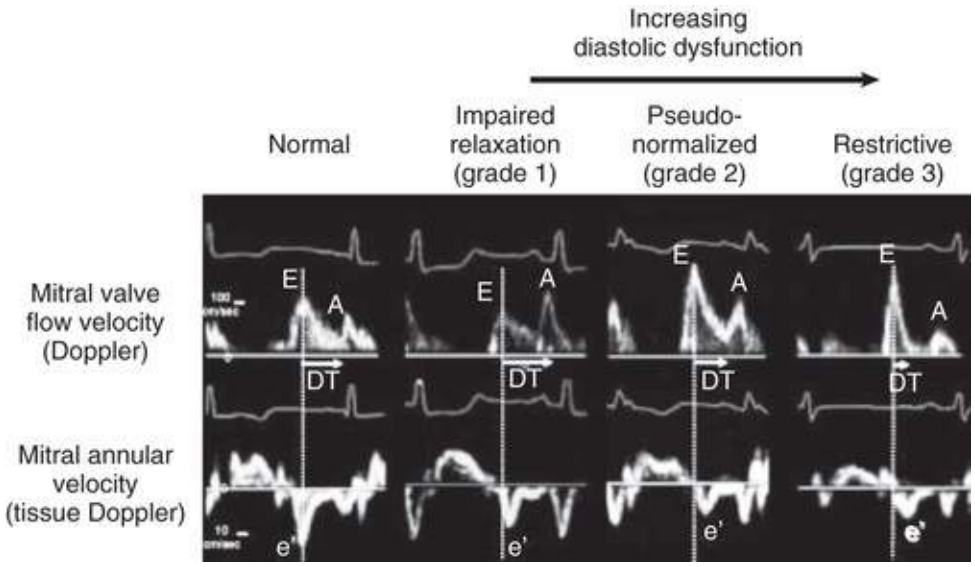

FIGURE 26.9 Evaluation of diastolic function based on the left ventricular filling dynamics determined by Doppler measurement of mitral valve flow velocity and tissue Doppler measurement of mitral annular velocity. Normally, the early diastolic mitral flow velocity (*E*) and the mitral annular velocity (*e′*) are brisk and occur almost simultaneously. With mild diastolic dysfunction (impaired relaxation pattern—grade 1) the mitral E velocity is reduced and is less than the late diastolic mitral flow velocity (*A*). The E deceleration time (*DT*) is increased. With more severe diastolic dysfunction (grades 2 and 3), E is increased and the DT is reduced. In these patterns, e′ is reduced and delayed relative to the mitral E. (From Little WC, Oh JK. Echocardiographic evaluation of diastolic function can be used to guide clinical care. Circulation 2009;120:802.)

Grade 1 diastolic dysfunction is characterized by the presence of mild diastolic dysfunction with slow LV relaxation. The early diastolic pressure gradient between the left ventricle and the left atrium that accelerates transmitral flow into the left ventricle is decreased because there is no increase in LA pressure, and early LV diastolic pressure is higher because of abnormal relaxation.[25] This results in a decrease in both the early transmitral flow velocity (E) and the early tissue velocity (e′) and an increase in the importance of late diastolic mitral flow velocity (A), the transmitral velocity resulting from atrial contraction, producing an E/A ratio less than 1. The delayed relaxation results in a prolongation of E wave deceleration time (DT) and may be associated with a mid-diastolic peak of mitral flow (L wave).[63] The contribution to LV filling produced by atrial contraction is increased. This filling pattern has been termed an "impaired relaxation pattern" (abnormal relaxation) or grade 1 diastolic dysfunction.[64] In most patients with impaired relaxation pattern, the mean LA pressure is not elevated despite an increased LV end-diastolic pressure, which is maintained by a vigorous atrial contraction.

Grade 2 diastolic dysfunction occurs when progressive worsening of diastolic dysfunction is associated with an increase in LA pressure and there is restoration of the early diastolic pressure gradient despite increased early diastolic LV pressures. These changes result in a return of the E wave to the normal range (pseudonormal mitral inflow pattern). Displacement of the left ventricle onto a steeper portion of the pressure-volume curve results in a shortening of the DT. With slower relaxation, the e′ is delayed, occurring after the E. This indicates that the left ventricle is not expanding symmetrically in diastole, but that propagation of filling to the apex and longitudinal expansion occur slowly after the left ventricle is filled by the movement of blood from the left atrium into the LV inflow tract. In the presence of slow relaxation, e′ does not occur during the time of the LA-to-LV pressure gradient, so e′ is reduced and becomes almost independent of LA pressure.[26] Both the low mitral annular e′ and the delay in e′ relative to E correlate with increased time constant of LV isovolumetric pressure decline.[26] Thus the

pseudonormal mitral inflow pattern is distinguished from normal by a reduced and delayed e′ and increase in the E/e′ ratio.

Grade 3 diastolic dysfunction occurs when severe diastolic dysfunction causes a markedly slowed relaxation and elevated LA pressure; the E increases further, DT becomes very short, and e′ is further reduced and delayed resulting in a marked elevation of E/e.[27] With severe diastolic dysfunction, the late diastolic annular velocity (a′) also may be reduced, and pulmonary venous systolic forward flow velocity is reduced as well, to less than diastolic forward flow velocity. With grade 3 diastolic dysfunction, if a Valsalva maneuver causes a reduction of E wave velocity, the condition is designated *reversible* (grade 3a); if Valsalva does not change E, it is designated *irreversible* (3b).

Noninvasive Estimation of Left Ventricular Diastolic Filling Pressure.

Knowledge of LV diastolic pressure in patients with known or suspected HFpEF is important for establishing diagnosis, predicting prognosis, and directing therapy. However, because direct measures of diastolic pressure are invasive and not suitable for repeated measures, noninvasive echocardiographic and echo-Doppler measurements have been developed and clinically applied. The measurements used in the diastolic grading system also can be used to estimate LV diastolic filling pressures and to follow progression of disease and response to therapy. Pseudonormalized and restricted filling patterns indicate the presence of both diastolic dysfunction and elevated LA pressure.[27] By contrast, the impaired relaxation pattern indicates diastolic dysfunction without a marked elevation in LA pressure.

Additional echo-Doppler measurements that may reflect diastolic filling pressures include estimation of peak right ventricular systolic pressure (PRVSP) from the tricuspid regurgitation velocity and LA volume.[23] The most common cause of increased pulmonary artery systolic pressure in HFpEF is an elevation of LA pressure, and the echocardiographic parameters best correlated with PRVSP are DT and E/e′.[55] Diastolic dysfunction grade and PRVSP estimate instantaneous diastolic pressure. Changes in LA volume reflect longer-term changes in LV filling pressures.[2,55,62] LA volume is dependent on the product of diastolic pressure and time, so the longer pressures are increased and the higher they are increased, the larger the LA volume. Abnormal diastolic dysfunction grade, increased PRVSP, and increased LA volume are highly prevalent in patients with HFpEF and have significant prognostic value (**eFig. 26.4**).

and prognosis in heart failure with preserved ejection fraction: findings from the echocardiographic study of the Treatment of Preserved Cardiac Function Heart Failure with an Aldosterone Antagonist (TOPCAT) Trial. Circ Heart Fail 2014;7:740-51.)

All the previous measures are useful in identifying patients with or without elevations of LA pressure. However, the most frequently used and easily interpretable parameter to estimate LA pressure is the E/e′ ratio.[25] E/e′ has been found to correlate with pulmonary capillary wedge pressures (PCWPs) in a wide range of patients studied in multiple laboratories.[64,65] An E/e′ greater than 15 has been found clearly to indicate elevated PCWP, whereas E/e′ less than 8 is associated with normal LA pressure[64] (**see Fig. 26.4**). The cutoff value for E/e′ of 15 to recognize elevated LA pressure was obtained using e′ velocity from the medial mitral annulus. Because e′ velocity from the lateral annulus usually is higher than the medial e′ velocity, the cutoff value should be adjusted to 12 if the lateral annular velocity is used. An average of the medial and lateral annular velocities has been recommended.[64] In some situations, however, E/e′ may not provide an accurate assessment of PCWP. The clinical settings in which this application of E/e′ may be inaccurate are described in an online supplement for this chapter (Limitations in Use of E/e′ Ratio).[25]

Prevalence and Prognosis for Diastolic Dysfunction in HFpEF.

The frequency distribution of diastolic dysfunction grade, increased PRVSP, and LA volume varies according to the characteristics of the population studied, that is, the patient's level of hemodynamic compensation and severity of disease. A truly normal diastolic function profile, however, is uncommon in patients with HFpEF.[66] For example, an abnormal diastolic dysfunction grade was found in 60% to 70% of the patients enrolled in the TOPCAT, I-Preserve, and CHARM studies; LA enlargement was present in 66%, and either diastolic dysfunction of grade II to IV or LA enlargement was found in 85%.

Echocardiographic findings related to diastolic function provide important prognostic information in a wide variety of patient populations. A normal filling pattern in community-dwelling patients indicates an excellent prognosis.[67] By contrast, an abnormal filling pattern along with progressively worsening abnormalities of LV filling pattern (impaired relaxation versus pseudonormalized and restricted filling) indicates patients with a progressively increased risk of subsequent mortality. The stage of diastolic dysfunction correlates with the impairment of exercise capacity in patients without myocardial ischemia, whereas LV EF does not.[68] In patients with HF, the stage of diastolic dysfunction is a stronger predictor of mortality than EF.[69]

A short DT indicates an increased LV operating stiffness, is a hallmark of restrictive filling pattern, and connotes poor prognosis in patients with a history of myocardial infarction (MI), those with dilated cardiomyopathy (DCM), heart transplant recipients, and patients with hypertrophic or restrictive cardiomyopathy.[64] Both pseudonormalized and restricted filling patterns are associated with a fourfold increase in the risk of death in HF patients withCAD.[70] Similarly, an elevated E/e′ indicates a poor prognosis in a wide variety of patients.[64] Lastly, in patients with HFpEF, abnormal diastolic function measured as diastolic dysfunction grade, LA enlargement, or increased PRVSP also predicts marked increase in morbidity and mortality events (**eFig. 26.4**).

Systolic Properties

Global LV systolic chamber properties are normal at rest in patients with HFpEF. By definition, patients with HFpEF have a normal (or near-normal) EF. In addition, at rest, patients with HFpEF have normal dP/dt_{max}, stoke volume, stroke work, and preload-recruitable stroke work. Furthermore, indices of chamber contractility such as LV end-systolic elastance are actually increased in HFpEF, matching the

increased arterial elastance, so that the coupling between these properties is preserved.[71,72] By contrast, in HFrEF, LV systolic elastance is reduced and arterial elastance is elevated so that ventricular-vascular coupling is impaired. In fact, the presence of a normal EF indicates that the coupling of the left ventricle and arterial system is almost optimal to convert the energy of contraction into the stroke work.[73] Thus, arterial vasodilation improves LV systolic performance in HFrEF but not in HFpEF.[74] Because indices of end-systolic elastance are altered by remodeling, chronic changes in chamber contractility should be normalized to the LV mass/end-diastolic volume ratio. With this adjustment, elastance measurements in patients with HFpEF are normal in the resting state. (See the online supplement for this chapter, Indices of Myocardial Contractile Function and Assessment of Exercise Capacity in Heart Failure with Preserved Ejection Fraction).

Therapy

Many prospective RCTs have been conducted in patients with HFrEF, with findings used to guide evidence-based therapy. By contrast, such evidence is lacking for patients with HFpEF: No treatment has yet been shown, convincingly, to reduce morbidity or mortality in patients with HFpEF.[75] Therapies with proven benefit in HFrEF, including pharmacologic regimens of ACE inhibitors, ARBs, beta blockers, or hydralazine/nitrates, as well as placement of implantable defibrillators and cardiac resynchronization, have not shown any clear benefit in HFpEF, or data from RCTs are not available for HFpEF. Nevertheless, the practical clinical approach presented in this section will reduce symptoms, prevent acute decompensation, and improve exercise tolerance.

Summary of Randomized Controlled Trials

Eight large RCTs have enrolled patients with HFpEF (with EF entry criteria ranging from >35% to >50%), six had HF hospitalization or CV death as the primary endpoint, two had exercise or activity level endpoints. Six of these RCTs had a clearly neutral outcome; in a post hoc analysis, one demonstrated a reduction in HF hospitalization or CV death in patients who actually had HFpEF and were treated with spironolactone, and one demonstrated that therapy could be facilitated using an implantable hemodynamic sensor (**Fig. 26.10**; **see Table 26.1**).

DIG Trial.

The Digitalis Investigators Group (DIG) Trial included a separate cohort of 988 patients with ambulatory HFpEF (EF >45%) in normal sinus rhythm. In this HFpEF group, digoxin did not alter the primary endpoint of HF-related hospitalization or CV mortality but did reduce the number of such hospitalizations. Total CV hospitalizations were not reduced, however, because of an increased rate of admissions for unstable angina, which completely negated the benefit of reduced HF hospitalizations.[76]

Charm.

The Candesartan in Heart Failure: Assessment of Reduction in Mortality and Morbidity (CHARM) program of trials evaluated the ARB candesartan in HF patients. In the CHARM-Preserved arm,[77] HF patients with an EF above 40% were randomly assigned to receive candesartan or placebo in addition to standard therapy. Fewer patients in the candesartan group than in the placebo group reached the primary endpoint of CV death or HR-related hospitalization, a finding that reached statistical significance only after adjustment for small differences in baseline characteristics. Furthermore, there was no impact on mortality.

PEP-CHF.

In the Perindopril in Elderly People with Chronic Heart Failure (PEP-CHF) trial, patients older than 70 with HFpEF (EF >0.45) with echocardiographic evidence of diastolic dysfunction were randomly assigned to receive perindopril (an ACE inhibitor) or placebo.[78] The primary endpoint was a composite of all-cause mortality or unplanned HF-related hospitalization. Both enrollment and event rates were lower than anticipated, and a high rate of cessation of blinded therapy, with crossover to open-label ACE inhibitor use, was reported for both groups. These factors limited the power of the study, which did not show significant reduction in the primary endpoint. Some trends toward benefit, primarily driven by reduction in HF-related hospitalizations, were observed in a post hoc analysis of the results at 1 year, when crossover therapy rates were lower.

I-Preserve.

The Irbesartan in Heart Failure with Preserved Ejection Fraction Study (I-Preserve) tested the ARB irbesartan in 4128 patients who were at least age 60 and had New York Heart Association (NYHA) Class II, III, or IV HF, with an EF above 45%.[79] The primary outcome was death from any cause or hospitalization for a CV cause (HF, MI, unstable angina, arrhythmia, or stroke). Secondary outcomes included death from HF or hospitalization for HF, death from any cause and from CV causes, and impaired quality of life. Irbesartan had no effect on any of the prespecified outcomes.

Seniors.

The Study of the Effects of Nebivolol Intervention on Outcomes and Rehospitalization in Seniors with Heart Failure (SENIORS) trial tested the effect of the $beta_1$-selective blocking agent nebivolol in HF

patients without an EF requirement.[80] Nebivolol also has vasodilator properties thought to be related to its effects on nitric oxide (NO) release. A modest but significant reduction was observed in the primary endpoint of all-cause mortality or CV hospitalizations, driven primarily by the effect on hospitalizations. Prespecified subgroup analysis in patients with EF above versus below 35% did not detect any trends toward reduced benefit in those with higher EF. Unfortunately, very few patients with EF above 50% were included in the trial. Thus it is not possible to draw conclusions about the benefit of beta blockers in HFpEF from this study. However, analysis of a large observational study found no mortality benefit of treatment with a beta blocker after a hospitalization for HF in patients with EF above 40%. By contrast, in patients with EF below 40%, a clear mortality benefit was found, consistent with the results of randomized trials of beta blockers with HFrEF.

Topcat.

Mineralocorticoid receptor antagonists (MRAs) have been shown to improve measures of diastolic function and exercise capacity in HFpEF patients. Furthermore, MRAs have shown favorable effects on LV load (both preload and afterload) and myocardial fibrosis. The Treatment of Preserved Cardiac Function Heart Failure with an Aldosterone Antagonist (TOPCAT) trail was performed to determine whether treatment with spironolactone would improve clinical outcomes in patients with symptomatic HFpEF. TOPCAT was a randomized, double-blind trial; 3445 patients with symptomatic HFpEF (EF ≥45%) were assigned to receive either spironolactone (15 to 45 mg daily) or placebo. The primary outcome was a composite of death from CV causes, aborted cardiac arrest, or hospitalization for the management of HF. With a mean follow-up of 3.3 years, the primary outcome occurred in 18.6% of the spironolactone group and 20.4% of the placebo group (hazard ratio [HR], 0.89; 95% CI 0.77 to 1.04; P = 0.14).[81] Although the primary endpoint of the TOPCAT trial was not significant statistically, hospitalization for HF, which was one of the components of the primary endpoint, was significantly lower in the spironolactone group than the placebo group (12.0% versus 14.2%; HR, 0.83; 95% CI 0.69 to 0.99, P = 0.04). Further analysis of TOPCAT found that (1) patients enrolled from Russia and Georgia had rates of HF hospitalization and CV mortality roughly equivalent to age- and gender-matched controls, suggesting that they did not have symptomatic HFpEF, and (2) enrolled patients from Russia and Georgia who were treated with spironolactone had no significant changes in blood pressure, creatinine, or potassium, and the metabolic product of spironolactone was low or undetected, suggesting that these patients were likely not compliant with drug therapy. A non-prespecified post hoc analysis of TOPCAT that excluded patients enrolled in Russian and Georgian sites showed that there was a clear and significant reduction in the primary study endpoint (HR, 0.82; 95% CI 0.69 to 0.98).[82]

Champion.

See discussion later, Remote Monitoring Systems to Help Tailor Management.

Relax.

Because phosphodiesterase-5 (PDE5) metabolizes the NO and NP systems' second-messenger cyclic guanosine monophosphate, it was hypothesized that PDE5 inhibition may increase NO and NP actions in the heart, vasculature, and kidneys and improve clinical status in HFpEF. Early phase II and single-center studies suggested that the PDE5 inhibitor sildenafil would have salutary effects in patients with HFpEF, but the Phosphodiesterase-5 Inhibition to Improve Clinical Status and Exercise Capacity in Heart Failure with Preserved Ejection Fraction (RELAX) trial showed that sildenafil did not improve exercise capacity or clinical status.[83] This was a moderate-sized (216 patients), short-term (24 weeks) study performed by

the National Heart, Lung and Blood Institute (NHLBI)–sponsored Heart Failure Clinical Research Network (HFCRN).[83]

NEAT-HFpEF.

Because the hemodynamic effects of nitrates might attenuate pulmonary congestion with exertion and improve exercise capacity in HFpEF, the Nitrate's Effect on Activity Tolerance in Heart Failure with Preserved Ejection Fraction (NEAT-HFpEF) trial was performed to test the hypothesis that extended-release isosorbide mononitrate would enhance the daily activity level in patients with HFpEF, as assessed by patient-worn accelerometers. This was a moderate-sized (110 patients), short-term (6 weeks) study also performed by the NHLBI-sponsored HFCRN. HFpEF patients who received isosorbide mononitrate were less active and did not have better quality of life or submaximal exercise capacity than patients who received placebo.[84] Current studies are now focused on the potential use of organic nitrites in oral and inhaled preparations that target the nitrate-nitrite-NO pathway.

Phase II Studies of Novel Management Strategies for HFpEF

Several novel approaches to the management of HFpEF are being developed and examined in phase II and phase III trials. These include treatment with the angiotensin receptor neprilysin inhibitor (ARNI) sacubitril/valsartan (Entresto), oral and inhaled nitrites, serelaxin, soluble guanaline cyclase agonists, and placement of atrial septostomy device. Sacubitril/valsartan has progressed to a full phase III trial.

Prospective comparison of ARNI versus ARB on Management of Heart Failure with Preserved Ejection Fraction (PARAMOUNT) was a phase II, randomized, parallel-group, double-blind, multicenter trial in patients with NYHA Class II or III HFpEF (EF >45%) and NT-proBNP level greater than 400 pg/mL.[85] The ARNI sacubitril/valsartan appears to have antifibrotic effects.[85] A cohort of 149 patients were assigned to receive therapy with sacubitril/valsartan (200 mg twice daily) and another 152 patients to receive valsartan (160 mg twice daily) for 36 weeks. The primary endpoint was change in NT-proBNP from baseline to 12 weeks. At 12 weeks, sacubitril/valsartan significantly reduced NT-proBNP by approximately 15%, compared with valsartan (no significant change; for difference in response, $P = 0.005$). At 36 weeks, sacubitril/valsartan significantly reduced LA volume by approximately 5% compared with valsartan (no significant change; for difference in response, $P = 0.003$). Sacubitril/valsartan improved NHYA functional class versus valsartan ($P = 0.05$). Sacubitril/valsartan was well tolerated, with adverse effects similar to those for valsartan. Whether these findings will translate into improved outcomes is being tested in a large randomized trial, PARAGON-HF.

Management of Heart Failure Patients with Preserved Ejection Fraction

The practical clinical management of HFpEF has three main components. The first aspect of management is reduction and prevention of pulmonary and peripheral venous congestion. These objectives can be accomplished with fluid and sodium restriction, judicious use of diuretics and nitrates, selective application of neurohormonal modulation, and appropriate remote monitoring–based tailored care. The second component is aggressive treatment of antecedent and comorbid diseases. Strategies include controlling blood pressure at rest and modifying blood pressure response to exercise, controlling glucose, treating and preventing ischemia, maintaining adequate renal function, and treating obesity with medical

and surgical weight loss management and exercise training. The third component of management is optimization of cardiac functional status—to prevent excessive tachycardia or bradycardia, to match heart rate to metabolic needs, to maintain or restore normal sinus rhythm, and to control ventricular response rate during atrial arrhythmias.

Nonpharmacologic Therapy

General measures that may be used in the management of patients with HFpEF include attention to diet and lifestyle, avoidance or reversal of obesity, increase in exercise, adherence to management strategies, daily monitoring of weight, patient education, and close medical follow-up using facilitated home management. Sodium restriction to less than 2 g/day may be effective. Excessive fluid volume intake should be avoided but balanced with respect to renal function (see later). If sodium and fluid restriction together with diuretic use results in decreased glomerular filtration rate (GFR), optimal volume status may be characterized by some amount of permissive peripheral edema. Modest-sized randomized studies have demonstrated that exercise training in patients with HFpEF improves exercise tolerance, although the effects on indices of diastolic function have been variable.[86,87]

Treatment of Comorbid Conditions

Patients with HFpEF frequently have important antecedent and comorbid diseases that can contribute to the development of HFpEF, affect its clinical severity, and precipitate decompensation. Accordingly, treating comorbid illnesses is an important element of management of patients with HFpEF. The most important and frequent comorbid conditions include arterial hypertension, obesity, diabetes, chronic kidney disease, obstructive sleep apnea, and anemia.

Most patients (>85%) with HFpEF have either current or previous hypertension. Untreated hypertension is a strong risk factor for the development of HF. Treatment of systolic hypertension in elderly patients (who have the highest risk for development of HFpEF) is associated with a more than 50% reduction in HF frequency.[86] Evidence-based therapy of HFpEF therefore includes control of systolic hypertension. The goal of therapy is systolic arterial pressure below 140 mm Hg and diastolic blood pressure below 90 mm Hg. However, recent large RCTs on hypertension suggest that even lower blood pressure targets less than 120 mm Hg systolic pressure may reduce the incident development of HFpEF.[88,89] Because of the arterial stiffening present in many patients, especially the elderly, adequate blood pressure control may be difficult to achieve. These patients also are prone to the development of orthostatic hypotension. Adequate treatment of patients with hypertensive heart disease includes not only control of the blood pressure but also prevention of LV hypertrophy or measures to induce regression of the hypertrophy, which will lead to reduced morbidity and mortality, improved exercise tolerance, and improved diastolic function.[90]

Diabetes and obstructive sleep apnea are common in HFpEF and are associated with worse outcomes. The available data suggest that treatment of diabetes and sleep apnea improves diastolic function and clinical status in patients with HFpEF. Thus, use of proven therapies for these conditions is an important component of managing patients with HFpEF.

Obesity is highly prevalent among patients with HFpEF. For example, the large ADHERE Registry found that more than half of patients weigh more than 172 pounds, and one quarter weigh more than 213 pounds. This is an impressive finding, because a majority of the patients are elderly women.[91] Obesity

itself impairs exercise intolerance but also contributes to the development of hypertension, diabetes, and sleep apnea. BMI is an important predictor of outcomes in patients with HFpEF. Weight loss produced by bariatric surgery, caloric reduction, and exercise improves indices of diastolic function. Thus, weight loss through diet, bariatric surgery, or appetite-suppressant drugs may represent an important management strategy for obese patients with HFpEF.

Chronic kidney disease frequently accompanies HFpEF and contributes to decompensations. GFR is an important predictor of outcomes in patients with HFpEF, with decreasing estimated GFR predicting increased event rates. Finally, anemia is common in HFpEF and is associated with a worse prognosis.

Sensor-Based Strategies

A number of novel sensor-based management strategies are being developed that provide facilitated management of HFpEF using remote monitoring–based tailored therapy. These include both implantable hemodynamic monitors (IHMs), subcutaneous and cutaneous sensors, noninvasive monitors (to assess measures of volume status, heart rate, rhythm, sympathetic tone, and activity), and serum/plasma-measured biomarkers.

Remote Monitoring Systems to Help Tailor Management

In the Chronicle Offers Management to Patients with Advanced Signs and Symptoms of Heart Failure (COMPASS-HF) trial, 70 patients with HFpEF (with EF >50%) were studied using an IHM that measured an estimated pulmonary artery diastolic pressure (ePAD), a measurement that in the absence of pulmonary vascular disease approximates PCWP. This study demonstrated that (1) patients with HFpEF demonstrated significantly increased filling pressures even while they were considered to be in a compensated state by their physicians; (2) these pressures rose further when they became decompensated; and (3) both baseline pressures and change from baseline pressures predicted outcomes, including the rates of HF hospitalization and CV mortality.[92-95] Additional measurements that reflect diastolic pressure and interstitial volume, such as baseline and change from baseline measures of thoracic impedance, also have been shown to predict outcomes, including rates of HF hospitalization and CV mortality.[96] The investigators hypothesized that modifying treatment based on data obtained from remote monitoring using an IHM would decrease baseline pressure, prevent an increase in pressure, and lower HF events in HFpEF. This hypothesis was tested in the CardioMEMS Heart Sensor Allows Monitoring of Pressure to Improve Outcomes in NYHA Class III Heart Failure Patients (CHAMPION) trial. One half of the 152 enrolled patients with HFpEF were managed using pulmonary artery diastolic pressure information from an IHM; the other half received standard medical therapy without knowledge of the IHM data. Those in the active treatment arm demonstrated a 152% decrease in pulmonary artery diastolic and systolic pressures and a 52% decrease in HF-related events (both $P < 0.0001$ and control) and a decrease in CV mortality rate. In addition to IHM systems, noninvasive systems measuring indices of impedance and heart rate variability, rhythm, and activity are being developed and tested[96-99] (**see Fig. 26.8**).

Future Perspectives

Evidence-based guidelines for the treatment of symptomatic patients with HFrEF include the use of multiple drugs and devices. Thus, patients with HFrEF (EF <30%) and NYHA Class III status may be receiving a beta blocker, ACE inhibitor, or ARB; aldosterone antagonist; digitalis; diuretics; CRT; and implantable cardioverter-defibrillator (ICD) treatment. Each of these treatments targets a number of

different underlying pathophysiologic mechanisms that have been demonstrated to be operative in the development or progression of HFrEF. To date, when beta-blocker, ACE inhibitor, ARB, and digitalis treatments have been applied in HFpEF, outcomes have not been successful. These facts should inform the development of novel and effective management strategies for HFpEF in the following manner. First, the difference in outcomes of RCTs using the same agents in HFrEF versus HFpEF provides evidence of important and fundamental differences between these two heart failure syndromes. These differences include distinct underlying pathophysiologic targets for treatment. Novel and effective management of HFpEF must target these pathophysiologic mechanisms, including treatments that alter LV, myocardial, cellular/extracellular, and molecular structure and function. For example, treatments that restore calcium homeostasis, change the phosphorylation state of titin, reduce ECM fibrosis, and normalize natriuretic peptide levels may each contribute to improved outcomes in HFpEF. Second, comprehensive treatment will require multiple drugs and devices that individually target multiple independent mechanisms. This multitargeted approach is necessary because each mechanism, independent of other mechanisms, probably contributes to disease progression. Therefore, as in HFrEF patients, who often require five drugs and two devices for effective treatment, HFpEF patients will require a similar multitargeted approach with components that act synergistically to reduce morbidity and mortality in HFpEF.[100]

Guidelines

Heart Failure with a Preserved Ejection Fraction

Michael R. Zile and Sheldon E. Litwin

A joint task force of the American College of Cardiology and the American Heart Association (ACC/AHA) published updated comprehensive guidelines for the evaluation and management of heart failure with a preserved ejection fraction (HFpEF) in 2013.[1] An ACC/AHA/Heart Failure Society of America (HFSA)–focused update in 2017 made several important new recommendations to the guidelines (**Table 26G.1**).[2] The European Society of Cardiology (ESC) guidelines for the diagnosis and treatment of heart failure with a preserved ejection fraction (HFpEF) were published 2016.[3] Most notably, the 2017 ACC/AHA/HFSA guidelines provide qualified support (class IIb, level of evidence B-R) for the use of aldosterone receptor antagonists to decrease hospitalizations. The 2017 guidelines also provide a class III: no benefit recommendation for the routine use of nitrates or phosphodiesterase-5 inhibitors to increase activity or quality of life in patients with HFpEF.

TABLE 26G.1

ACC/AHA/HFSA Guidelines for Treatment of Patients with Stage C Heart Failure and Preserved Left Ventricular Ejection Fraction (HFpEF)

CLASS	INDICATION	LEVEL OF EVIDENCE
I	Systolic and diastolic blood pressure should be controlled in accordance with published clinical practice guidelines to prevent morbidity.	B
	Diuretics should be used for relief of symptoms due to volume overload.	C
IIa	Coronary revascularization is reasonable in patients with coronary artery disease in whom symptoms (angina) or demonstrable myocardial ischemia is judged to be having an adverse effect on symptomatic heart failure.	C
	Management of atrial fibrillation according to published clinical practice guidelines is reasonable to improve symptomatic heart failure.	C
	The use of beta-blocking agents, ACE inhibitors, and ARBs in patients with hypertension is reasonable to control blood pressure.	C
IIb	In appropriately selected patients with HFpEF (with EF ≥45%, elevated BNP levels or heart failure admission within 1 year, estimated glomerular filtration rate >30 mL/min, creatinine <2.5 mg/dL, potassium <5.0 mEq/L), aldosterone receptor antagonists might be considered to decrease hospitalizations.	B-R
IIb	The use of ARBs might be considered to decrease hospitalizations.	B
III: no benefit	The routine use of nitrates or phosphodiesterase-5 inhibitors to increase activity or quality of life in patients with HFpEF is ineffective.	B-R
III: no benefit	Routine use of nutritional supplements is not recommended.	C

ACE, Angiotensin-converting enzyme; *ARB,* angiotensin receptor blocker; *BNP,* B-type (brain) natriuretic peptide.

Morbidity of HFpEF

Among patients with HFpEF, morbidity rates are comparable to those with HFrEF; heart failure (HF)–related hospital readmission rates approximate 50% at 6 months for both HFrEF and HFpEF. The lifetime burden for all-cause hospitalization is high and nearly equivalent for patients with HFpEF and those with HFrEF. All patients with heart failure (both HFpEF and HFrEF) have many comorbid conditions that

influence both morbidity and mortality. Like mortality, the HF hospitalization rates in patients with HFpEF are not based solely on the presence of antecedent or comorbidities themselves. Data from RCTs have shown that the HF hospitalization rates in patients with HFpEF (who have antecedent and comorbid factors such as hypertension, coronary artery disease, and diabetes mellitus) are more than twice those in patients with hypertension, CAD, or DM who do not have HFpEF (**Fig. 26.3D**).[1] Rates of progressive functional decline after hospital admission for HF also are similar in patients with HFpEF and those with HFrEF. In addition to HF-related hospitalizations, abnormalities in exercise tolerance, maximum myocardial oxygen consumption (MVO_2), and quality-of-life assessment are similar for HFrEF and HFpEF.

Conversion From Heart Failure with Preserved Ejection Fraction to Heart Failure with Reduced Ejection Fraction

Conversion from HFpEF to HFrEF is uncommon and generally is associated with an incident injury (e.g., myocardial ischemia, viral infection, alcohol abuse, cancer chemotherapy).[2-6] For example, in one study, 1233 patients with HF had serial echocardiograms to determine the time course of changes in the left ventricular ejection fraction (LVEF) over a 5-year observation period.[5] On average, the LVEF decreased by approximately 0.06 over 5 years in the HFpEF group, whereas it increased by nearly 0.07 in the HFrEF group. These rates should be interpreted in light of the following limitations: HFpEF and HFrEF were divided on the basis of an EF of 50%; this value is an arbitrary cutoff. Clearly, patients with EF of 51% and those with EF of 49% are not substantially different and are likely to cross back and forth across the threshold. In addition, no uniform deterioration in EF occurred in patients with HFpEF. Some experienced no fall in EF, and a majority (>60%) did not demonstrate a decline in EF below 50%. Another prospective study of 343 patients with concentric LV remodeling (but no HF) found that over 7 years, only 7% developed eccentric remodeling with LV dilation and a fall in EF.[6] Thus, although treatment of HFrEF may result in normalization of EF, a decline in EF in HFpEF appears usually to be caused by an intercurrent event, most frequently ischemic injury.

Cellular Mechanisms of Myocardial Relaxation

The detachment of actin from myosin requires prompt decreases in cytosolic calcium concentrations during diastole. There are several causes for prolongation of the calcium transient (**see Chapter 24**), but particularly by reduced reuptake of calcium (Ca^{2+}) into the sarcoplasmic reticulum (SR) because of decreases in the amount or activity of the sarcoendoplasmic reticulum Ca^{2+}-ATPase (SERCA).[1] Beta-adrenergic stimulation activates protein kinase A (PKA), which phosphorylates phospholamban and removes its tonic inhibition of SERCA activity, hastening calcium reuptake and left ventricular (LV) relaxation. Beta-adrenergic/PKA-mediated phosphorylation of troponin I also hastens relaxation by decreasing calcium sensitivity, and reduced troponin I phosphorylation may accentuate afterload-induced changes in relaxation.[2] Impaired beta-adrenergic signaling is well established in HFrEF (**see Chapter 25**), in animal models of pressure overload with relevance to HFpEF, and with increasing clinical evidence in patients with HFpEF.[3] Chronic catecholamine activation contributes to beta-adrenergic receptor downregulation and desensitization, and catecholamine levels are elevated in HFpEF, suggesting that impaired beta-adrenergic signaling may contribute to relaxation impairment in HFpEF. More recently, chronotropic incompetence and impaired systolic and lusitropic reserve function have been reported in HF with normal (nl) EF, findings that further support a role for impaired beta-adrenergic signaling in HFpEF.[4-9] Phospholamban phosphorylation may also be reduced by increases in protein kinase C (PKC) through effects on protein phosphatases.[10] PKC activity is increased in HF with reduced EF and in animal models of pressure overload relevant to HFpEF. In addition, transsarcolemmal extrusion of calcium, while only 5% of all calcium movement in normal patients, is increased in animal models of pressure overload with relevance to HFpEF and appears to fail during decompensation. Therefore, impaired beta-adrenergic/PKA signaling, reduced SERCA amount and activity, increased PKC activity, and decreased Na-Ca exchanger function all contribute to the development of abnormal diastolic function and may provide potential novel therapeutic targets for HFpEF therapies.

Energy (ATP) supply influences relaxation by regulating calcium reuptake via SERCA and by influencing cross-bridge detachment at the myosin heads, where the phosphocreatine shuttle mechanism ensures delivery of adenosine triphosphate (ATP) from the mitochondria and removal of adenosine diphosphate (ADP) and inorganic phosphate (P_i) from the site of cross-bridge formation (**see Chapter 24**). Inadequate ATP and increased levels of ADP at the cross-bridge sites impair cross-bridge detachment and slow relaxation. Impaired relaxation is the first functional abnormality to occur during acute ischemia and with persistent ischemia is accompanied by parallel upward shifts of the diastolic pressure-volume relationship (decreased distensibility) due to rigor bonds. Both features may contribute to the elevated filling pressures with ischemia. Hypertrophied hearts are more sensitive to ischemia, with greater increases in filling pressures resulting from ischemia. Impaired creatinine kinase ATP kinetics have been described in patients with HFpEF and linked to impaired relaxation and systolic reserve function.[7]

Changes in myofilament proteins such as titin and extramyofilament proteins such as microtubules may also affect the elastic properties of the cardiomyocyte and alter diastolic function in patients with HFpEF. Changes in titin isoforms and phosphorylation state affect cardiomyocyte distensibility, as does microtubule polymerization state. These proteins, along with calcium homeostasis, myofilament function, and energetics, determine the elastic properties of the cardiomyocyte (and as a result the left ventricle) and determine the distending force necessary to achieve an adequate end-diastolic volume (EDV) and resultant stroke volume (SV).

Limitations in Use of E/e′ Ratio

There are several situations where E/e′ may not provide an accurate assessment of pulmonary capillary wedge pressure (PCWP).[1] First, in a normal heart, e′ (early tissue velocity) occurs coincidentally with E (early transmitral flow velocity) and responds to changes in LA pressure. For example, E/e′ was not increased, but may decrease in response to massive fluid loading in normal experimental animals.[2] However, left atrial (LA) pressure is rarely elevated in patients with a normal heart.[3] Thus the failure of E/e′ to recognize elevated LA pressure in normal individuals is of little clinical importance. Second, E/e′ does not increase in patients with constrictive pericarditis despite elevated PCWP.[4] In fact, the medial e′ increases as constriction becomes worse, which results in a decrease in E/e′ as constriction becomes more severe and diastolic filling pressure increases (annulus paradoxus). If a patient has clinical signs of HF, especially with increased jugular venous pressure, a normal or increased medial e′ velocity strongly suggests constrictive pericarditis. Third, E/e′ may not provide an estimate of LA pressure in patients with mitral stenosis or mitral regurgitation, especially without a reduction in EF.[5,6] The mitral annular velocity should not work as well in patients with aortic or mitral valve replacement and mitral annulus calcification. However, this issue has not been systematically evaluated. Fourth, although E/e′ correlates with LA pressure in patients with hypertrophic cardiomyopathy, there is substantial scatter, limiting its use

alone in an individual patient.[7]

Indices of Myocardial Contractile Function and Assessment of Exercise Capacity in Heart Failure with Preserved Ejection Fraction

Indices of Myocardial Contractile Function

Although global left ventricular (LV) systolic performance at rest is normal in HFpEF, indices of myocardial contractile function such as midwall shortening, long-axis shortening, global longitudinal strain (GLS) and strain rate, and reduced apical systolic torsion may be reduced.[78] These regional abnormalities on LV ejection performance appear to be offset by concentric remodeling or hypertrophy, and enhanced circumferential shortening offsets the impact. Although these abnormalities of regional performance occur during systole, their greatest impact may occur during diastole. Decreased long-axis shortening and torsion lessen the diastolic recoil of elastic elements compressed during ejection, thereby diminishing the ability of the left ventricle to function as a suction pump, so LV filling becomes more dependent on left atrial (LA) pressure. Thus these regional systolic abnormalities result in significant increases in pulmonary venous filling pressures and symptoms of congestion and volume overload.

During exercise, patients with HFpEF have a decreased ability to augment indices of LV chamber systolic performance, function, and contractility. This decrement in adaptability to the demands of exercise may result from abnormalities in diastolic function, chronotropic incompetence, decreased response to sympathetic and renin-angiotensin-aldosterone system (RAAS) stimulation, or exaggerated increase in afterload. For example, decreased diastolic distensibility prevents the left ventricle from recruiting Starling forces in patients with HFpEF; thus abnormal diastolic function limits augmentation of systolic properties. In addition, because hypertensive heart disease is common in HFpEF, many patients with HFpEF have limited exercise tolerance because of the exaggerated increase in blood pressure that accompanies exercise; this increased afterload prolongs relaxation and decreases diastolic distensibility. Finally, because systolic and arterial elastances are increased in HFpEF, exercise-induced increases in

RAAS and sympathetic stimulation are unable to augment systolic properties sufficiently to maintain adequate stroke volume.[79]

Assessment of Exercise Capacity

Patients with HFpEF have a symptomatic disability that is evident by a reduction in their exercise tolerance. This disability can be objectively assessed by a 6-minute hall walk (6MHW), standard exercise treadmill, and cardiopulmonary exercise testing. These tests have important diagnostic utility in HFpEF patients, particularly if the cause of the exercise intolerance is unclear or the diagnosis is uncertain. In addition, cardiopulmonary exercise testing can identify poor motivation, deconditioning, and pulmonary disease as alternate explanations for dyspnea (**see Chapter 13**). These objective measures of exercise tolerance are similarly impaired in HFpEF and HFrEF, with equivalent decreases in time and distance on the treadmill and decreases in maximum myocardial oxygen consumption (MVO_2). Exercise testing can identify factors that contribute to the clinical syndrome of HFpEF and that potentially can be modified. For example, an exaggerated increase in systolic arterial pressure during exercise can cause load-dependent diastolic dysfunction. Pharmacologic reduction of this response can improve exercise tolerance in HFpEF. Because augmentation of the stroke volume is limited in HFpEF, the cardiac output is very dependent on increased heart rate. In HFpEF patients with an inadequate increase in heart rate with exercise (chronotropic incompetence), limiting beta-adrenergic blockers or even rate-responsive pacing may improve exercise tolerance. Finally, exercise training improves exercise tolerance in HFpEF by reversing some of the effects of deconditioning. Exercise training may also improve indices of diastolic function. Changes in exercise capacity that limit functional capacity can be assessed by a variety of quality of life (QOL) measurements. A number of QOL surveys have been validated and used in studies in HFpEF. These include Quality of Life in Severe Heart Failure Questionnaire (QLSHFQ), the Chronic Heart Failure Questionnaire (CHQ), the Left Ventricular Dysfunction Questionnaire (LVD), and the Minnesota Living with Heart Failure Questionnaire (MLHFQ). The three most commonly used are the QLSHFQ, CHQ, and MLHFQ.[1]

Devices for Monitoring and Managing Heart Failure

William T. Abraham

The U.S. Food and Drug Administration (FDA) approval of the first cardiac resynchronization therapy (CRT) device in 2001 initiated a new era of implantable device therapies for the management of heart failure (HF). Since then, implantable cardioverter-defibrillators (ICDs) and combined CRT-ICD devices have also received FDA approval for the management of HF. ICDs became indicated for the primary prevention of all-cause mortality through a reduction in the incidence of sudden cardiac death (SCD) in patients with heart failure and reduced ejection fraction (HFrEF). Combined CRT-ICD devices were shown to reduce morbidity and mortality in HF patients with ventricular dyssynchrony, with a suggestion of additive benefit over a CRT device alone. In acknowledgment of the evidence-based benefits of these

devices, the 2005 update to the American College of Cardiology/American Heart Association (ACC/AHA) heart failure guideline strongly supported, with class I indications, the use of ICD and CRT devices in the management of eligible HF patients[1]; these indications were updated in 2013[2] (**see Table 27G.1**).

In addition to these therapeutic devices, implantable devices that monitor physiologic parameters such as patient activity level, heart rate variability, intrathoracic impedance, and hemodynamics have been developed. In some cases these data are already available in currently implantable CRT and ICD devices. The utility of such device-based diagnostic or monitoring information is unknown and currently under investigation. This chapter reviews the use of CRT and ICDs for the management of heart failure and discusses the potential utility of implantable HF-monitoring devices. The medical management of HF is discussed in **Chapters 25 and 26**.

Ventricular Dyssynchrony: the Target of Cardiac Resynchronization Therapy

Several conduction abnormalities are commonly seen in association with chronic heart failure. Among these are abnormalities of ventricular conduction, such as bundle branch blocks, that alter the timing and pattern of ventricular contraction so as to place the already failing heart at a further mechanical disadvantage. These ventricular conduction delays produce suboptimal ventricular filling, a reduction in left ventricular (LV) contractility, prolonged duration of mitral regurgitation, and paradoxical septal wall motion.[3,4] Taken together, these mechanical manifestations of altered ventricular conduction have been termed *ventricular dyssynchrony*. Ventricular dyssynchrony has been defined by a prolonged QRS duration, generally greater than 120 milliseconds, on the surface electrocardiogram (ECG). By this definition, about one third of patients with systolic HF have ventricular dyssynchrony. In addition to reducing the ability of the failing heart to eject blood, ventricular dyssynchrony has also been associated with increased mortality in HF patients.

Ventricular dyssynchrony may now be addressed with pacing therapy, through the implantation of pacing leads to both right and left ventricles. This form of pacing therapy is now known as *cardiac resynchronization therapy*. Favorable single-case experiences with CRT in the mid-1990s lead to small observational studies evaluating the acute effects of CRT on hemodynamics and other measures of cardiac performance.[5] These studies provided additional proof of concept supporting the use of CRT. Several uncontrolled or unblinded studies soon followed to evaluate further the acute and longer-term effects of CRT on clinical status in HF patients.[5] The results of these trials were equally encouraging, with patients demonstrating consistent, sustained improvement in exercise tolerance, quality of life, and New York Heart Association (NYHA) functional class. Finally, large-scale randomized controlled trials (RCTs) confirmed the beneficial effects of CRT on functional status and outcomes, leading to the initial indications for this therapy. More recent trials have both expanded and limited the indications for CRT.

Randomized Controlled Trials of CRT in NYHA Class III and IV Patients

More than 4000 patients have been evaluated in RCTs of CRT in NYHA Functional Class III and IV heart failure. The following RCTs are considered among the landmark studies of CRT in this patient population: the Multisite Stimulation in Cardiomyopathy (MUSTIC) studies,[6,7] Multicenter InSync

Randomized Clinical Evaluation (MIRACLE) trial,[8,9] MIRACLE ICD trial,[10] CONTAK CD trial,[11] Cardiac Resynchronization in Heart Failure (CARE HF) trial,[12,13] and Comparison of Medical Therapy, Pacing and Defibrillation in Heart Failure (COMPANION) trial.[14,15] To understand the clinical benefits, risks, and limitations of CRT with or without an ICD, these studies are reviewed.

Multisite Stimulation in Cardiomyopathy Trials

The MUSTIC trials were designed to evaluate the safety and efficacy of CRT in patients with advanced HF, ventricular dyssynchrony, and either normal sinus rhythm[6] or atrial fibrillation (AF).[7] They represent the first randomized single-blinded trials of CRT for HF. The first study involved 58 randomized patients with NYHA Class III HF, normal sinus rhythm, and a QRS duration of at least 150 milliseconds. All patients were implanted with a CRT device, and after a run-in period, patients were randomized to either active pacing or no pacing. After 12 weeks, patients were crossed-over and remained in the alternate study assignment for 12 weeks. The second MUSTIC study involved fewer patients (only 37 completers) with AF and a slow ventricular rate (either spontaneously or from radiofrequency ablation). A VVIR biventricular pacemaker and leads for each ventricle were implanted, and the same randomization procedure described above was applied; however, biventricular VVIR pacing versus single-site right ventricular VVIR pacing (rather than no pacing) were compared in this group of patients with AF.

The primary endpoints for MUSTIC were exercise tolerance assessed by measurement of peak oxygen consumption (VO_2) or the 6-minute hall walk distance (6MHWD) test and quality of life determined using the Minnesota Living with Heart Failure (MLWHF) questionnaire. Secondary endpoints included rehospitalizations and/or drug therapy modifications for worsening HF. Results from the normal sinus rhythm arm of MUSTIC provided strong evidence of benefit. The mean 6MHWD was 23% greater with CRT than without CRT ($P < 0.001$). Significant improvement was also seen in quality of life and NYHA functional class ranking. There were fewer hospitalizations during active resynchronization therapy. The AF cohort evaluated in MUSTIC demonstrated similar improvements, although the magnitude of benefit was slightly less.

Multicenter InSync Randomized Clinical Evaluation

MIRACLE was the first prospective, randomized, double-blind, parallel-controlled clinical trial designed to evaluate the benefits of CRT.[8,9] Primary endpoints were NYHA class, quality of life score (using the MLWHF questionnaire), and 6MHWD. Secondary endpoints included assessments of a composite clinical response, cardiopulmonary exercise performance, cardiac structure and function, a variety of measures of worsening HF, and combined morbidity and mortality.

The MIRACLE trial was conducted between 1998 and 2000. It included 453 patients with moderate to severe symptoms of HF associated with a left ventricular ejection fraction (LVEF) of 35% or less and a QRS duration of at least 130 milliseconds. They were randomized (double-blind) to CRT ($n = 228$) or to a control group ($n = 225$) for 6 months, while conventional therapy for HF was maintained. Compared with the control group, patients randomized to CRT demonstrated a significant improvement in quality of life score (–18.0 versus –9.0 points; $P = 0.001$), 6MHWD (+39 vs. +10 meters [m]; $P = 0.005$), NYHA functional class ranking (–1.0 vs. 0.0 class; $P < 0.001$), treadmill exercise time (+81 vs. +19 sec; $P = 0.001$), peak VO_2 (+1.1 vs. 0.1 mL/kg/min; $P < 0.01$), and LVEF (+4.6% vs. –0.2%; $P < 0.001$). Patients randomized to CRT demonstrated a highly significant improvement in a composite clinical HF response endpoint, compared to controls, suggesting an overall improvement in HF clinical status (**Fig. 27.1**). In addition, when compared with the control group, fewer patients in the CRT group required hospitalization

(8% vs. 15%) or intravenous medications (7% and 15%) for the treatment of worsening HF (both $P < 0.05$). In the CRT group, the 50% reduction in hospitalization was accompanied by a significant reduction in length of stay, resulting in a 77% decrease in total days hospitalized over 6 months compared to the control group. The major limitation of the therapy resulted from unsuccessful implantation of the device in 8% of patients. The results of this trial led to FDA approval of the InSync system in August 2001, the first approved CRT system in America, allowing the introduction of CRT into clinical practice.

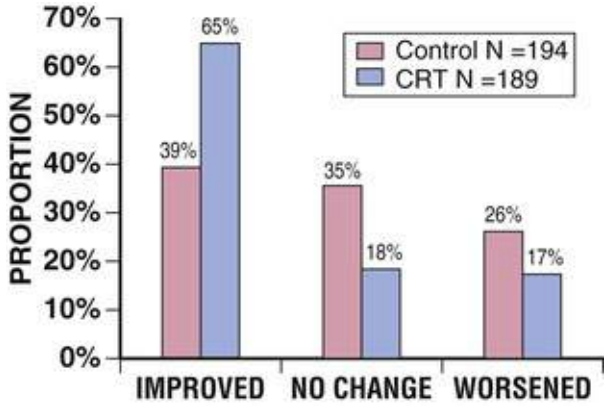

FIGURE 27.1 Effect of cardiac resynchronization therapy (CRT) on a composite clinical response endpoint in the MIRACLE trial. *Worsened:* Patient dies; or is hospitalized due to or associated with worsening heart failure; or demonstrates worsening in NYHA class at last observation carried forward (LOCF) or moderate-marked worsening of patient global assessment score at LOCF. *Improved:* Patient has not worsened (as defined above) and demonstrates improvement in NYHA class at LOCF and/or moderate-marked improvement in patient global assessment score at LOCF. *Unchanged:* Patient is neither improved nor worsened. $P < 0.001$ for chi-square analysis. (Modified from Abraham WT, Fisher WG, Smith AL, et al, for the Multicenter InSync Randomized Clinical Evaluation (MIRACLE) Investigators and Coordinators. Double-blind, randomized controlled trial of cardiac resynchronization in chronic heart failure. N Engl J Med 2002;346:1845-53.)

The MIRACLE trial also provided persuasive evidence supporting the occurrence of reverse LV remodeling with chronic CRT. Serial Doppler echocardiograms were obtained at baseline, 3 months, and 6 months in a subset of 323 patients. CRT for 6 months was associated with reduced end-diastolic and end-systolic volumes (both $P < 0.001$), reduced LV mass ($P < 0.01$), increased LVEF ($P < 0.001$), reduced mitral regurgitant blood flow ($P < 0.001$), and improved myocardial performance index ($P < 0.001$), compared with controls. These effects are similar to those seen with beta-adrenergic blockade in HF but were seen in MIRACLE in patients already receiving beta-blocker therapy.

Multicenter InSync–Implantable Cardioverter-Defibrillator Randomized Clinical Evaluation

The MIRACLE ICD study was designed to be almost identical to the MIRACLE trial. MIRACLE ICD was a prospective, multicenter, randomized, double-blind, parallel-controlled clinical trial intended to assess the safety and efficacy of a combined CRT-ICD system in patients with dilated cardiomyopathy (LVEF ≤35%; left ventricular end-diastolic dimension [LVEDD] ≥55 mm), NYHA Class III or IV HF, ventricular dyssynchrony (QRS ≥130 msec), and an indication for an ICD.[10] Primary and secondary efficacy measures were essentially the same as those evaluated in the MIRACLE trial, but also included measures of ICD function.

Of 369 patients receiving devices and randomized, 182 were controls (ICD activate, CRT inactive), and 187 were in the resynchronization group (ICD activate, CRT active). At 6 months, patients assigned to active CRT had a greater improvement in median quality-of-life score (–17.5 vs. –11.0; $P = 0.02$) and

functional class (–1 vs. 0; $P = 0.007$) than controls, but were no different than controls in the change in distance walked in 6 minutes (55 vs. 53 m; $P = 0.36$). Peak $\dot{V}O_2$ increased by 1.1 mL/kg/min in the resynchronization group, versus 0.1 mL/kg/min in controls ($P = 0.04$), while treadmill exercise duration increased by 56 seconds in the CRT group and decreased by 11 seconds in controls ($P = 0.0006$). The magnitude of improvement was comparable to that seen in the MIRACLE trial, suggesting that HF patients with an ICD indication benefit as much from CRT as those without an indication for an ICD. The combined CRT-ICD device used in this study was approved by the FDA in June 2002 for use in NYHA Class III and IV systolic HF patients with ventricular dyssynchrony and an ICD indication.

CONTAK CD

The CONTAK CD trial enrolled 581 symptomatic HF patients with ventricular dyssynchrony and malignant ventricular tachyarrhythmias, who were all candidates for an ICD.[11] Following unsuccessful implant attempts and withdrawals, 490 patients were available for analysis. The study did not meet its primary endpoint of a reduction in disease progression, defined by a composite endpoint of HF hospitalization, all-cause mortality, and ventricular arrhythmia requiring defibrillator therapies, although the trends were in a direction favoring improved outcomes with CRT. However, the CONTAK CD trial did demonstrate statistically significant improvements in peak $\dot{V}O_2$ and quality of life in the resynchronization group compared to controls, although quality of life was improved only in NYHA Class III and IV patients without right bundle branch block. LV dimensions were also reduced, and LVEF increased, as seen in other trials of CRT. Importantly, the improvement seen in peak $\dot{V}O_2$ with cardiac resynchronization was again comparable to that observed in the MIRACLE trial. Improvements in NYHA functional class were not observed in this study. The CONTAK CD device was approved by the FDA for use in NYHA Class III and IV systolic HF patients with ventricular dyssynchrony and an ICD indication in May 2002.

Cardiac Resynchronization in Heart Failure Trial

The CARE HF trial was designed to evaluate the effects of CRT without an ICD on morbidity and mortality in patients with NYHA Class III or IV HF and ventricular dyssynchrony.[12,13] In this unblended RCT, 819 patients with an LVEF of 35% or less and ventricular dyssynchrony (defined as QRS duration ≥150 msec or 120-150 msec, with echocardiographic evidence of dyssynchrony) were followed for an average of 29.4 months; 404 patients were assigned to receive optimal medical therapy alone, and 409 were randomized to optimal medical therapy plus CRT. The primary endpoint, risk of death from any cause or unplanned hospitalization for a major cardiac event, analyzed as time to first event, was significantly reduced by 37% in the treatment group compared to the control group (hazard ratio [HR], 0.63; 95% confidence interval [CI] 0.51 to 0.77; $P < 0.001$). In the CRT group, 82 patients (20%) died during follow-up compared to 120 patients (30%) in the medical group, yielding a significant 36% reduction in all-cause mortality with CRT (HR, 0.64; 95% CI 0.48 to 0.85; $P < 0.002$; **Fig. 27.2**). CRT also significantly reduced the risk of unplanned hospitalization for a major cardiac event by 39%, all-cause mortality plus HF hospitalization by 46%, and HF hospitalization by 52%.

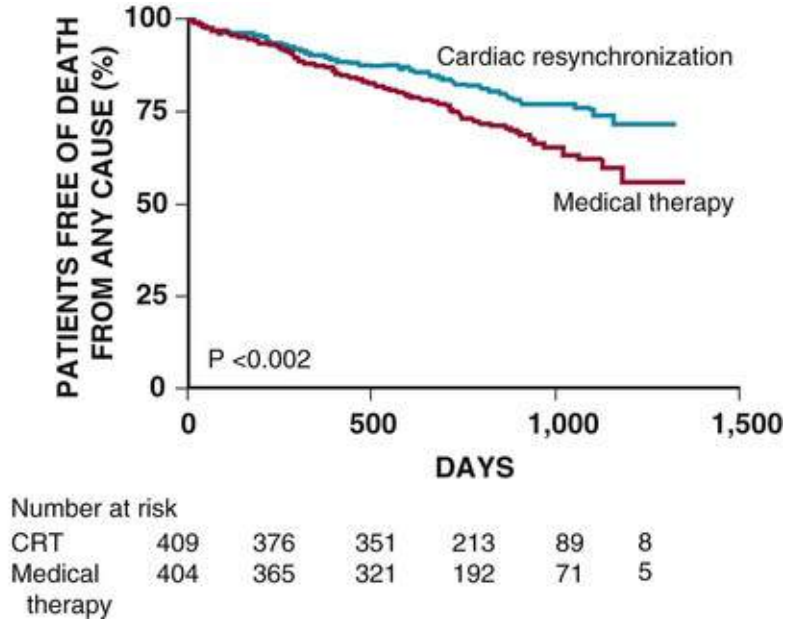

FIGURE 27.2 Kaplan-Meier estimates of survival in patients randomized to CRT compared to conventional medical therapy in the CARE-HF trial. (Modified from Cleland JGF, Daubert JC, Erdmann E, et al, for the Cardiac Resynchronization–Heart Failure (CARE-HF) Study Investigators. The effect of cardiac resynchronization on morbidity and mortality in heart failure. N Engl J Med 2005;352:1539-49.)

Comparison of Medical Therapy, Pacing, and Defibrillation in Heart Failure

Begun in early 2000, COMPANION was a multicenter, prospective RCT designed to compare drug therapy alone to drug therapy combined with CRT in patients with dilated cardiomyopathy, an intraventricular conduction defect (IVCD), NYHA Class III or IV HF, and no indication for a device.[14,15] The COMPANION trial randomized 1520 patients into one of three treatment groups in a 1 : 2:2 allocation: group I (308 patients) received optimal medical care only, group II (617 patients) received optimal medical care and the Guidant CONTAK TR (biventricular pulse generator), and group III (595 patients) received optimal medical care and the CONTAK CD (combined HF/bradycardia-tachycardia device). The primary endpoint was a composite of all-cause mortality and all-cause hospitalization, measured as time to first event, beginning from time of randomization. Secondary endpoints included all-cause mortality and a variety of measures of CV morbidity. Compared to optimal medical therapy alone, the combined endpoint of mortality or HF hospitalization was reduced by 35% for patients receiving CRT and 40% for patients receiving CRT-ICD (both $P < 0.001$). For the mortality endpoint alone, CRT patients had a 24% risk reduction ($P = 0.060$), and CRT-ICD patients experienced a risk reduction of 36% ($P < 0.003$), compared to optimal medical therapy (**Fig. 27.3**). COMPANION confirmed the results of earlier CRT trials in improving symptoms, exercise tolerance, and quality of life for HF patients with ventricular dyssynchrony. In addition, COMPANION showed for the first time the impact of CRT-ICD in reducing all-cause mortality and suggested incremental benefit from combined device therapies.

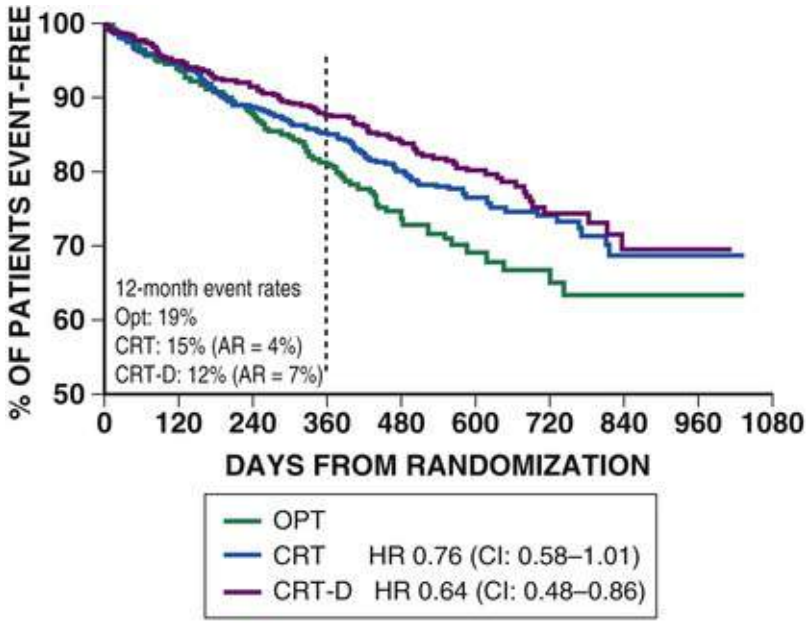

FIGURE 27.3 Kaplan-Meier estimates of the time to death from any cause in patients randomized to optimal medical therapy (OPT) alone versus OPT with CRT alone versus OPT with a combined CRT-ICD device in the COMPANION trial; AR, absolute risk; HR, hazard ratio; RR, relative risk. (Modified from Bristow MR, Saxon LA, Boehmer J, et al. Cardiac-resynchronization therapy with or without an implantable defibrillator in advanced chronic heart failure. N Engl J Med 2004;350:2140-50.)

Guideline Recommendation

These trials in NYHA Class III and IV HF patients established the initial guideline recommendation for CRT: “Patients with LVEF less than or equal to 35%, sinus rhythm, and NYHA Functional Class III or ambulatory Class IV symptoms despite recommended optimal medical therapy and who have cardiac dyssynchrony, which is currently defined as a QRS greater than or equal to 0.120 seconds, should receive CRT, with or without an ICD, unless contraindicated (Level of Evidence: A).”[1] These guidelines have been updated and are discussed later under indications for CRT.

More recent clinical trials in CRT have focused on delaying progression of HF in asymptomatic or less symptomatic patients. The MIRACLE-ICD II trial suggested such a benefit in a small cohort of NYHA Class II patients,[16] leading to subsequent large-scale trials in this population.

Randomized Controlled Trials of CRT in NYHA Class I and II Patients

More than 4500 patients have been evaluated in trials of CRT in NYHA Functional Class I and II heart failure. The following RCTs are considered among the landmark studies of CRT in this patient population: the Resynchronization Reverses Remodeling in Systolic Left Ventricular Dysfunction (REVERSE) trial,[17,18] Multicenter Automatic Defibrillator Implantation Trial with Cardiac Resynchronization Therapy (MADIT-CRT),[19,20] and Resynchronization/defibrillation for Ambulatory Heart Failure Trial (RAFT).[21]

Resynchronization Reverses Remodeling in Systolic Left Ventricular Dysfunction Trial

The REVERSE trial was a double-blinded RCT designed to address the benefit of CRT on heart failure morbidity in patients with mild HF compared to optimal medical therapy alone;[17,18] 610 patients with NYHA Class I and II HF (QRS ≥120 msec, LVEF ≤40%, LVEDD ≥55 mm) were randomized. All patients received a CRT device with or without an ICD, and 191 were assigned to the control of optimal medical therapy alone (CRT off) and 419 to the CRT group combined with optimal medical therapy. The primary endpoint was a clinical composite HF score. The study goal was to determine the effect on preventing disease progression, so a "worsened" status was considered a negative outcome.

While the percent worsened in the clinical composite response endpoint was not significantly reduced in the CRT compared to control group (16% vs. 21%; $P = 0.10$), a significant benefit of CRT was seen in improvement in ventricular structure and function and in HF morbidity, which was also significantly improved with a 53% relative risk reduction (RRR) in the time to first HF hospitalization (HR, 0.47; $P = 0.03$). Thus, REVERSE was the first large, randomized, multicenter trial to demonstrate the potential for CRT to slow progression of disease through reverse remodeling in NYHA Class I and II HF patients with ventricular dyssynchrony.

Multicenter Automatic Defibrillator Implantation Trial with Cardiac Resynchronization Therapy

The MADIT-CRT trial was a multicenter RCT designed to address the potential survival and morbidity benefit of CRT in NYHA Class I and II HF patients by assessing the reduction in risk of death and nonfatal HF events in this population.[19] Prophylactic CRT combined with an ICD was compared to ICD only in 1820 patients (LVEF ≤30%, QRS ≥130 msec) with either an ischemic (Class I patients) or any (Class II patients) cause. The study was not blinded; the treating physicians were aware of the study group assignments.

During the average follow-up of 2.4 years, the primary endpoint of death from any cause or nonfatal HF event occurred in 17.2% of the CRT-ICD group versus 25.2% of the ICD-only group, with RRR of 34% (HR, 0.66; 95% CI 0.52 to 0.84; $P = 0.001$). This significant benefit was driven by a 41% reduction in HF events (13.9% vs. 22.8%; HR, 0.59; 95% CI 0.47 to 0.74; $P < 0.001$). In terms of prespecified subgroups, both ischemic and nonischemic groups showed benefit with CRT; however, a greater benefit was noted for women versus men and in patients with QRS of 150 milliseconds or longer. Another factor predicting CRT responsiveness in this trial was QRS morphology; patients benefiting most had left bundle branch block (LBBB).[22] The MADIT-CRT trial led the FDA to expand the indication for CRT to NYHA Class II or ischemic Class I patients, with LVEF less than 30%, QRS duration longer than 130 milliseconds, and LBBB, for the devices evaluated in this study.

Resynchronization/Defibrillation for Ambulatory Heart Failure Trial

The RAFT trial differed from the REVERSE and MADIT-CRT trials in that, initially, patients in NYHA Class II and III were included. However, after data from the CARE HF trial showed a clear reduction in mortality for patients in NYHA Class III, the protocol was revised to include only patients in Class II. Importantly, the RAFT trial was the first to show a mortality benefit of combined CRT-ICD over an ICD alone, and a mortality reduction with the addition of CRT in patients in NYHA Class II HF.[21] The primary outcome of all-cause mortality or hospitalization for HF occurred in 40% and 33% of the ICD and CRT-ICD groups, respectively, with a significant delay to time of occurrence of the primary outcome in the CRT-ICD group. Overall, 23.5% of the patients died. The 5-year actuarial death rate was lower (28.6% vs. 34.6%) and the time to death longer in the CRT-ICD patients than in the ICD group. On the basis of

these results, 14 patients would need to be treated with a CRT-ICD for 5 years to prevent one death, compared to those treated with an ICD alone. These benefits were at the expense of an increased rate of procedure-related adverse events.

Nevertheless, the results from RAFT and REVERSE resulted in the FDA expanding the indication for certain CRT devices to include patients with mildly symptomatic HF (NYHA Class II, with LVEF ≤30%, LBBB, and QRS ≥130 msec).

CRT in Patients with Narrow QRS Complex

Mechanical dyssynchrony occurs in patients with a narrow QRS complex, suggesting the potential usefulness of CRT in HF patients with narrow QRS and imaging-identified (usually echocardiographic) ventricular dyssynchrony. Preliminary studies suggested the benefits of CRT in such patients; however, a definitive trial, Echocardiography Guided Cardiac Resynchronization Therapy (EchoCRT), did not confirm these benefits.[23] The EchoCRT trial evaluated the effect of CRT in patients with NYHA Class III or IV HF, LVEF of 35% or less, QRS duration less than 130 milliseconds, and echocardiographic evidence of LV dyssynchrony. All patients underwent device implantation and were randomly assigned to have CRT turned on or off. The primary efficacy outcome was the composite of death from any cause or first hospitalization for worsening HF. The study was stopped for futility on the recommendation of the Data and Safety Monitoring Board. Of the 809 randomized patients followed for a mean of 19.4 months, the primary outcome occurred in 116 of 404 patients in the CRT group, versus 102 of 405 in the control group (28.7% vs. 25.2%; HR, 1.20; 95% CI 0.92 to 1.57; *P* = 0.15) (**Fig. 27.4**). There were 45 deaths in the CRT group and 26 in the control group (11.1% vs. 6.4%; HR, 1.81; 95% CI 1.11 to 2.93; *P* = 0.02), demonstrating the potential for harm in using CRT in narrow-QRS patients. Thus, CRT is considered contraindicated in these patients.

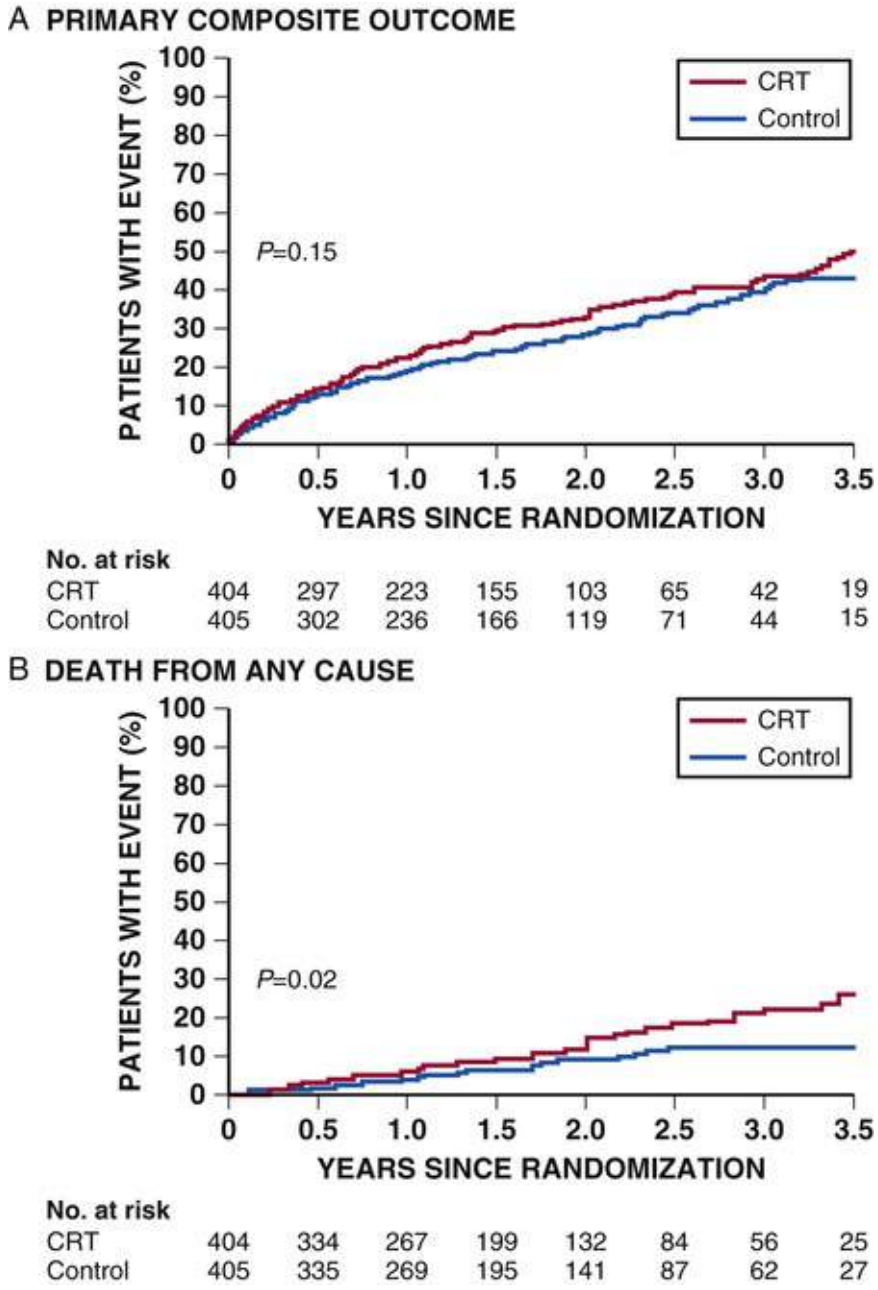

FIGURE 27.4 Effect of CRT on morbidity and mortality in heart failure patients with narrow QRS complex and echocardiographic ventricular dyssynchrony. **A,** Kaplan-Meier curves for the primary composite outcome of death from any cause or hospitalization for heart failure. **B,** Kaplan–Meier curves for death from any cause. (From Ruschitzka F, Abraham WT, Singh JP, et al. Cardiac-resynchronization therapy in heart failure with a narrow QRS complex. N Engl J Med 2013;369:1395-405.)

Indications for CRT in Patients with Heart Failure

Since the original 2005 guideline recommendation for CRT, the indications for CRT have been expanded to less symptomatic patients, but also limited on the basis of QRS morphology and QRS duration.[2,24] Current guideline recommendations define ventricular dyssynchrony by QRS duration, rather than by imaging (echocardiography)–assessed ventricular dyssynchrony. Subgroup analyses from REVERSE, MADIT-CRT, and RAFT suggest that patients with QRS duration of 150 milliseconds or more and/or with LBBB morphology benefit most from CRT. Based on these observations, the recommendations for the use of CRT were substantially revised in 2012 (**see Table 27G.1**).[24]

According to these revised CRT guidelines, indications for CRT include patients who have an LVEF of 35% or less, sinus rhythm, LBBB with QRS of 120 milliseconds or longer, and NYHA Class II, III, or

ambulatory IV symptoms while receiving optimal medical treatment. Although the level of indication is somewhat stronger for patients fulfilling these criteria with QRS of 150 milliseconds or greater, CRT should generally be offered to all HF patients with a reduced EF and LBBB. In patients with more advanced HF (i.e., NYHA Class III or ambulatory Class IV patients), those fulfilling the aforementioned criteria with a QRS duration of at least 150 milliseconds and non-LBBB morphology should also be considered for CRT.

Limitations of CRT

The success rate for placement of a transvenous cardiac resynchronization system has ranged from about 88% to 92% in clinical trials, although in contemporary clinical experience it is as high as 97% to 98% in some centers (e.g., Ohio State University experience). Thus, some patients undergoing an implant procedure will not receive a functioning system using this approach. Implant-related complications are similar to those seen with standard pacemakers and defibrillators, with the additional risk of dissection or perforation of the coronary sinus. This is a rare event but may lead to substantial morbidity and even mortality in HF patients

Despite the results of randomized controlled CRT trials, some patients do not respond to this therapy. The nonresponder rate for cardiac resynchronization therapy appears to be about 25%, a rate that is similar to the nonresponder rate for HF drug therapies. Factors proposed as contributing to the nonresponder rate associated with CRT include suboptimal LV lead placement, suboptimal AV and VV timing, ventricular scar, and HF disease progression.

Sudden Cardiac Death in Heart Failure

Patients with heart failure and left ventricular systolic dysfunction are at increased risk for sudden cardiac death[25-27] (**see also Chapter 42**). SCD is the leading cause of mortality in patients with HF and occurs at a rate six to nine times that seen in the general population. Given this high incidence of SCD in HF patients, it was easy to hypothesize that an ICD used as prophylactic therapy would reduce total mortality by reducing the incidence of SCD. A series of studies have tested this hypothesis.

Randomized Controlled Trials of Implantable-Cardioverter Defibrillators for Heart Failure

Several early studies supported the benefit of prophylactic ICD implantation, but none of them proved this conclusively. The landmark trials establishing a role for ICDs as primary prevention of mortality in HF patients are the Multicenter Automatic Defibrillator Implantation II (MADIT II),[28] Prophylactic Defibrillator Implantation in Patients with Nonischemic Dilated Cardiomyopathy (DEFINITE),[29] and the National Institutes of Health (NIH)–sponsored Sudden Cardiac Death–Heart Failure Trial (SCD-HeFT).[30] A more recent study, the Danish Study to Assess the Efficacy of ICDs in Patients with Non-ischemic Systolic Heart Failure on Mortality (DANISH) trial, has raised questions regarding the efficacy of prophylactic ICD use in nonischemic HF patients.[31]

Multicenter Automatic Defibrillator Implantation II Trial

MADIT II was prospectively designed and powered to assess the survival benefit of ICDs in a population

of post–myocardial infarction (MI) patients with reduced EF (<30%). Importantly, this trial included no arrhythmic markers, such as nonsustained or inducible ventricular tachycardia, for inclusion. The 1232 patients were randomly assigned in a 3 : 2 ratio to receive an ICD (742 patients) or conventional medical therapy (490 patients).[28] During an average follow-up of 20 months, the all-cause mortality rates were 19.8% in the conventional therapy arm and 14.2% in the ICD group (31% RRR; *P* = 0.016). The effect of ICD therapy on survival was similar in subgroup analyses stratified according to age, gender, EF, NYHA class, and QRS duration. Moreover, beta-blocker use was 72% in these patients and was well balanced between the ICD and conventional therapy groups.

Of note, the majority of patients enrolled in MADIT II were NYHA Class II or III. Class IV patients were excluded, and the Class I cohort was relatively small. The average LVEF was 23%. These findings suggest that HF patients with mild to moderate symptoms and moderate to severe reductions in LVEF may benefit the most from a prophylactic ICD. Moreover, the survival benefit observed in MADIT II began approximately 9 months after the device was implanted. This observation may be important when considering the timing of device placement in eligible patients.

Prophylactic Defibrillator Implantation in Patients with Nonischemic Dilated Cardiomyopathy Trial

Whereas MADIT II enrolled exclusively post-MI patients with an ischemic cause of LV systolic dysfunction and HF, the DEFINITE trial was the first RCT of primary prevention therapy with an ICD in nonischemic cardiomyopathy patients.[29] Such patients also exhibit high rates of SCD; until recently, however, there has been little consensus regarding the management of SCD risk in such patients, partly because of limitations in objective risk assessment, in that no invasive or noninvasive testing procedure has been shown to determine accurately which nonischemic HF patient is likely to die suddenly. Also, clouding the picture were older observations suggesting that the prophylactic administration of an antiarrhythmic agent, amiodarone, might prolong survival in nonischemic cardiomyopathy patients.

The DEFINITE trial was a prospective evaluation of 458 patients with nonischemic dilated cardiomyopathy. Entry criteria included EF of 35% or less, history of symptomatic HF, and presence of ambient arrhythmias, defined as an episode of nonsustained ventricular tachycardia (VT) or at least 10 premature ventricular complexes (PVCs) per 24-hour period on continuous ambulatory electrocardiographic monitoring. The 229 patients were randomized to each study arm to receive either an ICD and standard medical therapy or standard medical therapy alone. Compliance with medical therapy was excellent and included an angiotensin-converting enzyme inhibitor (ACEI) in 86% of the cohort and a beta blocker in 85%. The patients were followed for a mean of 29.0 ±14.4 months, with a primary endpoint of all-cause mortality.

There were 68 deaths reported in DEFINITE, 28 in the ICD group and 40 in the standard therapy group. The implantation of an ICD yielded a nonsignificant 35% reduction in death from any cause (HR, 0.65; 95% CI 0.40 to 1.06; *P* = 0.08) and significantly reduced the risk of SCD by a remarkable 80% (HR, 0.20; 95% CI 0.06 to 0.71; *P* = 0.006). In the subgroup of NYHA Class III patients, all-cause mortality was significantly decreased in the ICD arm (HR, 0.37; 95% CI 0.15 to 0.90; *P* = 0.02). Although this study was underpowered and did not reach statistical significance with respect to the primary endpoint of all-cause mortality for the entire randomized cohort, the results demonstrated a strong trend toward a survival advantage for patients receiving an ICD.

Sudden Cardiac Death–Heart Failure Trial

The results of the SCD-HeFT trial were published in 2005 and have had a substantial impact on current practice guidelines for ICDs.[30] This landmark RCT enrolled 2521 patients between 1997 and 2001. Patients with NYHA Class II (70%) or III (30%) HF and reduced LVEF (≤35%; mean ≈ 25%) of either ischemic or nonischemic etiology were eligible for the study. SCD-HeFT was a three-arm trial, comparing treatment with an ICD to amiodarone and placebo. Thus, SCD-HeFT addressed at least two important issues in HF management: (1) whether or not empiric amiodarone therapy saved lives in well-treated NYHA Class II and III HF patients with no arrhythmic indication for the drug, and (2) whether or not a prophylactic ICD saved lives in such patients with HF from either an ischemic or a nonischemic cause.

In SCD-HeFT, patients received standard HF therapy, if tolerated, which included an ACEI or angiotensin receptor blocker (ARB) in 85%, beta blocker in 69%, and aldosterone antagonists in 19%, compatible with then-current guideline recommendations. The median follow-up was 45.5 months. Importantly, the cohort was equally divided between ischemic and nonischemic causes of HF, allowing an important subgroup analysis of these cohorts. Mortality rates in the ICD, amiodarone, and placebo groups were, respectively, 17.1%, 24%, and 22.3% at 3 years and 28.9%, 34.1%, and 35.9% at 5 years (**Fig. 27.5**). The ICD was associated with a statistically significant 23% reduction in all-cause mortality compared to placebo (HR, 0.77; 97.5% CI 0.62 to 0.96; $P = 0.007$). Mortality in the amiodarone arm was not significantly different from placebo across all subgroups (HR, 1.06; 97.5% CI 0.86 to 1.30). Similar degrees of benefit with the ICD were noted in patients with ischemic (21% mortality reduction) and nonischemic (27% mortality reduction) HF, thus confirming the findings of MADIT II and DEFINITE, respectively.

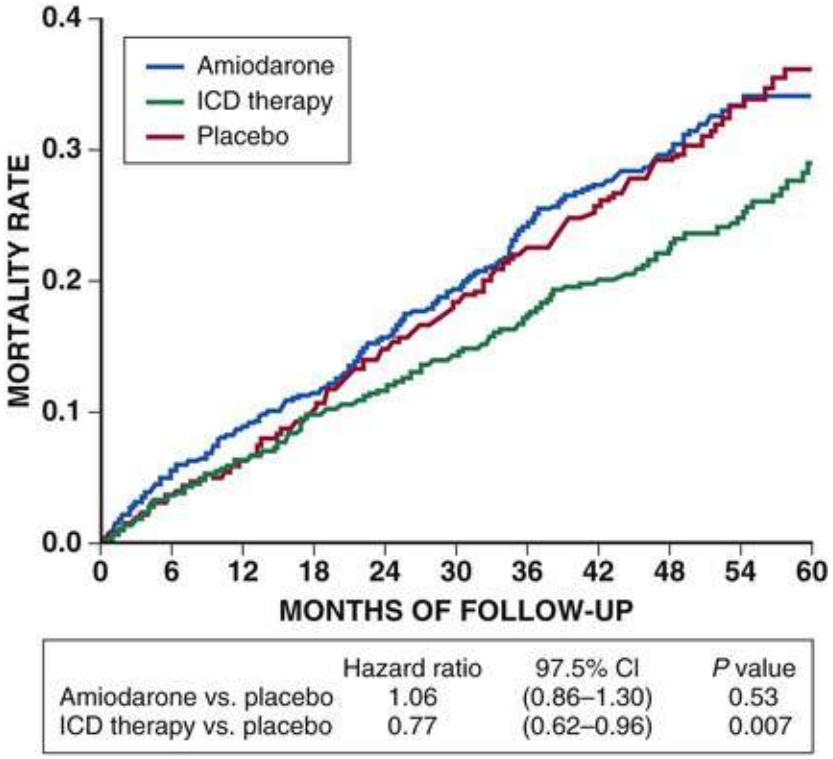

FIGURE 27.5 Kaplan-Meier estimates of survival in patients randomized to an implantable cardioverter-defibrillator (ICD) compared to conventional medical therapy or conventional medical therapy plus amiodarone in the SCD-HeFT Trial. (Modified from Bardy GH, Lee KL, Mark DB, et al. Amiodarone or an implantable cardioverter-defibrillator for congestive heart failure. N Engl J Med 2005;352:225-37.)

The SCD-HeFT trial provides the most robust evidence to date supporting the prophylactic use of an

ICD in patients with NYHA Class II and III systolic HF.

Danish Study to Assess the Efficacy of ICDs in Patients with Non-Ischemic Systolic Heart Failure on Mortality (DANISH)

The DANISH trial randomly assigned 1116 patients with systolic HF not caused by coronary artery disease (CAD; i.e., nonischemic cardiomyopathy) to receive an ICD (556 patients) versus usual care (560 patients).[31] In both groups, 58% of patients received CRT. Results showed that at after 5.6 years, the primary outcome of death from any cause occurred in 120 patients in the ICD group compared to 131 patients in the usual-care group (HR, 0.87; 95% CI 0.68 to 1.12; *P* = 0.28) (**Fig. 27.6**). The secondary endpoint of SCD occurred in 24 patients in the ICD group versus 46 patients in the usual-care group (*P* = 0.005). The authors concluded “prophylactic ICD implantation in patients with symptomatic systolic heart failure not caused by coronary artery disease was not associated with a significantly lower long-term rate of death from any cause than was usual clinical care.” These results and this conclusion questioned the routine use of prophylactic ICDs in the treatment of such patients.

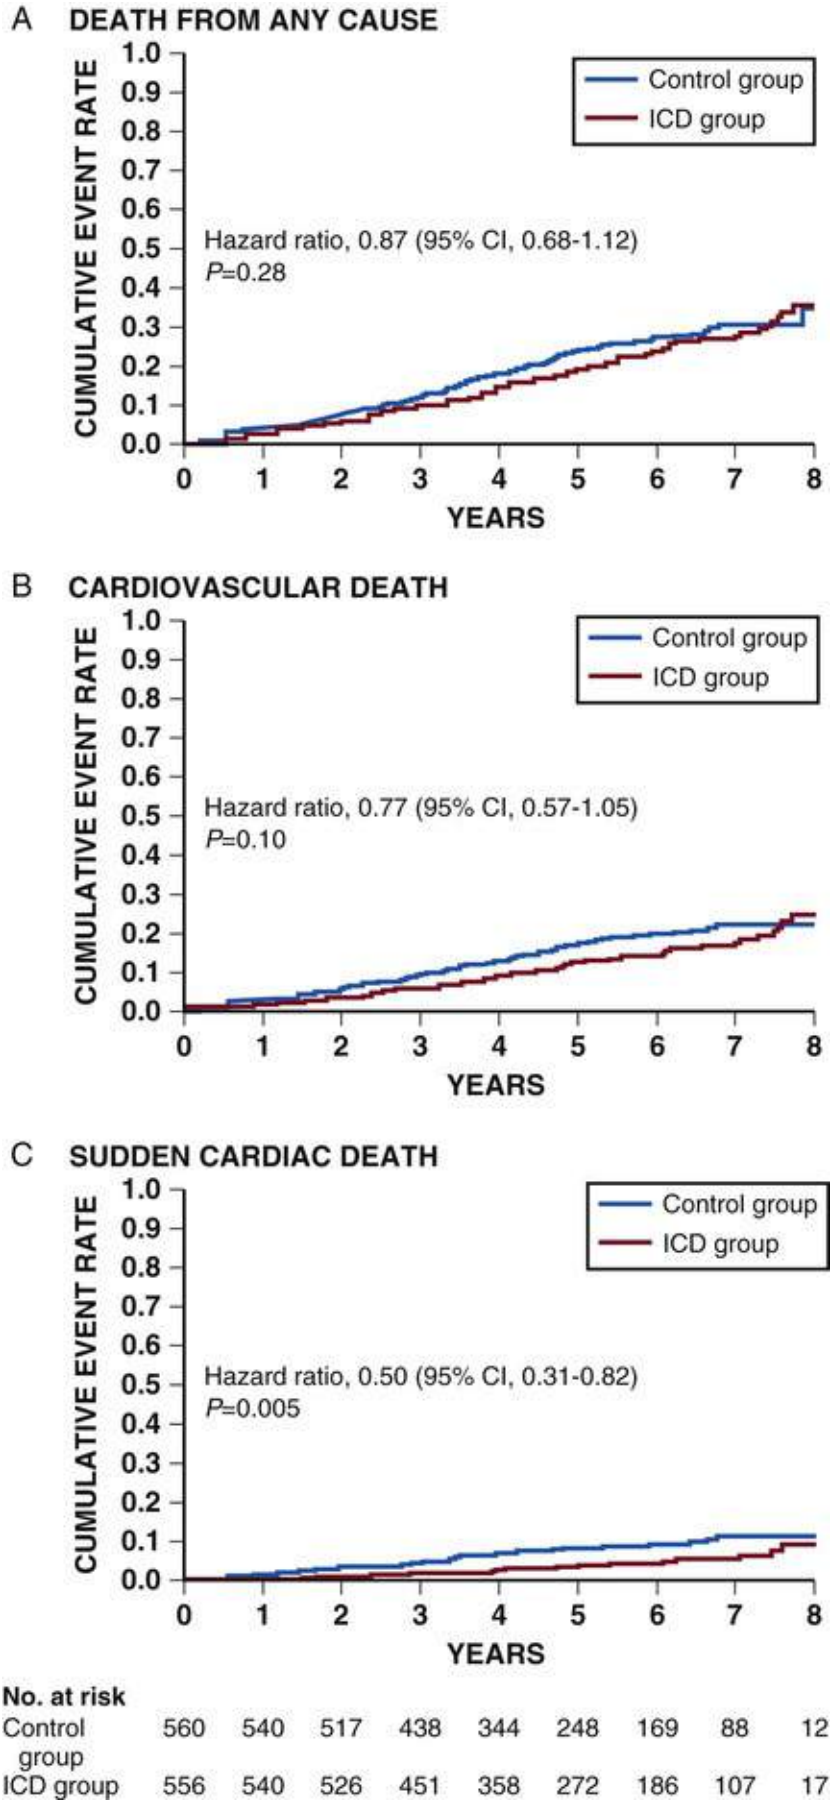

FIGURE 27.6 Effect of prophylactic ICD in heart failure patients with nonischemic cardiomyopathy. Kaplan-Meier estimates for **A,** all-cause mortality; **B,** cardiovascular mortality; and **C,** sudden cardiac death. (From Kober L, Thune JJ, Nielsen JC, et al. Defibrillator implantation in patients with nonischemic systolic heart failure. N Engl J Med 2016;375:1221-30.)

However, an updated meta-analysis supports the efficacy of ICD use for nonischemic cardiomyopathy, despite the results of the DANISH trial.[32] This analysis identified six RCTs enrolling 2970 patients with

nonischemic cardiomyopathy to study the efficacy of ICDs for primary prevention. Pooled analysis demonstrated a statistically significant 23% risk reduction (RR) in all-cause mortality in favor of ICD therapy (HR, 0.77; 95% CI 0.64 to 0.91). Thus it is unlikely that current guideline recommendations for ICDs will change, despite the negative result of the DANISH trial.

Indications for Prophylactic ICD Implantation in Heart Failure Patients

The 2013 ACC/AHA heart failure guidelines provided strong (level I) recommendations for prophylactic ICDs in patients with HF and reduced EF.[2] ICD therapy is recommended for primary prevention of SCD to reduce total mortality in select patients with nonischemic dilated cardiomyopathy or ischemic heart disease at least 40 days after MI and with LVEF of 35% or less and NYHA Class II or III symptoms receiving chronic guideline-directed medical therapy (GDMT), who have reasonable expectation of meaningful survival for more than 1 year (level of evidence A). ICD therapy is also recommended for NYHA Class I patients with ischemic heart disease at least 40 days post-MI with LVEF of 35% or less, who have reasonable expectation of meaningful survival for more than 1 year (level of evidence B). Of note in the context of these recommendations, a recent study showed the importance of ICD programming in minimizing inappropriate shocks and improving patient outcomes.[33] This trial demonstrated that programming of ICD therapies for tachyarrhythmias of 200 beats/min or higher or with a prolonged delay in therapy for tachyarrhythmias of 170 beats/min or higher, compared to conventional programming, was associated with reductions in inappropriate therapy and all-cause mortality during an average follow-up of 1.4 years.

Implantable Devices to Monitor Heart Failure

Device-Based Heart Failure Diagnostics

Implantable devices can provide substantial physiologic information about HF patients. Such information may be useful in evaluating HF clinical status and in predicting episodes of HF decompensation. If these devices are reliable in the latter sense, the use of this information may improve HF outcomes by reducing the risk of worsening heart failure (WHF). For example, many implantable CRT and ICD devices can provide information on atrial heart rate and rhythm, ventricular heart rate and rhythm, patient activity level, heart rate variability, and in some cases intrathoracic impedance, proposed as a measure of lung "wetness." Many implantable devices record an activity trend, providing an objective record of the number of hours per day that patients are physically active. The activity level may serve as a useful teaching and reinforcement tool for both patient and family about the importance and level of activity. Because exercise intolerance is a manifestation of WHF, a decrease in patient activity level may provide one objective clue to disease progression or decompensation.

Heart rate variability (HRV) reflects the balance between sympathetic and parasympathetic nervous system activity in the heart; a decrease in HRV is as a marker of increased sympathetic and decreased parasympathetic tone (**see Chapter 99**). Adamson and colleagues[34] showed that HRV fell in the days to weeks leading up to a hospitalization for WHF, suggesting that decreases in HRV may predict episodes of WHF. Given our understanding of the changes in the neurohormonal milieu that occur as HF worsens, this approach to HF monitoring may ultimately prove useful.

Since most patients with decompensation exhibit pulmonary congestion caused by an elevated LV

filling pressure, indirect measurement of lung water or direct measurement of LV filling pressure or its surrogate may be useful in managing HF patients on an outpatient basis. Implantable devices can monitor fluid status by assessing changes in intrathoracic impedance. In 33 patients, intrathoracic impedance changes demonstrated the ability to predict hospitalization for decompensated HF 10 to 14 days in advance of the event.[35] A larger study confirmed this observation and demonstrated the superiority of intrathoracic impedance versus daily weight monitoring in predicting WHF events.[36]

Moreover, it appears that changes in device-based HF diagnostic parameters, using an algorithm based on combined parameters, can stratify patients into high-risk and low-risk subgroups. The Program to Access and Review Trending Information and Evaluate Correlation to Symptoms in Patients with Heart Failure (PARTNERS-HF) trial showed that patients with a positive combined HF device diagnostics score had a 5.5-fold increased risk of HF hospitalization within 1 month of the assessment.[37] Despite this apparent utility of device-based diagnostics, to date no RCT has demonstrated a reduction in HF hospitalization on the basis of this technology. One attempt to do so, the Diagnostic Outcome Trial in Heart Failure (DOT-HF), demonstrated an expected increase in outpatient HF clinic visits and an unexpected increase in HF hospitalizations.[38]

Implantable Hemodynamic Monitors

A new generation of even more sophisticated implantable hemodynamic monitors (IHMs) is under investigation. These devices allow continuous or intermittent assessment of hemodynamics, generally focused on the assessment of intracardiac or pulmonary artery pressures. Early observations supported the utility of these devices,[39-42] and a large RCT confirmed these observations.

The CardioMEMS Heart Sensor Allows Monitoring of Pressure to Improve Outcomes in NYHA Class III Heart Failure Patients (CHAMPION) trial randomized 550 patients, regardless of LVEF, to two groups; clinicians used a novel wireless monitoring system for daily measurement of pulmonary artery pressure (PAP) in addition to standard of care (treatment group; $n = 270$) versus standard of care alone (control group; $n = 280$).[43] The CHAMPION trial differed from prior studies of IHMs in that specific pressure targets and treatment algorithms were mandated by protocol to ensure adequate testing of the hypothesis. The primary endpoint of the trial was the rate of HF hospitalization over 6 months, and long-term outcomes were also prospectively evaluated.

Over a 6-month period, significantly fewer HF hospitalizations occurred in the treatment group (83) than in the control group (120). During the entire single-blinded follow-up averaging 15 months, the treatment group had a 37% RRR in HF hospitalizations compared with the control group (**Fig. 27.7**). The majority of pressure-based medication changes (≈75%) involved, as expected, diuretics and long-acting nitrates. All four prespecified and statistically powered secondary endpoints were met favoring the treatment group, including PAP reduction, proportion of patients hospitalized for HF, days alive and out of the hospital for HF, and quality-of-life score. Freedom from device- or system-related complications was 98.6%, and overall freedom from pressure-sensor failures was 100%. Subsequent subgroup analyses demonstrated the efficacy of PAP-guided HF management in patients with heart failure and a preserved ejection fraction (HFpEF),[44] and a report on long-term effects of this approach demonstrated sustained benefits.[45]

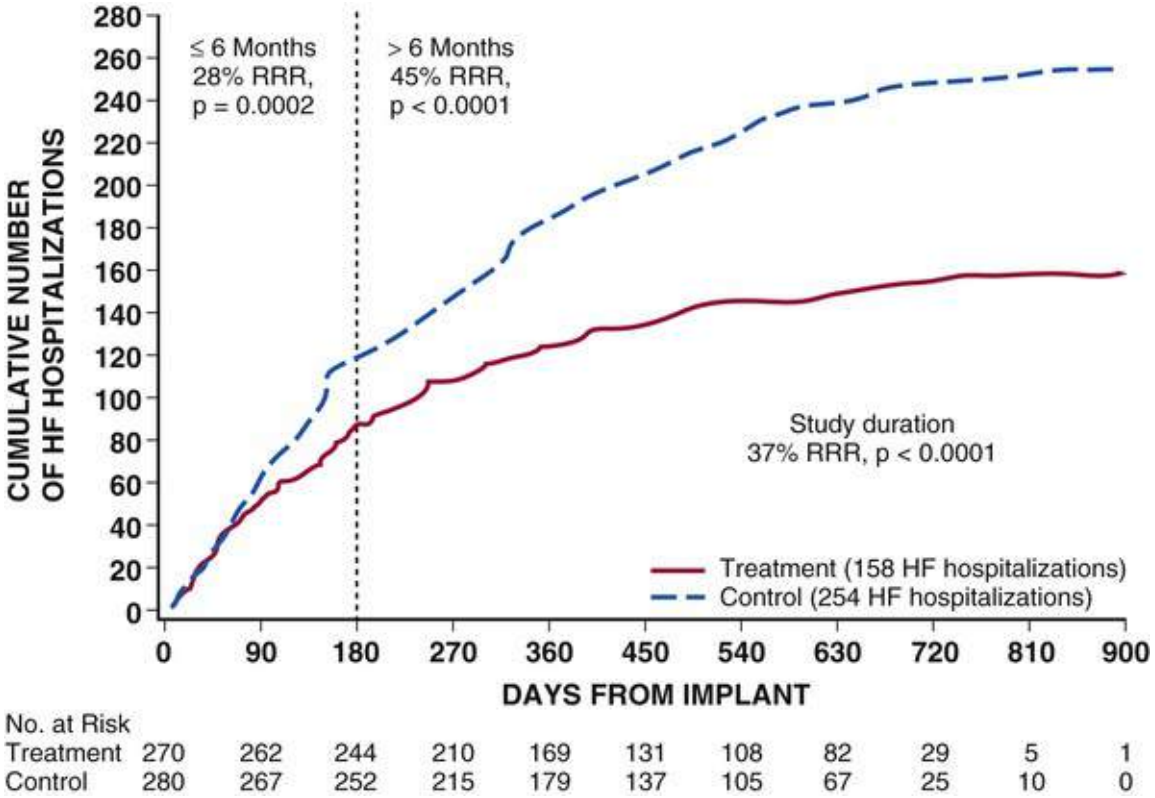

FIGURE 27.7 Primary (6-month) and extended results of the CHAMPION trial for the primary endpoint of heart failure (HF) hospitalization rate; RRR, relative risk reduction. (Modified from Abraham WT, Adamson PB, Bourge RC, et al. Wireless pulmonary artery haemodynamic monitoring in chronic heart failure: a randomised controlled trial. Lancet 2011;377:658-66.)

The results of the CHAMPION trial led to the FDA approval of the first implantable hemodynamic monitoring system in May 2014, for use in HF patients with NYHA Class III symptoms and a history of HF hospitalization within the past 12 months. Other IHMs are currently in development.

Conclusion

Cardiac resynchronization therapy offers a therapeutic approach for treating patients with ventricular dyssynchrony and heart failure. Substantial experience suggests that CRT is safe and effective, with patients demonstrating significant improvement in both clinical symptoms and multiple measures of functional status, exercise capacity, and outcomes. Recommendations for CRT are now based not only on QRS duration but also on morphology. Prophylactic implantation of an ICD is also of proven benefit in HF patients. Implantable hemodynamic monitoring technologies improve the clinician's ability to avoid episodes of HF decompensation and may improve the natural history of the disease.

Guidelines

Cardiac Resynchronization and Implantable Cardioverter-Defibrillators in Heart Failure with a Reduced Ejection Fraction

William T. Abraham

In 2012, the American College of Cardiology, American Heart Association, and Heart Rhythm Society (ACC/AHA/HRS) updated the 2008 guidelines for device-based therapy of cardiac rhythm abnormalities.[1] These revised guidelines were incorporated into the 2013 ACCF/AHA heart failure guidelines.[2] The revised guidelines include a comprehensive revision of cardiac resynchronization therapy (CRT) indications, based on all available studies through 2013 (**Table 27G.1**). The guidelines expand the indications for CRT to some NYHA Class II and very selected Class I patients, limit CRT indications by QRS morphology and QRS duration, and attempt to harmonize indications across NYHA classes when possible. The most certain indications are for those patients who have a left ventricular ejection fraction (LVEF) of 35% or less, sinus rhythm, left bundle branch block with a QRS duration of 150 milliseconds or longer, and NYHA Class II, III, or ambulatory IV symptoms and who are receiving optimal medical treatment.

TABLE 27G.1

ACCF/AHA Guidelines for Cardiac Resynchronization Therapy (CRT)

CLASS	INDICATION	LEVEL OF EVIDENCE
I	CRT is indicated for patients who have LVEF of 35% or less, sinus rhythm, LBBB with QRS duration of 150 msec or greater, and NYHA Class II, III, or ambulatory IV symptoms on GDMT.	A for NYHA Class III/I B for Class II
IIa	CRT can be useful for patients who have LVEF of 35% or less, sinus rhythm, non-LBBB pattern with QRS duration of 150 msec or greater, and NYHA Class III/ambulatory Class IV symptoms on GDMT.	A
	CRT can be useful for patients who have LVEF of 35% or less, sinus rhythm, LBBB with QRS duration of 120 to 149 msec, and NYHA Class II, III, or ambulatory IV symptoms on GDMT.	B
	CRT can be useful in patients with atrial fibrillation and LVEF of 35% or less on GDMT if (a) the patient requires ventricular pacing or otherwise meets CRT criteria and (b) atrioventricular nodal ablation or pharmacologic rate control will allow near-100% ventricular pacing with CRT.	B
	CRT can be useful for patients on GDMT who have LVEF of 35% or less and are undergoing placement of new or replacement device with anticipated requirement for significant (>40%) ventricular pacing.	C
IIb	CRT may be considered for patients who have LVEF of 35% or less, sinus rhythm, non-LBBB pattern with QRS duration of 120 to 149 msec, and NYHA Class III/ambulatory Class IV on GDMT.	B
	CRT may be considered for patients who have LVEF of 35% or less, sinus rhythm, non-LBBB pattern with QRS duration of 150 msec or greater, and NYHA Class II symptoms on GDMT.	B
	CRT may be considered for patients who have LVEF of 30% or less, ischemic etiology of HF, sinus rhythm, LBBB with QRS duration of 150 msec or greater, and NYHA Class I symptoms on GDMT.	C
III: no benefit	CRT is not recommended for patients with NYHA Class I or II symptoms and non-LBBB pattern with QRS duration less than 150 msec.	
	CRT is not indicated for patients whose comorbidities and/or frailty limit survival with good functional capacity to less than 1 year.	

GDMT, Guideline-directed medical therapy; *LBBB,* left bundle-branch block; *LVEF,* left ventricular ejection fraction; *NYHA,* New York Heart Association.

Patients with reduced LVEF are at increased risk for ventricular tachyarrhythmias leading to sudden cardiac death (SCD). Patients who have had sustained ventricular tachycardia, ventricular fibrillation, unexplained syncope, or cardiac arrest are at highest risk for recurrence. Indications for implantable cardioverter-defibrillator (ICD) therapy as secondary prevention of SCD is also discussed in the 2013 American College of Cardiology Foundation and American Heart Association (ACCF/AHA) guidelines for heart failure (**Table 27G.2**),[2] as well as the ACCF/AHA/HRS device-based therapy guidelines.[3]

TABLE 27G.2

ACCF/AHA Guidelines for Indications for Implantable Cardioverter-Defibrillators (ICDs)

CLASS	INDICATION	LEVEL OF EVIDENCE
I	ICD therapy is recommended for primary prevention of SCD in selected patients with HFrEF at least 40 days post-MI with LVEF less than 35% and NYHA Class II or III symptoms receiving chronic GDMT, who are expected to live more than 1 year.	A
I	ICD therapy is recommended for primary prevention of SCD in selected patients with HFrEF at least 40 days post-MI with LVEF less than 30% and NYHA Class I symptoms receiving GDMT, who are expected to live more than 1 year.	B
IIa	To prevent SCD, placement of ICD is reasonable in patients with asymptomatic ischemic cardiomyopathy who are at least 40 days post-MI, have an LVEF of 30% or less, are on appropriate medical therapy, and have reasonable expectation of survival with a good functional status for more than 1 year.	B
IIb	ICD therapy to prevent SCD in patients with nonischemic cardiomyopathy who are at least 40 days post-MI, have LVEF less than 35%, with NYHA Class II or III symptoms while undergoing chronic optimal medical therapy, and have reasonable expectation of survival for more than 1 year with good functional status.	B
	Usefulness of implantation of ICD is of uncertain benefit to prolong meaningful survival in patients with high risk of non-SCD, as predicted by frequent hospitalizations, advanced frailty, or comorbidities such as systemic malignancy or severe renal dysfunction.	B

HFrEF, Heart failure with reduced ejection fraction; *MI,* myocardial infarction; *SCD,* sudden cardiac death; see **Table 27G.1** for other abbreviations.

Surgical Management of Heart Failure

Mariell Jessup, Pavan Atluri, Michael A. Acker

In the current era of management of heart failure associated with a reduced left ventricular ejection fraction (HFrEF), clinicians frequently encounter optimally treated patients who remain symptomatic. Indeed, despite the variety of available medical therapies and electrophysiologic interventions, such as placement of biventricular pacemakers and implantable cardioverter-defibrillators (**see Chapter 27**), many patients who have been so treated are still left with a reduced quality of life and a poor prognosis. In a subpopulation of these patients, surgical intervention may be appropriate to alleviate ischemia, to

attenuate valvular dysfunction, to reduce mechanical disadvantages caused by ventricular remodeling, or, when all other treatment options have failed, to perform cardiac transplantation or implantation of a permanent ventricular assist device (VAD). This chapter describes the surgical management of patients with heart failure secondary to a decreased left ventricular ejection fraction (LVEF). The medical management of patients with a reduced ejection fraction is discussed in **Chapter 25** and the role of circulatory assist devices in **Chapter 29**.

Coronary Artery Revascularization

Selection of Patients

Until the design, completion, and publication of the original STICH (Surgical Treatment of Ischemic Heart Failure) trial[1] and now the 10-year follow-up of this trial,[2] no randomized clinical trials had evaluated the outcomes of revascularization in patients with ischemic cardiomyopathy. The term *ischemic cardiomyopathy* is used to describe the myocardial dysfunction that arises secondary to occlusive or obstructive coronary artery disease (**see Chapter 61**). Although ischemic cardiomyopathy was considered the second most common cause (after hypertension) of heart failure (HF) in the Framingham Study (**see Chapter 21**), ischemic cardiomyopathy is now recognized as the most common cause of HF in clinical trials of patients with HFrEF.

Ischemic cardiomyopathy is composed of three interrelated pathophysiologic processes that may overlap: *myocardial hibernation*, defined as persistent contractile dysfunction at rest, caused by reduced coronary blood flow that can be partially or completely restored to normal by myocardial revascularization; *myocardial stunning*, wherein the viable myocardium may demonstrate prolonged but reversible postischemic contractile dysfunction caused by the generation of oxygen-derived free radicals on reperfusion and by a loss of sensitivity of contractile filaments to calcium; and irreversible *myocyte cell death*, leading to ventricular remodeling and contractile dysfunction.

The three major historical, randomized clinical trials that have compared coronary artery bypass grafting (CABG) with medical management—the Veterans Administration Cooperative Study, the European Coronary Surgery Study, and the Coronary Artery Surgery Study—all had excluded patients with HF or severe left ventricular (LV) dysfunction. Several clinical factors have traditionally played a major role in the decision-making process with respect to selection of suitable candidate patients with HF to undergo coronary artery revascularization, including the presence of angina, severity of HF symptoms, LV dimensions, degree of hemodynamic compromise, and presence and severity of comorbid conditions. Other major technical issues to be considered are the adequacy of target vessels for revascularization and an adequate conduit strategy. The most important determinant remains the extent of jeopardized but still-viable myocardium (**see Chapters 14, 16, and 17**). Studies have suggested that for a significant reduction in HF symptoms and improvement in LV function, as well as in survival after coronary revascularization, at least 25% of the myocardium should be viable. Of interest, in the STICH trial, the presence of viable myocardium was associated with a greater likelihood of survival in patients with coronary artery disease (CAD) and LV dysfunction, regardless of treatment. The assessment of myocardial viability, however, did not identify patients with a differential survival benefit with CABG versus medical therapy alone. The

role of viability testing in the decision-making process is still evolving after this STICH trial substudy.[3] The impact of viability on decision making for revascularization is discussed separately in **Chapter 16**.

Risks of Coronary Artery Bypass Grafting

The perioperative risks in patients with severe LV dysfunction range from 2% to almost 10%, depending on the availability of targets and their viability, right ventricular dysfunction, advanced HF symptoms (New York Heart Association [NYHA] Class IV), increased LV end-diastolic pressure, comorbidities of advanced age, peripheral vascular disease, renal dysfunction, mitral regurgitation, and chronic obstructive pulmonary disease.[4,5] The Society of Thoracic Surgeons (STS)–predicted risk of death in 2006 for a 70-year-old patient with no comorbid conditions but with a 20% LVEF was 1.3%; for a man of the same age with a normal LVEF, this risk was 0.5%. Mortality rates increase substantially when the LVEF is below 20% or when HF is severe (NYHA Class IV).

Studies show that for patients with clinical heart failure, perioperative mortality rates range from approximately 2.6% to 8.7%, depending on age and presence of one or more comorbid conditions. A recent study investigating CABG in patients with HF with either preserved or reduced ejection fraction (EF) found HF to be an independent predictor of mortality within 30 days either with reduced EF (hazard ratio [HR], 2.52; 95% confidence interval [CI] 1.99 to 3.19; 4.0% 30-day mortality) or preserved EF (HR, 1.83; 95% CI 1.26 to 2.66; 2.8% 30-day mortality).[6] Pocar and associates[7] found a 30-day mortality rate of 4.4% in 45 consecutive angina-free patients with NYHA Class III or IV, LVEF below 35%, and significant viability by positron emission tomography (PET). Predictors of death included LV end-diastolic pressure above 25 mm Hg, age older than 70 years, and significant peripheral vascular disease. In the CABG Patch trial, patients without angina or HF had a perioperative mortality of 1.3%. The mortality increased to 4.8% for patients with no angina and mild HF, NYHA Class I or II, and 7.4% with no angina and NYHA Class III or IV HF. For cardiogenic shock after myocardial infarction, the results of emergent CABG are poor but still better than medical therapy. The SHOCK (Should We Emergently Revascularize Occluded Coronaries for Cardiogenic Shock) trial gave 30-day and 6-month mortality rates after CABG of 47% and 50%, respectively, for patients in cardiogenic shock. These rates were 56% and 63% with medical therapy alone.[8]

The STICH trial was a prospective, randomized, intention-to-treat study of 2800 patients from 100 centers.[1] Patients on an optimal medical regimen with LV dysfunction and CAD amenable to CABG were randomly assigned to one of three different treatment strategies: CABG, CABG plus surgical ventricular reconstruction (SVR), or medical therapy alone (MED) (**Fig. 28.1**). This trial was powered to address two primary hypotheses: (1) CABG combined with medical therapy improves long-term survival over that achieved with MED, and (2) SVR provides additional long-term survival benefit when combined with CABG and medical therapy. Between July 2002 and May 2007, a total of 1212 patients with an LVEF of 35% or less and CAD amenable to CABG were randomly assigned to receive medical therapy alone (602 patients) or medical therapy plus CABG (610 patients). The primary outcome was the rate of death from any cause. Major secondary outcomes included the rates of death from cardiovascular (CV) causes and of death from any cause or hospitalization for CV causes. Of the 610 patients randomly assigned to CABG, 555 (91%) underwent CABG before the end of the study. A concurrent mitral valve

operation was performed in 63 patients (11%). The all-cause death rate within 30 days of assignment to treatment, which is an approximate estimation of perioperative mortality, was 4% in the medical treatment plus CABG arm, compared with 1% 30-day mortality rate in the MED group. A 10-year follow-up to the original STICH trial demonstrated a significantly lower mortality in patients who underwent CABG (58.9%) compared to medical therapy (66.1%)[2] (**Fig. 28.2**).

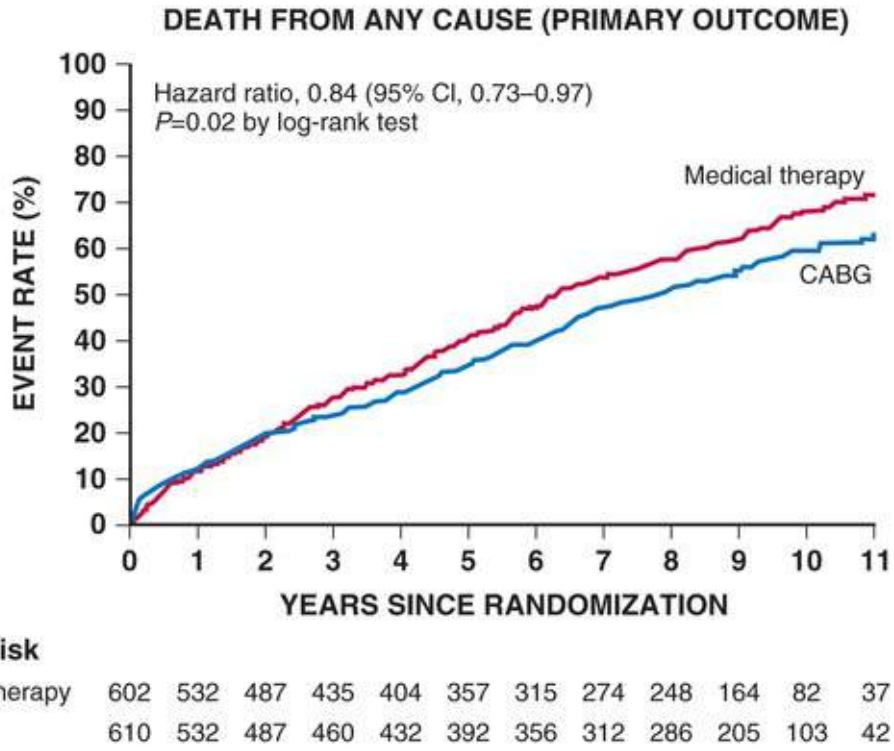

FIGURE 28.2 Kaplan-Meier curves for the probability of death from any cause in the STICHES study. CABG, Coronary artery bypass surgery. (From Velazquez EJ, Lee KL, Jones RH, et al. Coronary-artery bypass surgery in patients with ischemic cardiomyopathy. N Engl J Med 2016;374:1511.)

Benefits of Coronary Artery Bypass Grafting

The beneficial effect of revascularization should theoretically result from improved blood flow to hypoperfused but viable myocardium (hibernating myocardium), with a subsequent improvement in LV function and clinical outcomes. Alleviation of ischemia also may lessen the tendency toward proarrhythmias, thereby reducing the incidence of sudden cardiac death (SCD). Accordingly, coronary artery revascularization has the potential to relieve symptoms of HF, improve LV function, and enhance survival.

In the STICH trial the intention-to-treat analysis found no statistically significant difference in death from any cause between the medical and the surgical groups (HR for CABG, 0.86; 95% CI 90.7 to 1.04; $P = 0.12$), whereas the prespecified secondary analysis found a significant difference between the medical and surgical groups with respect to the combined endpoints of CV death, death from any cause, and hospitalization for CV causes (HR for CABG, 0.74; 95% CI 0.64 to 0.85; $P < 0.001$). The HR for CV death was 19% lower in the CABG arm (0.81; 95% CI 0.66 to 1.00) and for the composite of death or CV hospitalization was 16% lower in the CABG arm (0.84; 95% CI 0.71 to 0.98). These findings were consistent across several prespecified subgroups.

The updated 10-year follow-up of the STICH cohorts (STICHES) has further confirmed these findings, with a clear improvement in the primary outcome of all-cause mortality, with improved median survival in the CABG group compared to medical therapy (7.73 versus 6.29 years).[2] The prespecified secondary outcomes included death from CV causes, combined death from any cause or hospitalization for HF, death from any cause or hospitalization for any cause, death from any cause or revascularization, and death from any cause or nonfatal stroke. Beneficial improvements in all secondary outcomes were noted in the CABG cohort compared to medical management (**Table 28.1**). Furthermore, given the significant crossover of medically managed patients into the CABG arm (17%) within the first year of

randomization, the overall outcomes in the CABG group were likely adversely affected, limiting the real overall impact of CABG on survival. Based on the long-term follow-up data, the authors concluded that a significant benefit of CABG plus medical therapy over medical therapy alone with respect to the rate of death from any cause could be achieved among patients with ischemic cardiomyopathy. A follow-up study utilizing the original STICH dataset focused on the anatomic variables associated with improved outcomes in patients with reduced EF undergoing CABG. Three prognostic criteria were evaluated: EF less than the median (27%), end-systolic volume index (ESVI) above the median (79 mL/m^2), and the presence of three-vessel CAD. A net benefit to CABG with medical management compared to medical management alone was noted in patients with two or three of these criteria (HR, 0.53; 95% CI 0.37 to 0.75; $P < 0.001$), but not those with only one criterion (HR, 0.88; 95% CI 0.59 to 1.31; $P = 0.535$).

TABLE 28.1

The STICH Study Outcomes

OUTCOME	NO. OF SUBJECTS (%)		HAZARD RATIO WITH CABG (95% CI)	*P* VALUE*
	CABG (*n* = 610)	Medical Therapy (*n* = 602)		
Primary Outcome				
Death from any cause	359 (58.9)	398 (66.1)	0.84 (0.73-0.97)	0.02
Secondary Outcomes				
Death from cardiovascular causes	247 (40.5)	297 (49.3)	0.79 (0.66-0.93)	0.006
Death from any cause or hospitalization for cardiovascular causes	467 (76.6)	524 (87.0)	0.72 (0.64-0.82)	<0.001
Death from any cause or hospitalizations for heart failure	404 (66.2)	450 (74.8)	0.81 (0.71-0.93)	0.002
Death from any cause of hospitalizations for any cause	506 (83.0)	538 (89.4)	0.81 (0.71-0.91)	0.001
Death from any cause or revascularization†	388 (63.6)	478 (79.4)	0.63 (0.55-0.73)	<0.001
Death from any cause or nonfatal myocardial infarction‡	376 (61.6)	409 (67.9)	0.86 (0.74-0.98)	0.03
Death from any cause of nonfatal stroke‡	367 (60.2)	406 (67.4)	0.85 (0.74-0.98)	0.03

*Hazard ratios (CABG vs. medical therapy) are based on the Cox model, and the associated *P* values are based on the long-rank test. All assessments were adjusted for patient stratum (A vs. B; patients who met the eligibility criteria for random assignment to the coronary artery bypass grafting (CABG) group or medical therapy group but did not meet the criteria for eligibility for surgical ventricular reconstruction were enrolled in stratum A; patients who did meet the criteria for eligibility for surgical ventricular reconstruction were enrolled in stratum B).

†The method of revascularization was either percutaneous coronary intervention or CABG.

‡Death or nonfatal myocardial infarction and death or nonfatal stroke were not prespecified outcomes.

From Velazquez EJ, Lee KL, Jones RH, et al. Coronary-artery bypass surgery in patients with ischemic cardiomyopathy. N Engl J Med 2016;374:1511.

Several studies have reported marked reduction in HF symptoms after revascularization. A 1999 study from Verona followed 167 patients with angina and HF symptoms and an average LVEF of 28% and demonstrated significant freedom from angina after surgery, 98% and 81%, and from HF, 78% and 47%, at 1 and 5 years, respectively.[9] Only 54% of patients were symptom free of both angina and HF at follow-up evaluation. Di Carli and colleagues[10] studied 36 patients with LVEF of 28% by PET imaging and found a significant correlation between the total extent of a PET blood flow–metabolism mismatch and percentage improvement in functional class after CABG. A mismatch of more than 18% was associated with a sensitivity of 76% and a specificity of 78% for predicting a change in functional status after revascularization. A substantial objective improvement in physical activity was noted in patients with presurgical mismatches that occupied at least 20% of the ventricular myocardium. Thus, patients with large perfusion-metabolism mismatch exhibited the greatest clinical benefit after revascularization.

The impact of the CABG strategy on subsequent symptoms of patients in the STICH trial has further demonstrated benefits in both angina (odds ratio [OR], 0.70; 95% CI 0.55 to 0.90; $P < 0.01$),[11] as well as quality of life as measured with the Kansas City Cardiomyopathy Questionnaire.

A reasonable management strategy for patients who present with HF secondary to CAD (i.e., ischemic cardiomyopathy) includes coronary angiography (**see Chapter 20**), especially if patients have any component of angina pectoris. Viability studies may be appropriate for patients with severe disease and adequate surgical targets. The weight of currently available clinical evidence suggests that CABG may be superior to medical therapy alone in outcome measures of survival and quality of life. Current American and European guidelines for CABG in patients with HF include various strengths of recommendation for surgery (**Table 28.2**).

TABLE 28.2

Surgery for Management of Heart Failure (HF): Guideline Recommendations

2016 ESC Guidelines for the Diagnosis and Treatment of Acute and Chronic Heart Failure
Recommendations for Myocardial Revascularization in Patients with Chronic HF
• Myocardial revascularization is recommended when angina persists despite antiangina drugs; *class I, level of evidence A.* The choice between CABG and PCI should be made by the heart team after careful review. CABG is recommended for patients with angina and significant LM or LM-equivalent stenosis to improve prognosis. CABG is recommended for patients with HFrEF, significant CAD (LAD or multivessel disease), and LVEF <35%.
2014 ACC/AHA/AATS/PCNA/SCAI/STS Focused Update of the Guideline for the Diagnosis and Management of Patients with Stable Ischemic Heart Disease*
• A heart team approach to revascularization is recommended in patients with diabetes mellitus and complex multivessel CAD; *class 1, level of evidence C.* • CABG is generally recommended in preference to PCI to improve survival in patients with diabetes mellitus and multivessel CAD for which revascularization is likely to improve survival (3-vessel CAD or complex 2-vessel CAD involving the proximal LAD); *class 1, level of evidence B.*
2014 AHA/ACC Guideline for the Management of Patients with Valvular Heart Disease†
Indications for Aortic Valve Surgery in Aortic Stenosis (as) with Left Ventricular Dysfunction
• AVR is recommended for asymptomatic patients with severe AS and LVEF <50%; *class I, level of evidence B.* • AVR is reasonable in symptomatic patients with low-flow/low-gradient severe AS with reduced LVEF with a low-dose dobutamine stress study that shows an aortic velocity ≥4.0 m/sec or mean pressure gradient ≥40 mm Hg with a valve area of ≤1.0 cm^2; *class IIa, level of evidence B.* • AVR is reasonable for patients with moderate AS who are undergoing other cardiac surgery; *class IIa, level of evidence C.* • TAVR is recommended in patients who meet an indication for AVR for AS and who have a prohibitive surgical risk and post-TAVR survival >12 mo; *class I, level of evidence B.* • TAVR is a reasonable alternative to surgical AVR in patients who meet an indication for AVR and who have a high surgical risk; *class IIa, level of evidence B.*
Indications for Aortic Valve Surgery in Aortic Regurgitation (AR) with LV Dysfunction
• AVR is recommended for symptomatic patients with severe AR; *class I, level of evidence B.* • AVR is indicated for patients with severe AR and LV systolic dysfunction; *class I, level of evidence B.*
Indications for Mitral Valve Surgery in Functional Mitral Regurgitation (MR)
• Mitral valve surgery is reasonable for patients with chronic severe functional MR who are undergoing CABG or AVR; *class IIa, level of evidence C.* • Mitral valve surgery may be considered for severely symptomatic patients (NYHA Class III/IV) with chronic severe functional MR; *class IIb, level of evidence B.* • Mitral valve repair may be considered for patients with chronic moderate functional MR who are undergoing other cardiac surgery; *class IIb, level of evidence C.*
ESC/EACTS Guidelines on the Management of Valvular Heart Disease (Version 2012)‡
Indications for Mitral Valve Surgery in Chronic Secondary Mitral Regurgitation (MR)
• Surgery is indicated in patients with severe MR undergoing CABG and LVEF >30%; *class I, level of evidence C.* • Surgery should be considered in patients with moderate MR undergoing CABG; *class IIa, level of evidence C.* • Surgery should be considered in symptomatic patients with severe MR, LVEF <30%, option for revascularization, and evidence of viability; *class IIa, level of evidence: C.* • Surgery may be considered in patients with severe MR, LVEF >30%, who remain symptomatic despite optimal medical management (including CRT if indicated) and have low comorbidity, when revascularization is not indicated; *class IIb, level of evidence C.*

Valve Surgery in Patients With Left Ventricular Dysfunction

Mitral Valve

As discussed in **Chapter 69**, the surgical treatment of primary valvular heart disease that leads to LV dysfunction or HF is now widely accepted. However, patients who have valvular dysfunction *secondary* to, or in association with, a primary cardiomyopathy pose a much more difficult management problem. The following discussion focuses on the impact and outcome of valve repair or replacement for patients

with a dilated cardiomyopathy and secondary mitral regurgitation (MR). However, much of the same controversy relates to the decision to repair or replace the regurgitant mitral valve in the patient with an ischemic cardiomyopathy and a low LVEF who is undergoing CABG.

MR is frequently observed in patients with HF and is associated with a poor prognosis. Progressive LV remodeling, characterized by increasing LV dilation with change to a more spherical shape, can result in functional MR secondary to annular dilation, papillary muscle displacement, and chordal tethering. The functional MR leads to an increased preload, increased wall tension, and increased LV workload, all of which contribute in a positive feedback loop to progressive HF. The presence of MR itself is an independent risk factor for poor outcome, in both nonischemic and ischemic forms of the disorder. Even uncorrected mild MR, as well as moderate to severe MR associated with ischemic cardiomyopathy, is associated with reduced long-term survival. In addition, MR is a progressive disorder in which the regurgitation-related LV volume overload promotes further LV remodeling, leading to worsening of the problem.

Mitral valve repair or replacement to restore valve competency is a well-established procedure when symptoms of HF are present and the primary disease is of the valve leaflets (**see Chapter 69**). More recently, however, interest has focused on functional or secondary mitral insufficiency, in which the valve leaflets are anatomically normal but do not fully coapt because of annular dilation and restricted leaflet motion secondary to increased ventricular size and sphericity. Such remodeling of the ventricle often is associated with an LVEF of 40% or less and HF symptoms of NYHA Class III or IV. Surgery in this situation is controversial, because the MR is the consequence and not the cause of LV dysfunction, and the prognosis is therefore more specifically related to the underlying cardiomyopathic process.

Although it is clear that the advent of secondary mitral insufficiency is associated with a worse prognosis, it is unclear whether the worse outcomes arise from the MR itself or whether MR is simply a marker for worsening HF, in which case the correction of MR might not improve symptoms or survival. The historical point of view was that surgical correction of MR in patients with advanced HF patients and poor LV function is associated with prohibitive operative mortality. This view was challenged by Bolling in the mid-1990s, ushering in the era of both mitral valve repair and other surgical procedures for the failing heart. The traditional hypothesis held that the mitral valve functions as a “pop-off” mechanism for the failing ventricle and that surgical correction results in prohibitive mortality. The Bolling hypothesis is that there is an “annular solution for a ventricular problem … such that reconstruction of the mitral valve annulus' geometric abnormality by an undersized ring restores valvular competency, alleviates excessive ventricular workload, improves ventricular geometry and improves ventricular function.”[12] Subsequent studies in an ischemic sheep model of MR showed that reducing the annulus with a small ring reduces the radius of curvature of the left ventricle at the base equatorial and apical level, supporting the concept that a small ring can restore a more elliptical ventricular shape. It is now recognized that the surgical mortality for mitral valve replacement observed in the past probably resulted from the loss of the subvalvular apparatus, underscoring the paramount importance of maintaining annular and subvalvular continuity during mitral valve surgery.

In degenerative mitral valve disease, the repair of the mitral valve has been demonstrated to provide superior long-term outcomes in regard to survival and ventricular function compared to mitral valve replacement. Unfortunately, in the case of functional MR, multiple studies suggest that the rate of

recurrence of MR after repair is approximately 30% to 40%, bringing into question the appropriate surgical management strategy for severe functional MR: repair versus replacement. The landmark Cardiothoracic Surgical Trials Network (CTSnet), a randomized, prospective, multi-institutional study evaluating either mitral valve (MV) repair or chordal-sparing MV replacement for severe ischemic MR, provided insight into this complicated question. The study randomized 251 patients with severe ischemic MR to either MV repair with a rigid, complete, downsized annuloplasty (126 patients) or MV replacement with complete preservation of the subvalvular apparatus (125 patients). The primary endpoint of the initial study was LV remodeling as assessed by left ventricular end-systolic volume index (LVESI) at 12 months.[13] Secondary endpoints included mortality, a composite of adverse cardiac or cerebrovascular events (death, stroke, subsequent MV surgery, hospitalization for HF, or increase in NYHA class), serious adverse events, recurrent MR, quality of life, and rehospitalization. No difference in LVESI between groups was identified at 12 months. The mortality rate, rate of composite adverse events, functional status, and quality of life were noted to be equivalent at 12 months. The ensuing study followed this patient cohort for 2 years using clinical and echocardiographic endpoints.[14] At 2 years, the LVESI among survivors was not statistically significant ($P = 0.19$) between the two groups: 52.6 ±27.7 mL/m^2 for MV repair and 60.6 ±39.0 mL/m^2 for MV replacement. The 2-year mortality was 19.0% in the repair group and 23.2% in the replacement group (HR, 0.79; 95% CI 0.46 to 1.35; $P = 0.39$). As shown in **Fig. 28.3**, the rate of recurrence of moderate or severe MR over 2 years was markedly higher in the repair group than the replacement group (58.8% vs. 3.8%; $P < 0.001$). There was no significant difference in rates of serious adverse events and overall readmissions. However, patients in the repair group had more serious adverse events related to HF recurrence ($P = 0.05$) and CV readmissions ($P = 0.01$). Data from this trial support MV replacement over repair for severe ischemic MR. Similarly, a large, contemporaneous, retrospective, propensity-matched study (ISTIMIR) from Lorusso and colleagues[15] evaluating MV replacement and repair for severe ischemic MR demonstrated no difference in short- or long-term mortality between patients cohorts. They noted no difference in late LV function, cardiac and valve-related death, or functional capacity. MV repair was noted to be the strongest predictor of need for valve-related reoperation. In a subgroup analysis, patients who underwent MV repair without recurrent MR had significantly greater LV reverse remodeling than patients who underwent replacement. In the case of MV replacement, it is important to ensure complete chordal preservation of both anterior and posterior chords to limit myocardial remodeling.

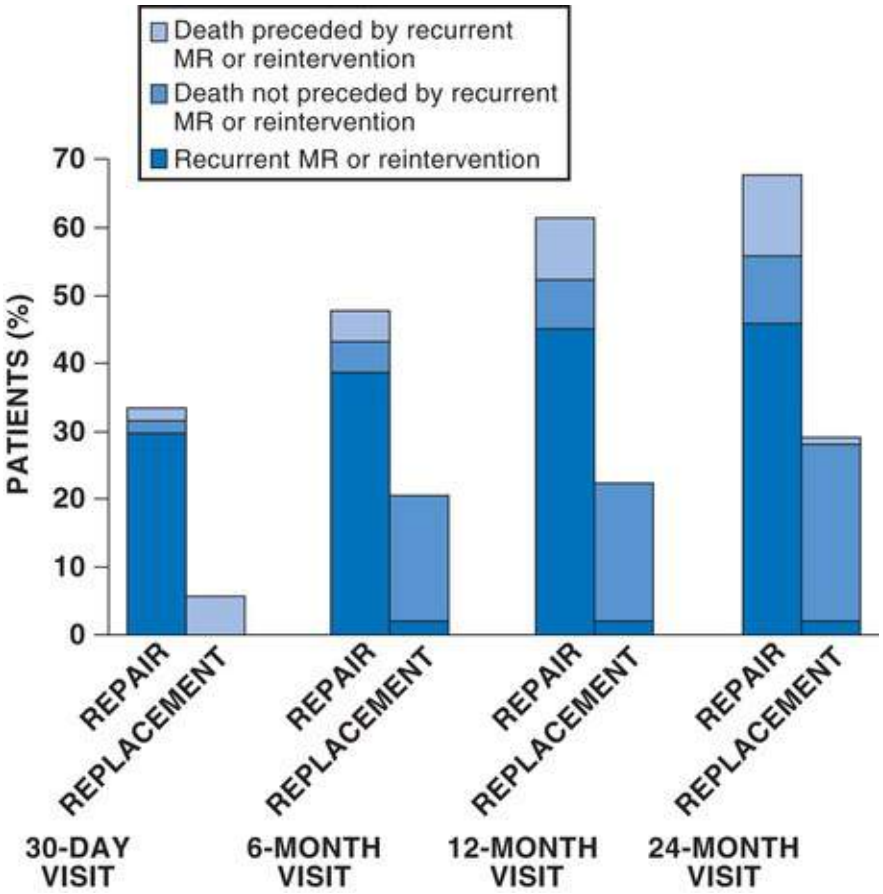

FIGURE 28.3 Results of CTSnet severe ischemic mitral regurgitation trial showing the cumulative failure of mitral valve repair or replacement at 2 years. Failure of the intervention was defined as death, moderate or severe mitral regurgitation (MR) as seen on transthoracic echocardiography, or mitral valve reintervention. (From Goldstein D, Moskowitz AJ, Gelijns AC, et al. Two-year outcomes of surgical treatment of severe ischemic mitral regurgitation. N Engl J Med 2016;374:344.)

Another common clinical scenario is the management of moderate ischemic MR in patients undergoing CABG. Proponents of MV repair have argued for the potential benefits of long-term reverse LV remodeling and symptomatic relief. The countervailing point of view is that revascularization alone will improve the MR and that MV repair will not have a long-term durable benefit. A randomized, prospective, multi-institutional CTSnet study evaluating the surgical treatment of moderate ischemic MR at the time of CABG addressed this clinical dilemma.[16] Patients with moderate ischemic MR were randomly assigned to either CABG alone (n = 151) or CABG plus MV repair (n = 150). The primary endpoint was the degree of LV remodeling by means of the LVESI. Secondary endpoints included a composite of major adverse cardiac or cerebrovascular events, mortality, serious adverse events, residual MR, functional status, quality of life, and rehospitalization. Assessment of LVESI at 1 year demonstrated no difference (z score = 0.50; P = 0.61). Moreover, the 2 year follow-up showed that the mean LVESI was 41.2 ±20.0 mL/m^2 in the CABG group, compared to 43.2 ±20.6 mL/m^2 in the CABG plus MV repair group (z score = 0.38; P = 0.71).[17] The mortality rate was similar for CABG (10.6%) and CABG plus MV repair (10.0% [HR, 0.90; 95% CI 0.45 to 1.83; P = 0.78]). Although the rate of moderate or severe MR was higher in the CABG group (32.3% vs. 11.2%; P < 0.001), the overall rates of hospital readmission and serious adverse events were similar between groups (**Fig. 28.4**). The authors concluded that in patients with moderate ischemic MR undergoing CABG, the addition of MV repair did not lead to significant differences in LV remodeling at 2 years.

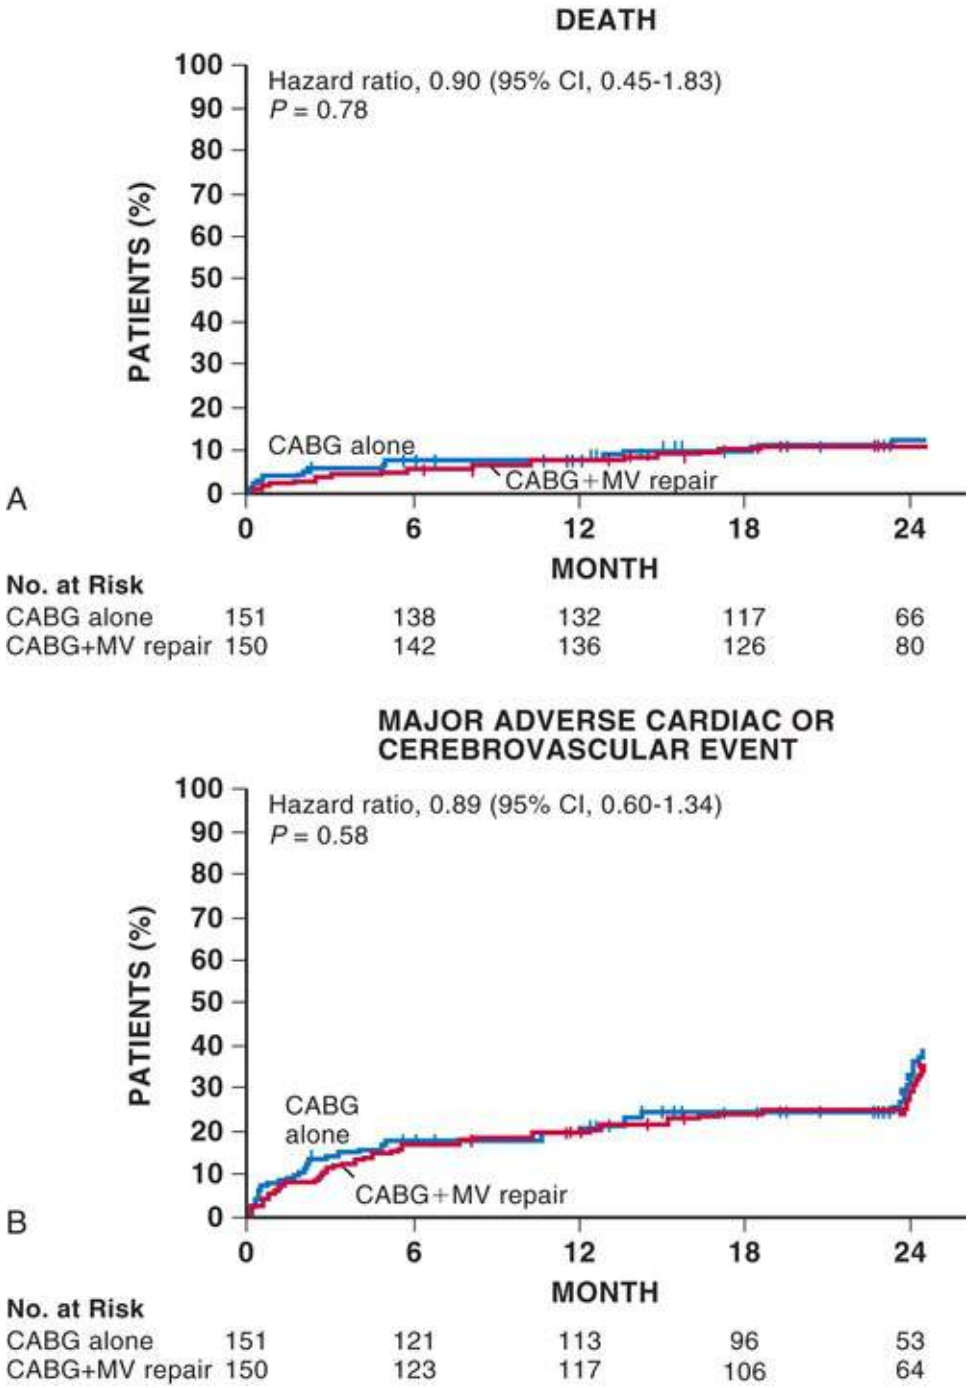

FIGURE 28.4 Results of CTSnet moderate ischemic mitral regurgitation trial showing mortality and cardiovascular events at 2 years. **A,** Rates of death, and **B,** a composite of major adverse cardiac and cerebrovascular events (defined as death, stroke, subsequent mitral valve surgery, hospitalization for heart failure, or worsening New York Heart Association class) among patients undergoing either coronary artery bypass grafting (CABG) or CABG plus mitral valve (MV) repair. (From Michler RE, Smith PK, Parides MK, et al. Two-year outcomes of surgical treatment of moderate ischemic mitral regurgitation. N Engl J Med 2016;374:1932.)

A subgroup analysis of the patients in the CTSnet trial who underwent MV repair identified the presence of a basal aneurysm or dyskinesis as the strongest predictor of repair failure. Additional predictors of recurrence include an anterior leaflet angle greater than 25 to 39.5 degrees, an LV end-diastolic diameter greater than 65 mm, and increased LV sphericity. The 2015 American Association for Thoracic Surgery guidelines support MV replacement in the presence of basal aneurysm/dyskinesis, significant leaflet tethering, or moderate to severe remodeling (LVEDD >65 mm) (class IIa, level of evidence A). In the absence of these findings, consideration of MV repair with an undersized, complete rigid ring should be considered (class IIb, level of evidence B).[18] **Table 28.2** summarizes recent guideline statements about surgery for MR in patients with HF. Additional content on this topic is presented in the

online supplement for this chapter (Mitral Valve Repair for Mitral Regurgitation in Ischemic Cardiomyopathy).

In summary, in experienced centers, MV repair for patients with LV dysfunction and MR may be appropriate for those undergoing CABG as well as for selected patients with idiopathic dilated cardiomyopathy who remain symptomatic despite optimal medical therapy. The current literature suggests that functional mitral insufficiency in patients with advanced HF and LV dysfunction can be corrected with a low operative mortality in either ischemic or nonischemic cardiomyopathies. Both randomized and nonrandomized series suggest a symptomatic benefit as well as a remodeling benefit in patients with idiopathic dilated cardiomyopathy who undergo MV repair. No randomized studies have compared surgical correction of severe MR with optimal medical management. Currently, no evidence indicates that elimination of mitral insufficiency in HF patients conveys a survival benefit, but rather that this is symptomatic therapy. Percutaneous MV repair is discussed in **Chapter 69**.

Aortic Valve

The indications for valve replacement in aortic stenosis (AS) and aortic regurgitation (AR) are discussed in **Chapter 68**. The focus here is on aortic valve replacement (AVR) for patients with aortic valve disease and significant ventricular dysfunction, typically causing HF. Patients with AS may develop ventricular dysfunction with a low gradient across the aortic valve. AVR is warranted in these patients if the LV dysfunction is secondary to the AS. Accordingly, it is important to differentiate between pseudo-obstruction, with poor ventricular function leading to reduced opening of the aortic valve, and true AS. In true AS, a primary valve obstruction leads to LV dysfunction in patients with AS and a low cardiac output. Dobutamine echocardiography is useful to make this determination (**see Chapter 14**).

Although patients with true AS and LV dysfunction have been deemed inoperable in the past because of the concern of perioperative mortality, the prognosis for these patients, if they do not receive an AVR, is extremely poor, with 1-, 5-, and 10-year survival rates of 62%, 32%, and 18%, respectively.[19] No definitive trials have been conducted to demonstrate that concomitant pharmacotherapy has any impact on survival. Conversely, studies have indicated that this population of patients can undergo surgery safely, with better outcomes than with medical therapy alone. In a study from the Cleveland Clinic, the in-hospital mortality for this group of patients was 8%, with a 1-year survival rate of 82%, versus 41% for those treated with medical therapy alone; 4-year survival rates of 78% and 15% were noted for those treated with AVR and medical therapy alone, respectively.[20] Assuming that the patient has true AS with a depressed cardiac output and a low gradient, the risk-to-benefit ratio would favor surgical intervention in patients who are otherwise healthy enough to undergo surgery. In the current era, *transcatheter aortic valve replacement* (TAVR) allows a further reduction in perioperative morbidity and mortality in treating patients with HF and AS (**see Chapter 68**). Analysis of the PARTNER trial data has demonstrated TAVR to be a safe treatment strategy in high-risk patients with LV dysfunction.[21] Midterm follow-up has demonstrated a significant improvement in EF (35.7 ±8.5% to 48.6 ±11.3% at 1 year). In another common clinical scenario, the patient undergoing CABG is found to have some degree of AS as well. Studies and guideline recommendations suggest that in many situations, a dual procedure of CABG and AVR can be safely performed with better long-term outcomes.

The management of patients with severe AR and LV dysfunction poses a different problem. Some patients develop advanced HF and have been considered for cardiac transplantation because the LV dysfunction was considered to be irreversible. Although the operative mortality in this group has been high historically, a study from the Brigham and Women's Hospital has demonstrated that surgical AVR for

patients with pure AR and LV dysfunction (LVEF <35%) is safe with negligible mortality.[22] In this series, positive ventricular remodeling with improvements in LV diameter, volume, and function were observed after AVR surgery. A recent study suggests that LV remodeling after AVR for chronic AR is greatest in patients with higher global longitudinal strain indexed for end-diastolic volume,[23] correlating improved outcomes with preserved ventricular dimensions. Although late survival may not be as good in the presence of LV dysfunction compared to patients with normal preoperative LV function with severe aortic insufficiency, the outcomes may be better than with cardiac transplantation or continued medical therapy. Although a number of series have examined the prognostic variables after aortic valve surgery, patients with both low LVEF and significant aortic insufficiency are included only in small numbers.[24] For many years, guidelines have encouraged the surgical management of patients with significant AR before the onset of significant HF symptoms or severe LV dilation. More recently, newer surgical procedures have used aortic valve repair or aortic root replacement as better procedures than AVR alone in the patient with primary AR.

In summary, aortic valve surgery can be performed safely, although at higher operative risk, in patients with severe LV dysfunction and HF, and it appears to have a better clinical outcome than that achieved with current medical therapy in observational studies.

Left Ventricular Reconstruction

Revascularization and valve operations lead to clinical improvement in many patients, but in others, ventricular dilation and dysfunction are so severe that direct ventricular surgery has been proposed to optimize cardiac function. Patients who have a transmural myocardial infarction (MI) may develop ventricular dilation and remodeling that lead to changes in increased LV wall stress and LV dysfunction. A host of adverse events are initiated, including increased myocardial oxygen consumption secondary to increased wall stress, increased neurohormone and cytokine levels, afterload mismatch, and subendocardial hypoperfusion. The stated goals of ventricular reconstruction are to remove or to exclude the infarcted segment to restore an elliptical ventricular chamber, to diminish remote wall stress, to promote helical fiber orientation and increase thickening of the akinetic or dyskinetic portion of the chamber, to reduce end-systolic volume, to diminish mitral insufficiency, and to eliminate residual ischemia. Concomitant CABG often is necessary, and if more than moderate MR is present, this should be corrected separately.

This type of operation is variously named *surgical ventricular reconstruction* (SVR) or the *Dor procedure* (after Vincent Dor), in which the aneurysm or akinetic segment is reconstructed, typically with a patch (endoventricular patch plasty).[25] The operation is performed through the area of scar. A pursestring suture is placed between the infarcted and normal myocardium. An endoventricular Dacron patch usually is used to exclude the infarcted segment, with closure of the aneurysm sac over the patch. A mandrel often is used to ensure that adequate ventricular volume is maintained. This operation typically is reserved for patients who have had a large anterior-apical infarct that involves the apex, anterior wall, and septum with resulting LV remodeling. Ideally, the operation was designed to reduce end-systolic volumes by at least 30% while ensuring adequate size of the ventricle.

The RESTORE (Reconstructive Endoventricular Surgery Returning Torsion Original Radius Elliptical Shape to the Left Ventricle) multicenter study investigated various techniques for LV reconstruction in a

registry of 1198 patients with post–anterior infarction HF operated on between 1998 and 2003. Concomitant procedures included CABG in 95% and MV repair in 22%. The operative mortality rate in patients who underwent LV reconstruction was 5.3%. At 5 years the overall survival rate was 68% ±2.8%, and freedom from hospital readmission for HF was confirmed in 78%. Logistic regression analysis identified LVEF of less than 30%, LV end-systolic volume index (LVESI) of 80 mL/m^2 or higher, advanced NYHA functional class, and age older than 75 years as risk factors for death. LV reconstruction resulted in a significant decrease in LVESI (from 80.0 ±5.1 to 56.0 ±34.3 mL/m^2) and a significant increase in LVEF (from 29% ±11.0% to 39% ±12.3%).[25] Clinicians worldwide embraced this reconstructive surgery, and one arm of the STICH trial further explored the usefulness of this operative procedure for patients with ischemic cardiomyopathy.

The SVR arm of the STICH trial (hypothesis 2) tested whether adding SVR to CABG in ischemic HF patients would decrease death from any cause or cardiac rehospitalization compared with CABG alone. This substudy included 1000 patients (operated on between 2002 and 2006) with HF who had concomitant CAD, LVEF of less than 35%, and anterior LV wall scar amenable to SVR. Bypass surgery alone was performed in 499 patients and CABG plus SVR in 501 patients. They were studied for a median follow-up of 48 months. No significant difference was found in the primary outcome endpoint of death from any cause or hospitalization for cardiac causes (HR for SVR plus CABG, 0.99; 95% CI, 0.84 to 1.17; $P = 0.90$) during the 5 years of the study (**Fig. 28.5**). The results have been criticized because the average percentage reduction in end-systolic volume after CABG plus SVR was only 19%—below the accepted criterion for successful LV reconstruction, which requires a 30% (minimum) reduction in end-systolic volume. In addition, the absolute LVESI in the STICH patients undergoing CABG plus SVR was 67 mL/m^2. The results of Oh and colleagues[26] demonstrated that patients who were left with a residual LVESI greater than 60 mL/m^2 had a worse survival than that achieved in those with a more optimal LVESI of less than 30 mL/m^2. An additional limitation of the STICH trial is that 13% of patients did not have an infarct before development of LV dysfunction. A final criticism is that with an ongoing selection bias, the study did not include patients thought to clearly benefit from SVR. Many surgeons think that because of these possible shortcomings in the trial, STICH did not prove or disprove the original hypothesis. Certainly, ongoing investigations are examining predictors of success using the SVR operation in other cohorts outside of the STICH trial.

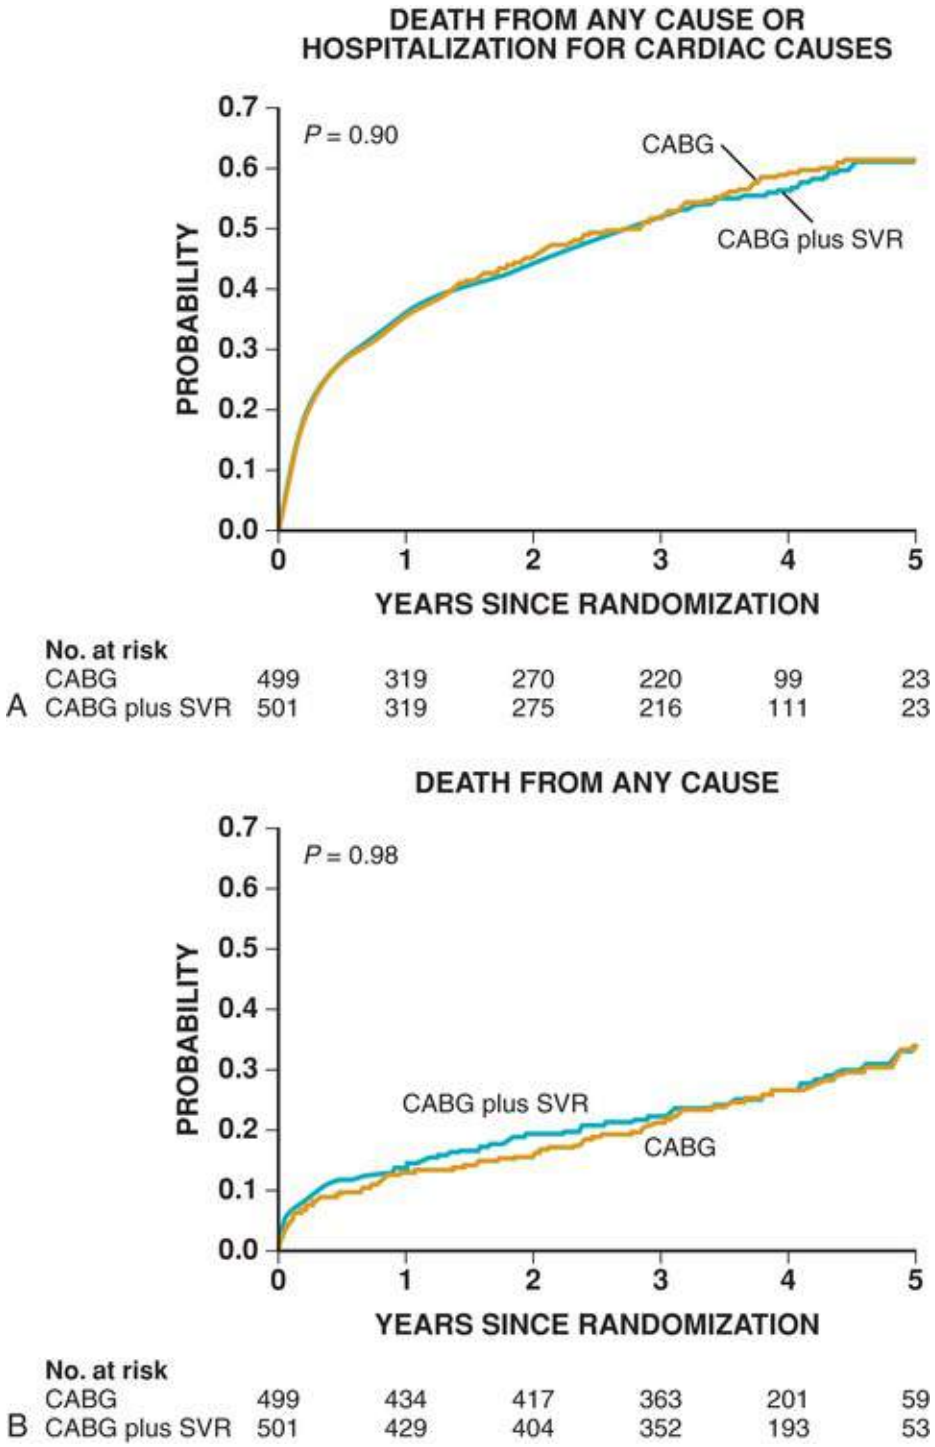

FIGURE 28.5 Results of STICH trial showing no benefit for surgical ventricular reconstruction (SVR) and CABG over CABG alone. (From Jones RH, Velazquez EF, Michler RE, et al. Coronary bypass surgery with or without surgical ventricular reconstruction. N Engl J Med 2009;360:1705.)

In addition to direct surgical ventricular reconstruction of the failing heart, a number of novel surgical approaches have also been studied to inhibit or to reverse LV remodeling, including passive cardiac support devices developed from original observations with dynamic cardiomyoplasty, which initially was intended to act as an auxiliary pump for the failing heart. Additional content on this topic is presented in the online supplement for this chapter (Passive Cardiac Support Devices).

Cardiac Transplantation

Donor Allocation System

In the United States, the allocation of donor organs is accomplished under the supervision of the United Network of Organ Sharing (UNOS), a private organization under contract to the federal government. The United States is divided geographically into 11 regions for donor heart allocation. Under UNOS policy, thoracic organs are distributed on the basis of blood type, medical urgency, and time on the waiting list. The physiologic limit of approximately 4 to 5 hours of ischemic out-of-body time for hearts precludes a national sharing of donor hearts. Currently, the highest priority for patients to receive donor organs is assigned according to the severity of illness. Each candidate awaiting heart transplantation is assigned a status corresponding to the medical urgency for that candidate. For a candidate who is 18 years of age or older at the time of listing, medical urgency is assigned according to UNOS policies[27] (**Table 28.3**). A candidate who is listed as "status 7" is considered temporarily unsuitable to receive a thoracic organ transplant. In the current system, there is marked regional variability in waitlist time across the United States[28,29]; a revised allocation proposal is under evaluation.[30,31]

TABLE 28.3

United Network of Organ Sharing (UNOS) Allocation of Hearts

Adult Heart Status 1A Requirements	
If Candidate Meets This Condition:	**Adult Status 1A Is Valid For:**
Candidates (at least 18 years old) Currently Hospitalized in Transplant Hospital	
Has a mechanical circulatory support device: Total artificial heart Intra-aortic balloon pump Extracorporeal membrane oxygenation	14 days, recertified every 14 days
Requires continuous mechanical ventilation	14 days, recertified every 14 days
Requires continuous infusion of a single high-dose IV inotrope or multiple IV inotropes and continuous hemodynamic monitoring of LV pressures	7 days, may be renewed for 7 days
Candidates (at least 18 years old), Current Hospitalization Not Required	
Has a mechanical circulatory support device: Left ventricular assist device (LVAD) Right ventricular assist device (RVAD) Left and right ventricular assist device (BiVAD)	30 days at any point after implantation
Has mechanical circulatory support, and there is medical evidence of significant device-related complication	14 days, recertified every 14 days
Adult Heart Status 1B Requirements	
If Candidate Meets This Condition:	**Adult Status 1B Is Valid For:**
Left ventricular assist device (LVAD) Right ventricular assist device (RVAD) Left and right ventricular assist device (BiVAD) Continuous infusion of IV inotrope	Unlimited time
Adult Heart Status 2 Requirements	
If Candidate Meets This Condition:	**Adult Status 2 Is Valid For:**
Registered for listing, not 1A or 1B	Unlimited time

Worldwide, patients waiting for a donor heart greatly exceed availability.[32] In the United States, as many as 40% of patients listed and waiting for a heart transplant are implanted with a mechanical circulatory support (MCS) device (**see Chapter 29**), typically a left ventricular assist device (LVAD), to maintain end-organ integrity, reduce pulmonary vascular resistance, and improve functional capacity. Serious debate has emerged concerning the additional cost of MCS to transplant and the outcomes for these patients compared with transplant recipients without a LVAD during the waiting period. Other transplant centers have chosen a strategy of accepting marginal donors for critically ill patients rather than using MCS as a bridge to transplant.

Evaluation of the Potential Recipient

Fig. 28.6 outlines the questions that must be answered to evaluate a potential patient for cardiac transplantation. Patients estimated to have less than a 1-year life expectancy are the usual candidates because the considerable risks of the transplant procedure must be taken into account; transplant

guidelines underscore this point.[33] Typically, patients for consideration have (1) cardiogenic shock requiring mechanical support or high-dose inotropic or vasopressor drugs (in which case the irreversibility of their course is usually clear); (2) chronic progressive, refractory, or stage D heart failure symptoms despite optimal therapy; (3) recurrent life-threatening arrhythmias despite maximal interventions, including implanted defibrillators; or, rarely, (4) refractory angina without potential for revascularization. Moreover, adult patients with repaired congenital heart disease, especially those with failing-Fontan physiology, are being increasingly considered for heart transplantation.

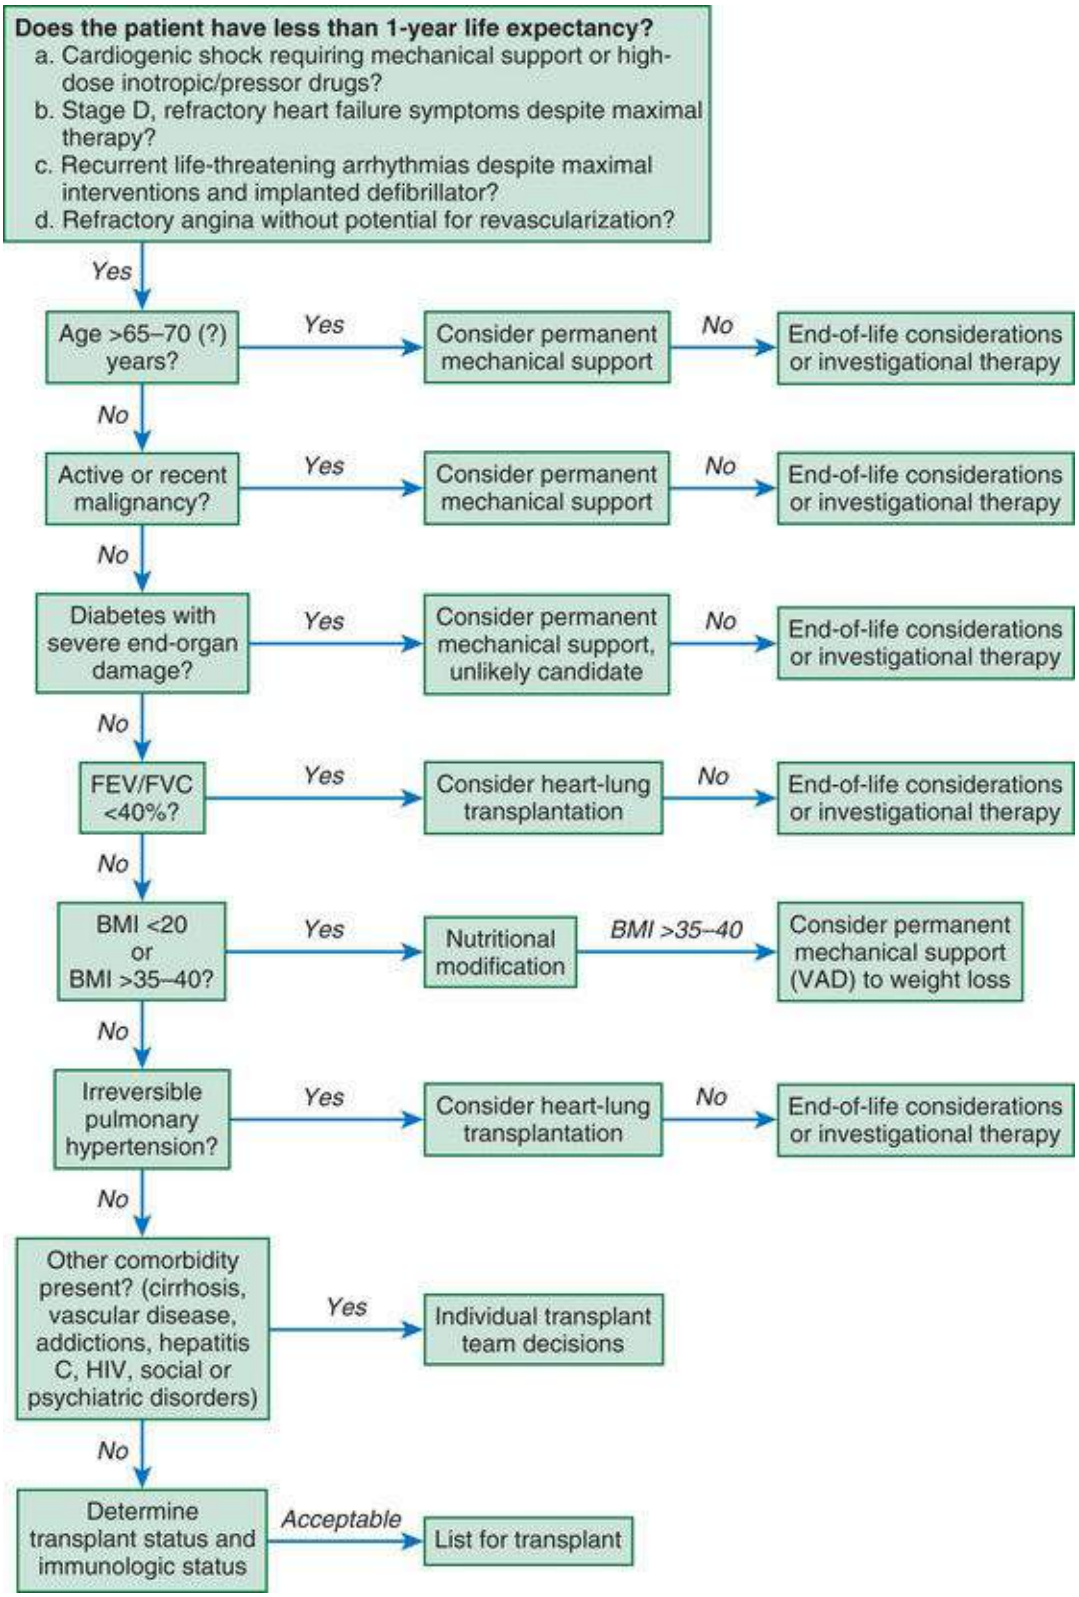

FIGURE 28.6 Algorithm for evaluation of the potential heart transplant recipient. BMI, Body mass index; FVC, forced vital capacity; FEV, forced expiratory volume; HIV, human immunodeficiency virus; VAD, ventricular assist device.

Several models have been proposed to assist in the risk stratification of HF patients with biomarkers using invasive and noninvasive methods. Models to assess the prediction of risk in a patient who will undergo transplantation also have been proposed[34-36] (**Fig. 28.7**). The most potent predictor of outcome in ambulatory patients with HF is a symptom-limited metabolic stress test to calculate peak oxygen consumption (Vo_2). A peak Vo_2 of less than 12 mL/kg/min indicates a poor prognosis, with likelihood of survival less than that with transplantation.[33] The lack of applicability of Vo_2 in patients too sick to exercise, however, has necessitated the use of other methods of risk assessment. Nonambulatory patients

requiring continuous intravenous (IV) inotropic support who cannot be weaned or who require mechanical support to maintain adequate cardiac index are more obviously at risk for a poor outcome without transplantation, but signs and symptoms of end-organ failure of the pulmonary, hepatic, and renal systems, which may signal an ominous prognosis even with a transplant procedure, are often manifested.[37,38]

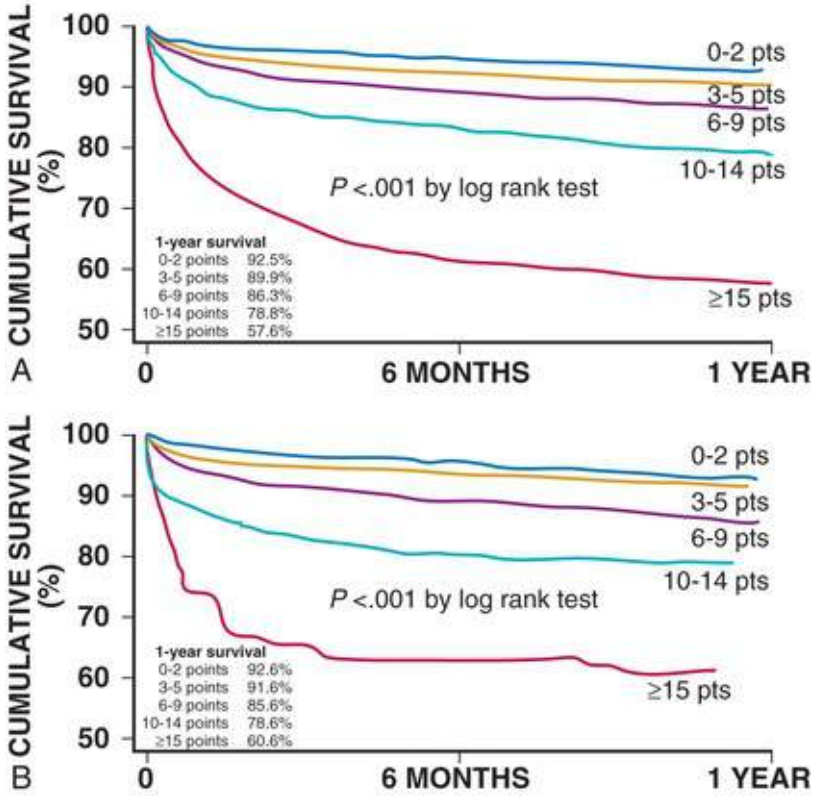

FIGURE 28.7 Kaplan-Meier cumulative 1-year survival of recipients in the derivation cohort **(A)** and validation cohort **(B)** as stratified by three-point increments of risk in the IMPACT score used to predict risk of death for patients undergoing orthotopic heart transplantation. (From Weiss ES, Allen JG, Arnaoutakis GJ, et al. Creation of a quantitative recipient risk index for mortality prediction after cardiac transplantation (IMPACT). Ann Thorac Surg 2011;92:914.)

Each patient must then undergo an extensive medical and psychosocial evaluation by the transplant team to exclude contraindications to transplantation, to further efforts at prognosis, to determine the urgency of transplantation, and to determine immunologic status.[39,40] A number of relative contraindications to heart transplantation are recognized; one of the most debated and variable among centers is the upper age limit for consideration. In general, patients older than 70 years are ineligible and more often are assigned to high-risk reparative surgery, permanent cardiac assist devices, or investigational therapies, such as cell transplantation, or to receive hearts from an alternate list of less-than-optimal donors. Nevertheless, some transplant centers maintain that carefully selected patients older than 70 can achieve outcomes equivalent to those obtained in younger patients. An active or recent malignant neoplasm, diabetes with severe end-organ damage, and other metabolic abnormalities that may limit life expectancy after transplantation are common reasons to exclude potential recipients. Significant lung disease complicates postoperative management and precludes the possibility of normal physical functioning; extremes of weight, as measured by body mass index (BMI), also have been shown to worsen post-transplantation prognosis. Patients with advanced HF associated with renal dysfunction generally are excluded from heart transplantation, because abnormal renal function increases morbidity after

transplantation. Alternatively, some centers have successfully performed simultaneous heart and kidney transplants in patients with advanced kidney disease, using organs from the same donor. Thus it is important to distinguish patients with potentially reversible renal failure from those in whom renal dysfunction is associated with advanced, irreversible end-stage renal disease.

Pulmonary arterial hypertension in a patient with pulmonary vascular resistance greater than 6 Wood units that cannot be reduced by medical therapy, or after placement of a VAD, is considered an absolute contraindication to cardiac transplantation. In the setting of fixed pulmonary hypertension, the donor right ventricle often will fail, leading to a high rate of early postoperative mortality.[41] In patients with irreversible pulmonary pressures, some centers may consider individual patients for a combined heart-lung transplant procedure. Other comorbid conditions that may have a negative impact on a transplant team's decision to further consider a potential recipient include peripheral or cerebral vascular disease, advanced neuropathy, human immunodeficiency virus (HIV) status, addictions to alcohol or illicit drugs, and social or psychiatric disorders. In selected patients with cirrhosis, a combined heart-liver transplant has been done.[42]

An increasingly sophisticated immunologic evaluation of each patient is done for ABO blood typing and antibody screening, panel-reactive antibody (PRA) level determination, and human leukocyte antigen (HLA) typing. The PRA test can identify the presence of circulating anti-HLA antibody but not the specificity or strength of antibody. Enzyme-linked immunoassay and flow cytometry can also determine PRA level and are more sensitive than the cytotoxic test.[43] Virtual crossmatch methods, in which flow cytometry–based single-antigen bead assays allow the clear identification of antibody specificities, are now widely used. Prospective donors with these antigens can be avoided, and a compatible donor can be selected without the need for a prospective crossmatch. This approach allows an increased rate of donor matching outside the geographic area of the local organ procurement organization.

The Cardiac Donor

In light of an inadequate number and increasing organ demand, efficacious donor management and selection are crucial in maintaining excellent transplant volumes and outcomes. It is critical to obtain a complete medical history for the donor, including any relevant cardiovascular disorders before brain death. All donors are screened for communicable diseases, including viral disorders such as hepatitis and HIV infection. Specific information that is relevant for the assessment of cardiac donor suitability also includes the presence or absence of thoracic trauma, disseminated cancer, donor hemodynamic stability, pressor and inotropic requirements, duration of cardiac arrest, and need for cardiopulmonary resuscitation. In some cardiac donors, hemodynamic deterioration may be caused by brain death. Cardiac echocardiography is required for all donors, and coronary arteriography is required to evaluate the presence of CAD in donors older than 45 to 50 years, depending on other risk factors.

The acceptable cold ischemia time for cardiac transplantation is approximately 4 to 5 hours; systems of ex vivo heart perfusion of human donors are under investigation.[44] Prolonged ischemic time has been shown to be a significant risk factor for death after cardiac transplantation, especially when coupled with other risk factors, such as older donor age. Donors up to age 60 to 65 years are currently considered, depending on transport distance and other donor risk factors. The final decision to accept a heart for transplantation is made at the time of harvesting, after direct examination of the heart for coronary calcification, as well as LV hypertrophy or dilation. Many regions have instituted a process of systematically reviewing donor turndown events to reduce variability and increase confidence in expanded criteria for donors. These outcome reviews have resulted in improved donor organ utilization

and transplant volumes.[45]

Surgical Considerations

The two most common surgical approaches for the implantation of the donor heart are the biatrial and the bicaval anastomoses. The *bicaval anastomosis* technique was introduced with the intention to reduce right atrial size, minimize distortion of the recipient heart, preserve atrial conduction pathways, and decrease tricuspid regurgitation. This alternative procedure entails five anastomoses: left atrium, pulmonary artery, aorta, inferior vena cava, and superior vena cava. Although no prospective trial has been conducted to establish the superiority of either technique, the bicaval technique is now being done most often in the United States, primarily because it appears to decrease the need for permanent pacemakers in transplant recipients.[46] Most important, the number of patients coming to transplantation with a VAD in place has steadily increased, so that transplant procedures are riskier and result in more device-related complications.

The most common reason for failure to wean a heart transplant recipient from cardiopulmonary bypass is right-sided heart failure, evidenced by a low cardiac output despite a rising central venous pressure. The right side of the heart can be seen in the surgical field to dilate and to contract poorly. Intraoperative transesophageal echocardiography shows a dilated, poorly contracting right ventricle and an underfilled, vigorously contracting left ventricle. Right ventricular function may be enhanced with inotropes and pulmonary vasodilators, but the prognostic importance of preoperative pulmonary vascular resistance becomes obvious in these first few hours after surgery.[41]

Immunosuppression

Immunosuppressive regimens begin with the simultaneous use of three classes of drugs: glucocorticoids, calcineurin inhibitors (CNIs), and antiproliferative agents.[47] In a subset of patients, transplant teams use a variety of drugs for induction therapy to rapidly enhance immune tolerance.[48] In the immediate postoperative period, immunosuppressive agents are given parenterally, with a quick transition to oral formulations.

Corticosteroids are nonspecific anti-inflammatory agents that work primarily by lymphocyte depletion. Patients initially receive high doses of IV and then oral corticosteroids, which are gradually tapered during the next 6 months; the goal often is to withdraw corticosteroid therapy completely. At many centers, corticosteroids are given several hours before the transplant surgery. Side effects include cushingoid appearance, hypertension, dyslipidemia, weight gain with central obesity, peptic ulcer formation and gastrointestinal bleeding, pancreatitis, personality changes, cataract formation, hyperglycemia progressing to corticosteroid diabetes, and osteoporosis with avascular necrosis of bone. The well-appreciated adverse side effect profile of the corticosteroids has led to a number of innovative strategies to eliminate them as early as possible after the transplant surgery. Corticosteroids usually are the agents of first choice to treat acute rejection as well.

There are two CNIs, *cyclosporine* and *tacrolimus*. Their main mechanism of action involves binding to specific proteins to form complexes that block the action of *calcineurin*, a key participant in T cell activation. The CNIs serve to block the signal transduction pathways responsible for T cell and B cell activation and therefore act specifically on the immune system and do not affect other, rapidly proliferating cells. Critical and often limiting adverse effects include nephrotoxicity in as many as 40% to 70% of patients and hypertension with the development of LV hypertrophy; both drugs cause

approximately equivalent numbers of these untoward events. Hirsutism, gingival hyperplasia, and hyperlipidemia are more frequent with cyclosporine, and diabetes and neuropathy are more common with tacrolimus. In addition, an increased incidence of deep vein thrombosis, tremor, headache, convulsions, and paresthesias of the limbs has been reported with both drugs.

Antiproliferative agents work to either directly or indirectly inhibit the expansion of alloactivated T cell and B cell clones. *Azathioprine* was the earlier agent used in this class and served as the mainstay of immunosuppression even before the routine use of cyclosporine. In the past decade, *mycophenolate mofetil* (MMF) has replaced azathioprine as the first-line antiproliferative agent, with several randomized trials demonstrating superiority compared with azathioprine.[49] MMF is hydrolyzed to mycophenolic acid, which inhibits de novo purine synthesis. Both azathioprine and MMF cause leukopenia as their major adverse effect; the use of MMF can be limited by debilitating diarrhea or nausea. The combination of MMF and tacrolimus likely potentiates their individual adverse effects.

Sirolimus (often called *rapamycin*) and *everolimus* are two newer agents that block activation of T cells after autocrine stimulation by interleukin-2 (IL-2). They also are known to inhibit proliferation of endothelial cells and fibroblasts. Their action is complementary to that of CNIs, and both sirolimus and everolimus have been used as maintenance immunosuppression, as alternatives to standard immunosuppression, and as rescue drugs for rejection. Sirolimus, an m-TOR inhibitor, has been shown to slow progression of *cardiac allograft vasculopathy* (CAV) with established disease,[50] and everolimus has been demonstrated to reduce both acute rejection and CAV. Because the drugs inhibit the proliferation of fibroblasts, they may cause significant difficulties with wound healing, and many centers do not use them for initial therapy immediately after the transplant surgery. The drugs have been associated with the development of significant pericardial effusions. Several investigators have explored using sirolimus as a primary immunosuppressive agent as an alternative to a CNI.[51] Sirolimus and everolimus have been used to replace CNIs as a strategy to improve renal dysfunction or to reverse LV hypertrophy.

With improved immunosuppression, the incidence of any cardiac rejection from donor heart implantation to 1 year has decreased from 30% in 2004 to 2006 to 25% in 2010 to 2012,[52] underscoring the efficacy of current immunosuppression. The TICTAC (Tacrolimus in Combination, Tacrolimus Alone Compared) trial reported that the addition of MMF to single-agent immunosuppression with tacrolimus did not provide an advantage over single-agent immunosuppression in terms of rejection, CAV, or 3-year survival.[53] Corticosteroids were successfully discontinued in all patients. The statistical power of the trial, which included only 150 patients, has been questioned, but these findings have led the heart transplant community to explore a strategy of even less immunosuppression in select patients.

Rejection

Rejection involves cell- or antibody-mediated cardiac injury resulting from recognition of the cardiac allograft as non-self. By histologic and immunologic criteria, this process is categorized into three major types of rejection: hyperacute, acute, and chronic. *Hyperacute* rejection results when an abrupt loss of allograft function occurs within minutes to hours after circulation is reestablished in the donor heart and is rare in modern-day transplantation. The phenomenon is mediated by preexisting antibodies to allogeneic antigens on the vascular endothelial cells of the donor organ, which is now avoided with current HLA typing techniques. These antibodies fix complement, which promotes intravascular thrombosis. Subsequently, rapid occlusion of graft vasculature occurs, followed by swift and overwhelming failure of the cardiac graft.

Acute cellular rejection or cell-mediated rejection is a mononuclear inflammatory response,

predominantly lymphocytic, directed against the donor heart. It is most common from the first week to several years after transplantation and occurs in up to 30% of patients during the first year after surgery. The key event in both the initiation and the coordination of the rejection response is T cell activation, moderated by IL-2, a cytokine. IL-2 is produced by $CD4^+$ cells and to a lesser extent by $CD8^+$ cells and exerts both an autocrine and a paracrine response. Unlike in renal and liver transplants, no reliable serologic markers for rejection in the cardiac transplant have been identified, although several reports have explored the utility of using high-sensitivity cardiac troponin I for this purpose. Therefore the endomyocardial biopsy remains the "gold standard" for the diagnosis of acute rejection (**see Chapter 79**). Biopsies are performed using a transjugular approach weekly and then every other week for several months; monthly biopsies continue for 6 to 12 months in many programs and for years thereafter in others. There is ongoing scrutiny of the cost-effectiveness of routine or surveillance biopsies after 1 year.[54]

Cell-mediated rejection is graded according to a universally agreed-on system[55] (**Table 28.4**). Endomyocardial biopsies are invasive and painful and may cause serious adverse events such as pericardial tamponade or tricuspid insufficiency. Accordingly, efforts continue to develop a serologic assay composed of gene expression or transcriptional factors that are significantly regulated during cardiac rejection. The largest trial to date, IMAGE (Invasive Monitoring Attenuation through Gene Expression), demonstrated that among select patients who had received a cardiac transplant more than 6 months before entering the study, and who were at a low risk for rejection, a strategy of monitoring for rejection that involved gene-expression profiling, compared with use of routine biopsies, was not associated with an increased risk of serious adverse outcomes and resulted in the performance of significantly fewer biopsies.[56] It is not clear how readily this assay has been adopted in the United States, although the study seems to have resulted in a lower rate of endomyocardial biopsies done for surveillance only. Cardiac magnetic resonance imaging has also been investigated as a modality to detect rejection.

TABLE 28.4

Current Grading System for Cell-Mediated Rejection in Heart Transplantation Compared with an Earlier System

2004 SYSTEM		1990 SYSTEM	
Grade 0 R	No rejection	Grade 0	No rejection
Grade 1 R, mild	Interstitial and/or perivascular infiltrate with up to one focus of myocyte damage	Grade 1, mild	
		A—focal	Focal perivascular and/or interstitial infiltrate without myocyte damage
		B—diffuse	Diffuse infiltrate without myocyte damage
Grade 2 R, moderate	Two or more foci of infiltrate with associated myocyte damage	Grade 2, moderate (focal)	One focus of infiltrate with associated myocyte damage
Grade 3 R, severe	Diffuse infiltrate with multifocal myocyte damage ± edema, ± hemorrhage, ± vasculitis	Grade 3, moderate	
		A—focal	Multifocal infiltrate with myocyte damage
		B—diffuse	Diffuse infiltrate with myocyte damage
		Grade 4, severe	Diffuse, polymorphous infiltrate with extensive myocyte damage ± hemorrhage ± vasculitis

Modified from Stewart S, Winters GL, Fishbein MC, et al. Revision of the 1990 working formulation for the standardization of nomenclature in the diagnosis of heart rejection. J Heart Lung Transplant 2005;24:1710.

Risk factors for early rejection include younger recipient age, female sex, female donor, positive cytomegalovirus (CMV) serologic test results, prior infections, black recipient race, and number of HLA mismatches; a risk score predictive for rejection has been developed.[57] Most important, patients who fail to take or to tolerate their immunosuppressant drugs, especially early in the postoperative course, are at very high risk for severe or recurrent cellular rejection. The occurrence of one or more episodes of treated rejection during the first year is a risk factor for both failure to attain 5-year survival and

development of transplant-related CAD. Likewise, treatment of acute rejection in the first 6 months after transplantation contributes to a slower overall rehabilitation of the patient.

The aggressiveness of treatment for cell-mediated rejection depends on the biopsy grade, clinical correlation, patient risk factors, rejection history, length of time after transplantation, and whether or not target levels of the immunosuppressant drugs are achieved. For example, an asymptomatic, early moderate rejection occurring soon after transplantation in a patient in whom immunosuppressants are at or above target levels, or who has one or more risk factors for early rejection, would be treated more aggressively than a low-risk patient with no previous history of cell-mediated rejection.

Another form of acute rejection is acute humoral rejection, or *antibody-mediated rejection,* which occurs days to months after transplantation and is initiated by antibodies rather than by T cells. The alloantibodies are directed against donor HLA or endothelial cell antigens. Antibody-mediated rejection is a serious complication after heart transplantation and is manifested as "graft dysfunction" or hemodynamic abnormalities in the absence of cellular rejection on biopsy. Antibody-mediated rejection is now recognized as a distinct clinical entity, and strict histopathologic and immunologic criteria for its diagnosis have been established (**eTable 28.1**).[58] Patients at greatest risk for antibody-mediated rejection are women and patients with a high PRA level or a positive crossmatch. It is estimated that significant antibody-mediated rejection occurs in about 7% of patients, but the rate may be as high as 20%. Because antibody assays are becoming more precise, more antibody-mediated rejection probably will be recognized, with a correlating need for newer treatment algorithms.

ETABLE 28.1

Findings in Acute Antibody-Mediated Rejection (AMR) of Cardiac Transplants

	REQUIRED FINDINGS	OPTIONAL
1. Clinical evidence of acute graft dysfunction		Recommended in combination with other evidence to support diagnosis of AMR
2. Histologic evidence of acute capillary injury (a and b required)	a. Capillary endothelial changes b. Macrophages in capillaries	c. Neutrophils in capillaries (severe) d. Interstitial edema hemorrhage (severe)
3. Immunopathologic evidence for antibody-mediated injury (a or b or c required)	a. IgG, IgM, and/or IgA + C3d and/or C4d or Clq (2-3+ intensity) by IF b. CD 68 for macrophiages in capillaries (CD31 or CD34) and/or C4d (2-3+ intensity) in capillaries by paraffin IH c. Fibrin in vessels (severe)	
4. Serologic evidence of anti-HLA or antidonor antibodies		Anti-HLA class I and/or class II or other antidonor antibody at biopsy (supportive of clinical and/or morphologic findings)

IF, Immunofluorescence; *IH,* immunohistochemistry.

Modified From Reed EF, Demetris AJ, Hammond E, et al. Acute antibody-mediated rejection of cardiac transplants. J Heart Lung Transplant 2006;25:153-9.

Chronic rejection, or late graft failure, is an irreversible gradual deterioration of graft function that occurs in many allografts months to years after transplantation. Current concepts suggest that donor heart dysfunction in the chronic stages of maintenance immunosuppression is related to chronic rejection, is mediated by antibodies, or is a result of progressive graft loss from ischemia. The latter process is characterized by intimal thickening and fibrosis, leading to luminal occlusion of the graft vasculature, and is often referred to as CAV or transplant CAD.[59]

Infection

Despite the advances in immunosuppressive management, a major untoward consequence remains the occurrence of life-threatening infections. Infections cause approximately 20% of deaths within the first year after transplantation and continue to be a common contributing factor in morbidity and mortality

throughout the recipient's life. The most common infections in the first month after surgery are nosocomial bacterial and fungal infections related to mechanical ventilation, catheters, and the surgical site; the use of MCS as a bridge to transplant has increased the overall infectious rate. Mortality is highest for fungal infections, followed by protozoal, bacterial, and viral infections. Aspergillosis and candidiasis are the most common fungal infections after heart transplantation. Viral infections, especially those caused by CMV, can enhance immunosuppression, potentially resulting in additional opportunistic infections. Accordingly, patients typically are given a prophylactic regimen against CMV, *Pneumocystis jiroveci*, and herpes simplex virus infections and oral candidiasis, to be used during the first 6 to 12 months after transplantation. Prophylactic IV ganciclovir or oral valganciclovir generally is given for variable periods in CMV-seronegative recipients of a transplant from a CMV-positive donor.

Medical Complications and Comorbid Conditions

The complications that follow heart transplantation reflect in part the premorbid status of a majority of transplant recipients, who have vascular disease and other significant medical conditions.[38] After 5 years, more than 90% of recipients have hypertension, at least 80% have hyperlipidemia, and more than 30% have diabetes[60] (**Table 28.5**). Each year after transplantation, clinically significant CAV—which is the major limitation to long life after transplantation—will develop in a large number of patients. By 5 years, almost 30% of recipients will have CAV, and at least half will be so afflicted at 10 years. Cardiac allograft vasculopathy is the most common reason why retransplant is undertaken in the United States (**Fig. 28.8**). Likewise, progressive renal insufficiency is an insidious problem that has only recently been addressed by substitution protocols to limit the administration of CNIs.

TABLE 28.5

Cumulative Post–Heart Transplant Morbidity Rates for Adult Patients*

OUTCOME	WITHIN 5 YEARS	TOTAL NO. OF PATIENTS WITH KNOWN RESPONSE	WITHIN 10 YEARS	TOTAL NO. OF PATIENTS WITH KNOWN RESPONSE
Hypertension	92%	13,023	N/A	N/A
Renal dysfunction	52%	15,769	68%	5428
Abnormal creatinine <2.5 mg/dL	33%		39%	
Creatinine >2.5 mg/dL	15%		20%	
Chronic dialysis	2.9%		6.0%	
Renal transplantation	1.1%		3.6%	
Hyperlipidemia	88%	14,372	N/A	N/A
Diabetes	38%	15,458	N/A	N/A
Cardiac allograft vasculopathy	30%	11,511	50%	3146

*Cumulative prevalence in survivors at 5 and 10 years after transplantation (January 1995 to June 2013). N/A, Not available.

Focus theme: retransplantation. J Heart Lung Transplant 2014;33:996-1008.)

Malignant Neoplasia

The magnitude of overimmunosuppression in many transplant recipients is illustrated by the prediction of a 30% to 40% incidence of neoplasia in these patients during the past 30 years. The risk of fatal malignant disease progressively increases in the years after transplantation, and there is a substantially higher risk in immunosuppressed patients than in the normal population.[61] Post-transplantation lymphoproliferative disease and lung cancer are the most common fatal malignant neoplasms (**Table 28.6**).

TABLE 28.6

First Malignancy Occurring after Adult Heart Transplant*

TYPE/LOCATION	TOTAL	MALES	FEMALES
	n (%)	*n* (%)	*n* (%)
Lung carcinoma	111 (21)	87 (21)	24 (23)
PTLD/lymphoma	88 (17)	76 (18)	12 (11)
Prostate carcinoma	81 (15)	81 (19)	—
Melanoma	35 (6.7)	32 (7)	3 (2.9)
Colon carcinoma	26 (4.9)	18 (4.5)	7 (6.7)
Breast carcinoma	22 (4.2)	—	21 (20)

*Excludes basal cell and squamous cell skin cancer.

Diabetes Mellitus

Patients in whom new-onset diabetes mellitus (DM) develops after transplantation are at increased risk for morbidity and mortality. Accumulating evidence suggests that long-term outcomes, including patient survival and graft survival, may be adversely affected. Much of the diabetes that occurs is attributed to the high-dose corticosteroids used early after transplant surgery, but it is now appreciated that the CNIs play an important role as well. Impaired B cell function appears to be the primary mechanism of CNI-induced new-onset DM.

The risk factors for the development of DM after transplantation include obesity, increased age, family history of DM, abnormal glucose tolerance, and African American or Hispanic descent. Changing trends in the demographics of transplant patients, such as increased age and increased BMI, suggest that these patients may now be at a greater risk for new-onset DM than in the past.[40] Increased BMI increases risk of insulin resistance, and corticosteroids can cause glucose intolerance, insulin resistance, and frank hyperglycemia. African Americans are more likely to develop new-onset DM regardless of the immunosuppression used but are particularly susceptible after treatment with tacrolimus.

Hypertension

The excess risk of hypertension is related primarily to the use of CNIs because of both direct effects of the drugs on the kidney and the associated renal insufficiency that also is highly prevalent. The incidence of hypertension may be lower with tacrolimus than with cyclosporine. Post-transplantation hypertension is difficult to control and often requires a combination of several antihypertensive agents.

Renal Insufficiency

The risk for the development of chronic renal failure after heart transplant is approximately 10% to 15% by 5 years.[62] Moreover, acute kidney failure complicates the early postoperative course in as many as 40% to 70% of patients. The various postulated causes of CNI-associated early renal insufficiency include direct CNI-mediated renal arteriolar vasoconstriction, increased levels of endothelin-1 (a potent vasoconstrictor), decreased nitric oxide production, and alterations in the kidney's ability to adjust to changes in serum tonicity. Once early renal insufficiency occurs, progressive renal failure has appeared to be inexorable, until recently. Investigators continue to evaluate the effects on renal function, as well as on rejection episodes, of substituting an m-TOR inhibitor (sirolimus or everolimus) for a CNI.[51,63]

Hyperlipidemia

Hyperlipidemia is common after transplantation, as it is in the general population. The concern has been that many studies have demonstrated an association of hyperlipidemia with the development of CAV and cerebrovascular and peripheral vascular disease, with the attendant morbidity and mortality of these vascular disorders. Typically, total cholesterol, low-density lipoprotein (LDL) cholesterol, and triglycerides increase by 3 months after transplantation and then generally fall somewhat after the first year. A number of drugs commonly used after transplantation contribute to the hyperlipidemia observed. Corticosteroids may lead to insulin resistance, increased free fatty acid synthesis, and increased very-low-density lipoprotein production. Cyclosporine increases serum LDL cholesterol and binds to the LDL receptor, decreasing its availability to absorb cholesterol from the bloodstream; tacrolimus probably causes less hyperlipidemia. Sirolimus and MMF also have unfavorable effects on lipids. Sirolimus in escalating doses has been shown to result in prominent elevation of triglyceride levels.

Lipid-lowering therapy with any statin, or HMG-CoA reductase inhibitor, was strongly associated with a marked improvement in 1-year survival in the Heart Transplant Lipid Registry. In heart transplant recipients, pravastatin and simvastatin have been associated with outcome benefits in survival, severity of rejection, incidence of CAV, and even malignancies.[64]

Cardiac Allograft Vasculopathy

The development of transplant vasculopathy remains the most prominent long-term complication of heart transplantation, with an annual incidence rate of 5% to 10%. The prognosis for heart transplant recipients is largely determined by the occurrence of CAV; after the first postoperative year, CAV becomes increasingly important as a cause of death. CAV can develop as early as 3 months after transplantation and is detected angiographically in 20% of grafts at 1 year and in 40% to 50% at 5 years. In contrast with eccentric lesions seen in atheromatous disease, CAV results from neointimal proliferation of vascular smooth muscle cells, so that it is a generalized process. The condition typically is characterized by concentric narrowing that affects the entire length of the coronary tree, from the epicardial to the intramyocardial segments, leading to rapid tapering, pruning, and obliteration of third-order branch vessels. A majority of patients will not experience anginal symptoms because of denervation of coronary arteries. The first clinical manifestation of CAV may be myocardial ischemia and infarction, HF, ventricular arrhythmia, or SCD.

The causes of transplant vasculopathy are multifactorial. The risk for CAV increases as the number of HLA mismatches and the number and duration of rejection episodes increase. Various nonimmunologic factors, including CMV infection of the recipient,[65] donor or recipient factors (e.g., age, sex, pretransplantation diagnosis), and factors related to surgery (e.g., ischemia-reperfusion injury), have been associated with development of CAV and increase the risk for CAV. Classic risk factors for vascular disease, such as smoking, obesity, diabetes, dyslipidemia, and hypertension, also contribute to development of CAV.

In an effort to detect CAV, transplant teams must devise an approach to screen for the disease and, when it is found, to control its progression. Coronary angiography is limited by the fact that CAV produces concentric lesions that affect the distal and small vessels, often before it becomes apparent in the main epicardial vessels. Intravascular ultrasound (IVUS) is the most sensitive imaging technique to study early transplant vasculopathy. IVUS provides quantitative information on vessel wall morphology and lumen dimensions. An increase in intimal thickness of at least 0.5 mm in the first year after transplantation is a reliable indicator of both CAV development and 5-year mortality. However, the inherent invasiveness of

IVUS and the cost of the procedure preclude its widespread application. Dobutamine stress echocardiography has been described as having high sensitivity (83% to 95%) and specificity (53% to 91%) compared with angiographic evaluation of CAV but has been challenged in preference to coronary computed tomographic angiography. Most transplant centers do either coronary angiography or another screening test on an annual basis to assess the risk of new CAV.

A number of trials have been undertaken to examine the efficacy of sirolimus or everolimus in preventing the development or progression of CAV in heart transplant recipients. The precise role of the two drugs in maintenance immunosuppression has not yet been determined, but they are used frequently, with promising results for reduction of coronary intimal thickening once CAV has been detected.[66] Percutaneous coronary intervention with or without coronary stents has been used, with some success.

Outcomes after Heart Transplantation

Survival

Fig. 28.9 depicts the latest data from the International Society for Heart and Lung Transplantation on overall transplant survival, grouped by age at transplant.[52] During the first year after transplantation, early causes of death are graft failure, infection, and rejection, with an overall survival rate at 1 year of 82%. Of interest, although worldwide approaches to the management of the cardiac transplant recipient are substantially different from center to center, the outcomes are surprisingly similar in high-volume programs. Indeed, this phenomenon of similar outcomes despite marked differences in programmatic management may be regarded as a testament to the overall antirejection strategy; institutional and recipient factors determine survival as well.[67-69] Nonspecific graft failure contributes to approximately 35% of deaths during the first 30 days after transplantation, whereas non-CMV infection was the primary cause of death during the first year. After 5 years, CAV and late graft failure (approximately 30% together), malignant neoplasia (25%), and non-CMV infection (10%) are the most prominent causes of death.[52,70] Management of this challenging group of patients has been enhanced by specialty-trained nurses and the development of a multidisciplinary care team.[70]

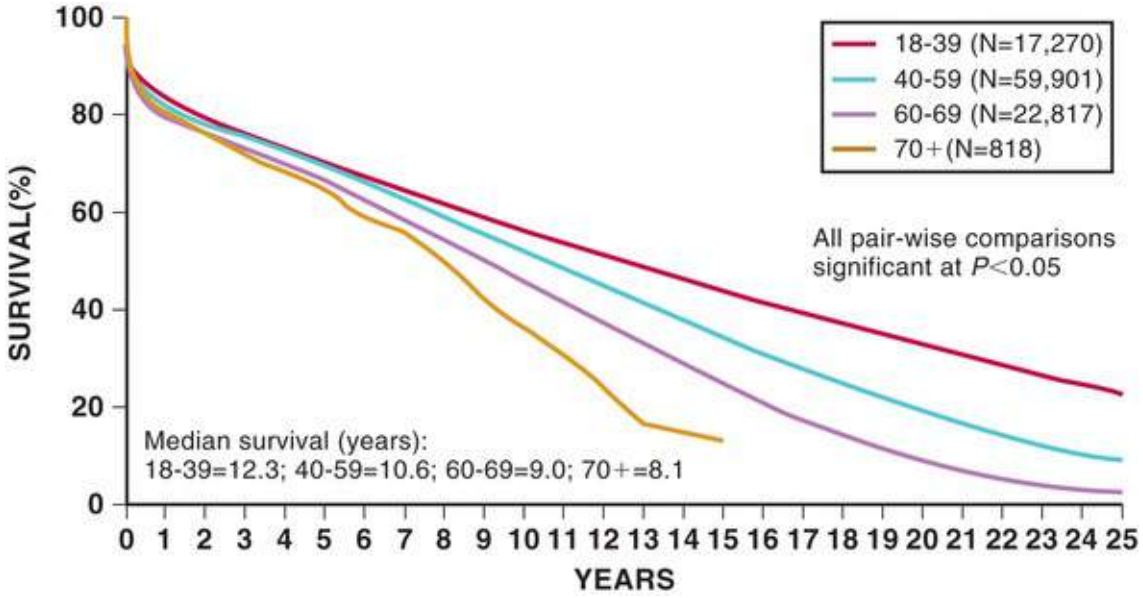

FIGURE 28.9 Kaplan-Meier long-term survival by age at transplant. (Transplants done between January 1982 and June 2013.) (From Lund LH, Edwards LB, Kucheryavaya AY, et al. The Registry of the International Society for Heart and Lung Transplantation: Thirty-second Official Adult Heart Transplantation Report—2015. Focus theme: early graft failure. J Heart Lung Transplant 2015;34:1244-54.)

Functional Outcomes

By the first year after transplantation surgery, 90% of surviving patients report no functional limitations, and approximately 35% return to work. These figures may change as the demographics of cardiac transplant recipients evolve. Numerous challenges to ensure optimal functional outcomes have been identified, including inadequate access to cardiac rehabilitation programs. Some U.S. employers are reluctant to hire the transplant survivor.

The heart transplant procedure greatly reduces cardiac filling pressures observed in the recipient before transplantation and augments cardiac output. Abnormal maximal cardiac output during exercise may be secondary to denervation, limited atrial function, decreased myocardial compliance from rejection or ischemic injury, and donor-recipient size mismatch. Much of this hemodynamic abnormality may be normalized with regular exercise. Immediately after surgery, a restrictive hemodynamic pattern frequently is observed that gradually lessens over a few days to weeks. Some 10% to 15% of recipients develop a chronic cardiac restrictive-type response during exercise that may produce fatigue and breathlessness. In the absence of parasympathetic innervation, which normally lowers the heart rate, the resting heart rate of a recipient typically is 90 to 115 beats/min. Likewise, beta blockers may further impair exercise response in the transplant recipient and should not be given as first-line agents for treatment of hypertension in this group.[71]

Future Perspectives

There are many potential reasons why surgery may be considered in patients with heart failure, especially those with ischemic cardiomyopathy. The most widely used surgical procedure for heart failure is coronary artery bypass grafting; the long-term results of the STICH trial results may impact the frequency of CABG in the future. Clearly, the immediate perioperative mortality for all surgical procedures has dropped remarkably over the past two decades. The availability of ventricular assist devices (VADs; **Chapter 29**) and less invasive procedures such as transcatheter aortic valve replacement (TAVR;

Chapter 72) will undoubtedly change the scope of HF surgery in the future. For the patient with advanced HF, a true comparative effectiveness trial between heart transplant and permanent VAD may be difficult, but the concept and the research required to undertake such a trial are often debated.

Mitral Valve Repair for Mitral Regurgitation in Ischemic Cardiomyopathy

Proponents of mitral valve repair (MVR) for functional mitral regurgitation (MR) argue that in appropriately selected patients, durable MVR will result in greater reverse left ventricular (LV) remodeling. Data to support this claim is also provided by several studies that evaluated MVR either alone or in combination with coronary artery revascularization for patients with ischemic disease. Braun and colleagues[1] showed that the combination of MVR and CABG resulted in a significant decrease in LV end-diastolic volume up to 4 years after surgery as a result of MVR. Fattouch and associates,[2] in a randomized study of coronary artery bypass grafting (CABG) versus CABG and MVR, demonstrated that the addition of MVR improves postoperative NYHA functional class and ventricular remodeling, decreases pulmonary artery pressure, and leads to a decrease in hospitalization for heart failure.[2] Although these studies are in contrast to the findings of the CTSnet prospective trial findings, they provide evidence to support the benefits of MVR in a subgroup of appropriately selected patients.

Several investigators have evaluated the combination of subvalvular repair techniques in addition to traditional restrictive annuloplasty to reduce recurrence of MR in the case of severe MR, including papillary muscle slings, papillary muscle relocation, anterior leaflet augmentation, and chordal cutting.[3,4] A recent randomized prospective trial evaluating the repair of severe ischemic MR ($n = 96$) with either isolated restrictive mitral annuloplasty or restrictive annuloplasty with papillary muscle reapproximation found a significant improvement in ventricular remodeling (LVEDD change, −5.8 ±4.1 mm vs. −0.2 ±2.3 mm; $P < 0.001$) and improvement in ejection fraction (mean change, +8.8 ±5.9% vs. 2.5 ±4.3%; $P < 0.001$) with the combination annuloplasty and papillary muscle reapproximation compared to restrictive

annuloplasty alone.[5] Interestingly, the authors noted only 15.0% and 13.2% recurrence of moderate to severe MR at 2 years, respectively, for the annuloplasty and annuloplasty and papillary muscle reapproximation groups. These reports provide further evidence for the role of MVR in severe functional MR that remains to be elucidated.

Passive Cardiac Support Devices

Novel surgical approaches have been undertaken to inhibit or to reverse LV remodeling, including passive cardiac support devices, which were developed from original observations with dynamic cardiomyoplasty, intended to act as an auxiliary pump for the failing heart.[1] Subsequent hemodynamic assessments in animals and humans have suggested that much of the observed benefit of dynamic cardiomyoplasty appeared to be derived from the passive girdling effect of the muscle wrap, which limits ventricular dilation, reduces LV wall stress, and prevents LV remodeling. These early experiences with dynamic cardiomyoplasty and the insights into its biologic effects led to the development of surgical therapies specifically aimed at inhibiting LV remodeling. Unfortunately, the two different cardiac support devices that have undergone clinical trials (Acorn Pivotal Trial and PEERLESS-HF) either were stopped for futility (PEERLESS-HF) or failed to show a convincing risk-to-benefit profile (Acorn Pivotal Trial), despite a long-term follow-up evaluation of the patients that did not identify any safety concerns and demonstrated apparently favorable outcomes. At present, no U.S. Food and Drug Administration (FDA)–approved cardiac support devices are available in the United States.

Mechanical Circulatory Support

Keith D. Aaronson, Francis D. Pagani

Mechanical circulatory support (MCS) devices are mechanical pumps designed to assist or replace the function of either the left or the right ventricle, or both ventricles, of the heart. Important characteristics of MCS devices include (1) location of the pumping chamber, (2) specific ventricle(s) supported, (3) pumping mechanism, and (4) indicated duration of support, for either temporary (days to weeks) or long-term (months to years) use (**Table 29.1**). Typically, short-term devices are *extracorporeal* (or *paracorporeal*) pumps (pump located outside the body), whereas durable devices are implantable (*intracorporeal*) systems.

TABLE 29.1

Terminology Describing Characteristics of Mechanical Circulatory Support (MCS) Devices

Pump Location
Extracorporeal: Pump located outside the body *Paracorporeal*: Pump located outside but adjacent to the body *Intracorporeal*: Pump implanted within the body *Orthotopic*: In the normal position of the heart (TAH)
Ventricle Supported
LV support (LVAD) RV support (RVAD) Biventricular support (BiVAD) Biventricular replacement (TAH)
Intended Use
Short-term: Days to weeks (BTR indication) 1. Patient remains hospitalized 2. Patient tethered to pump *Long-term*: Months to years (BTT or DT indication) 1. Patient discharged with untethered, "hands-free" mobility
Pump Mechanism[6,7]
Pulsatile flow, volume displacement with: 1. Pneumatic actuation, *or* 2. Electrical actuation *Continuous-flow* rotary pump with *axial design* (flow of blood is along axis of symmetry of pump) *and* 1. Bearing support of impeller (mechanical pivot), *or* 2. Magnetic or hydrodynamic levitation of impeller (bearingless design) *Continuous-flow* rotary pump with *centrifugal design* (flow of blood from center to periphery of pump) *and* 1. Bearing support of impeller, *or* 2. Magnetic or hydrodynamic levitation of impeller (bearingless design)

BiVAD, Biventricular support; *BTR,* bridge to recovery; *BTT,* bridge to transplantation; *DT,* destination therapy; *LVAD,* left ventricular assist device; *RVAD,* right ventricular assist device; *TAH,* total artificial heart.

Indications and Device Selection

Three indications for MCS are approved by the U.S. Food and Drug Administration (FDA) and reimbursed by the Centers for Medicare and Medicaid Services (CMS): bridge to recovery, bridge to transplantation, and destination therapy.

Bridge to Recovery

Bridge to recovery (BTR) refers to the use of MCS devices in patients with acute cardiogenic shock or acute decompensated heart failure that is refractory to optimal medical management (OMM), also characterized by a reasonable expectation that the myocardial injury is reversible and that myocardial function will recover during a short period of temporary MCS. The short-term use of MCS for BTR is the most common application of this modality in the United States. Examples of reversible forms of myocardial injury are acute myocardial infarction (AMI), acute myocarditis, and postcardiotomy cardiogenic shock resulting from ischemic myocardial stunning. Several types of devices can provide temporary circulatory support in these circumstances, including intra-aortic balloon pumps (IABP) (**Fig. 29.1**), surgically and percutaneously placed extracorporeal/paracorporeal ventricular assist devices (VADs) (**Figs. 29.2 to 29.4**), and systems for extracorporeal life support (**Fig. 29.5**), previously called extracorporeal membrane oxygenation, which provide both cardiac and pulmonary support. Typically, temporary MCS devices (e.g., IABP; Impella 2.5, CP, and 5.0; TandemHeart) are placed percutaneously to facilitate rapid initiation of cardiac support and ease of removal when cardiac function recovers. Some types of extracorporeal VAD systems require major operative procedures with sternotomy for access and

placement of the outflow and inflow cannulas and more frequently are initiated in the operating room for postcardiotomy heart failure (**Fig. 29.2**).

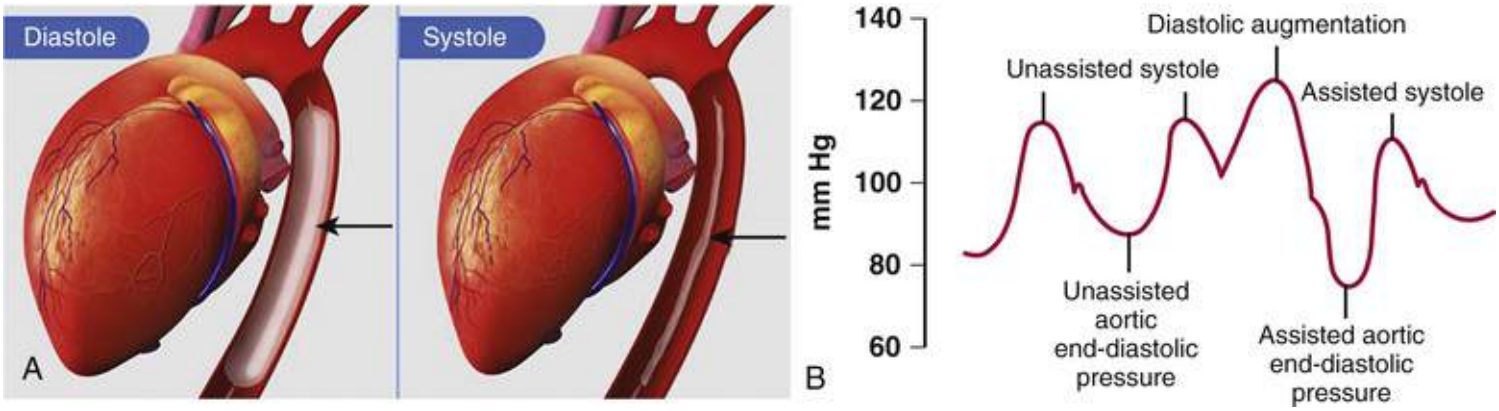

FIGURE 29.1 **A,** Intra-aortic balloon pump (IABP) positioned in descending aorta and inflated during diastole (increasing diastolic blood pressure and coronary perfusion) and deflated during systole (reducing ventricular afterload). **B,** Aortic pressure tracing during IABP support. Balloon counterpulsation is occurring after every other heartbeat (1 : 2 counterpulsation). With correct timing, balloon inflation begins immediately after aortic valve closure, signaled by the dicrotic notch of the arterial waveform. Compared with unassisted ejection, the pump augments diastolic blood flow by increasing peak aortic pressure during diastole. Balloon deflation before systole decreases ventricular afterload, with lower aortic end-diastolic pressure and lower peak systolic pressure.

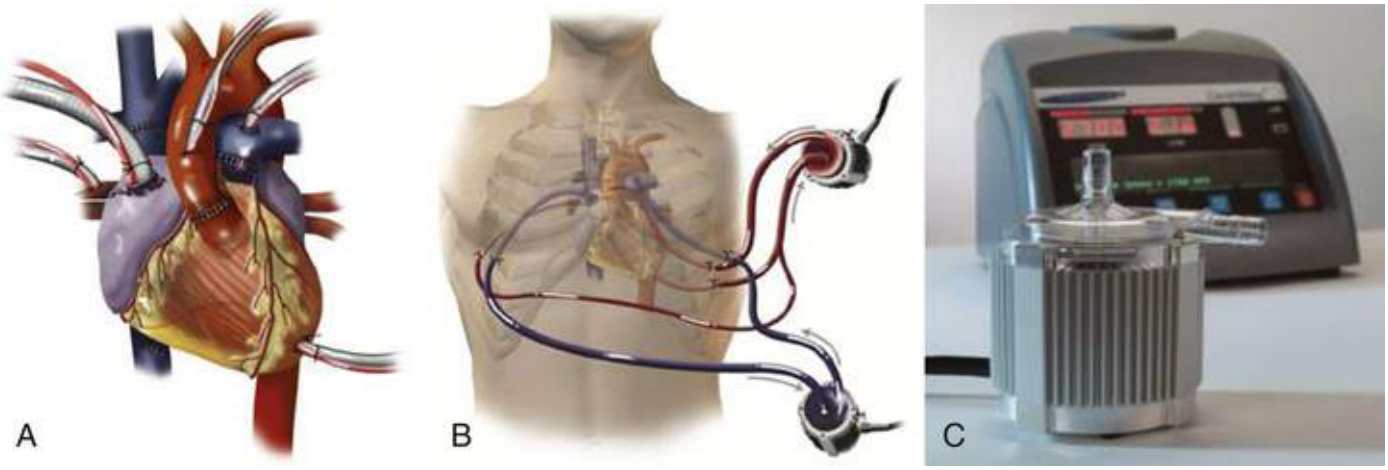

FIGURE 29.2 Temporary extracorporeal mechanical circulatory support—CentriMag Ventricular Assist System (St. Jude Medical, Minneapolis, Minn). **A,** Surgically implanted cannula for biventricular support configuration. *Left ventricular support*: A cannula is positioned in the right superior pulmonary vein and drains blood from the left atrium and pumps it back to the aorta. *Right ventricular support*: A cannula positioned in the right atrial appendage drains blood from the right atrium and pumps it to the main pulmonary artery. **B,** Cannula connected to external blood pumps (extracorporeal pumps). **C,** The CentriMag is a continuous-flow rotary pump with centrifugal design and full magnetic levitation of the internal rotor.

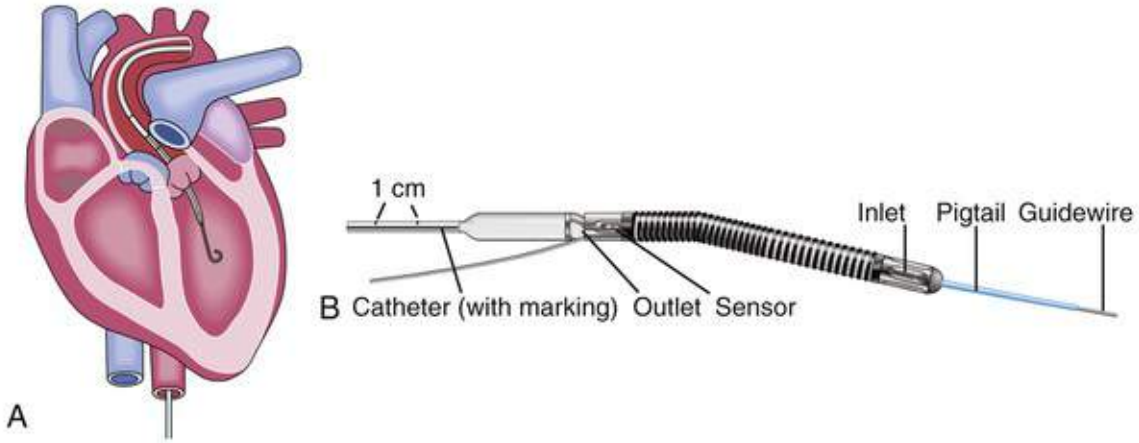

FIGURE 29.3 Temporary mechanical circulatory support—Impella (Abiomed, Danvers, Mass). **A,** The Impella is a continuous-flow, microaxial pump designed to propel blood from the left ventricle into the ascending aorta, in series with the left ventricle. The tip is positioned within the left ventricle, and blood is pumped from the left ventricle into the ascending aorta. **B,** The tip of the catheter is a flexible pigtail loop that stabilizes the device within the left ventricle. The catheter connects to a 12F (Impella 2.5), 14F (Impella CP), or 21F (Impella 5.0) cannula that contains the pump inlet and outlet areas, motor housing, and pump-pressure monitor. The proximal end of the catheter is connected to the external pump. (From Thunberg CA, Gaitan B, Arabia FA, et al. Ventricular assist devices today and tomorrow. J Cardiothorac Vasc Anesth 2010;24:656.)

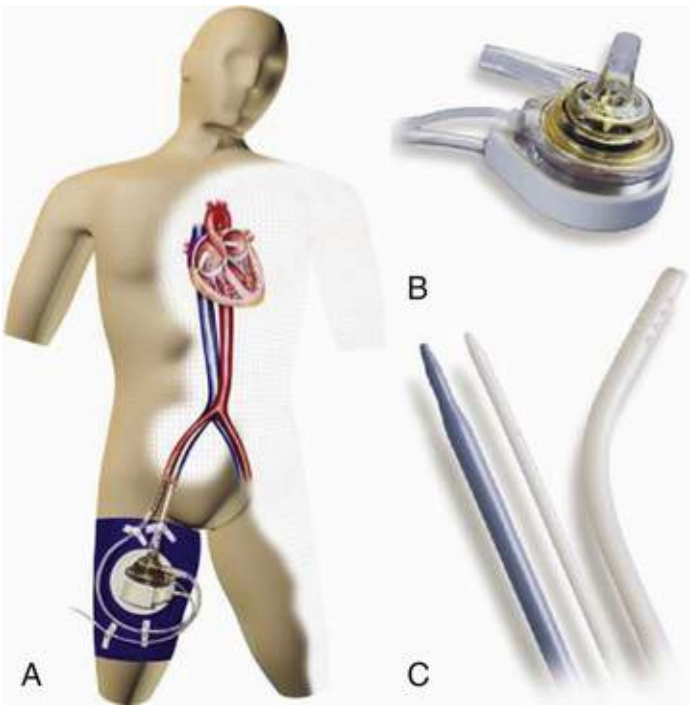

FIGURE 29.4 Temporary mechanical circulatory support—TandemHeart pVAD (CardiacAssist, Pittsburgh). **A,** The TandemHeart has four components: a centrifugal pump with hydrodynamic levitation of the internal rotor positioned on the right thigh **(B),** a 21F transseptal cannula **(C),** a femoral arterial cannula, and a control console.

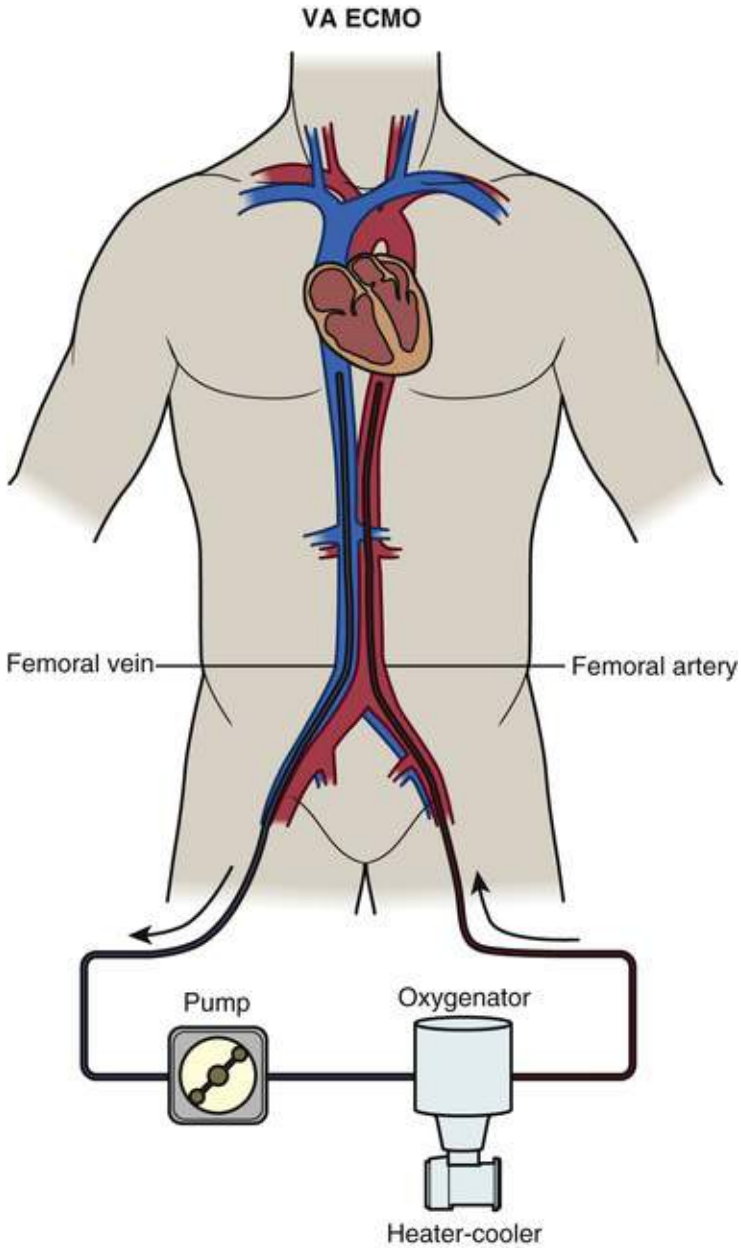

FIGURE 29.5 Extracorporeal life support (ECLS) or extracorporeal membrane oxygenation (ECMO) circuit. The ECMO circuit is used to establish rapid initiation of mechanical circulatory support. The circuit consists of a pump (typically a centrifugal pump system), oxygenator, and heater-cooler element. A typical configuration for emergent application of ECMO is percutaneous placement of cannulas in the femoral vein and femoral artery.

The assumption that the mechanism of myocardial injury is reversible may not be applicable in all clinical situations where the patient presents with significant hemodynamic compromise and significant organ injury. Temporary MCS may be instituted with good expectation of clinical improvement, with subsequent recognition that myocardial recovery is unlikely to occur or has not occurred despite an extended period of support. In such situations, temporary MCS can be continued as a bridge to placement of a long-term, implantable VAD (*bridge to bridge* [BTB] application), or as a bridge to heart transplantation. The use of temporary MCS in this way is not an approved indication but occasionally may be appropriate because of the inherent difficulties in accurately assessing the potential for myocardial recovery in all clinical settings. As a rule, *patients should be excluded from consideration for temporary MCS if myocardial recovery is unlikely and the option of heart transplantation or implantation of a long-term, durable VAD is not feasible*. In these patients, MCS generally is considered futile and should not be instituted.

Bridge to Transplantation

The second indication for MCS applies to patients presenting with cardiogenic shock or decompensated advanced heart failure (HF) refractory to OMM in whom myocardial function is unlikely to recover (e.g., longstanding ischemic, valvular, or idiopathic cardiomyopathy; severe AMI or myocarditis), and who are considered eligible for heart transplantation. Durable, implantable MCS devices designed for long-term use that permit untethered patient mobility and discharge from the hospital are appropriate devices for bridge to transplantation (BTT) indication (**Figs. 29.6 to 29.8**). A major operative procedure, including cardiopulmonary bypass (CPB), is required for placement in most patients, although newer, small-device designs permit less invasive implant techniques without CPB. These devices ideally are placed in patients with significant symptoms of HF who are either receiving intravenous (IV) inotropes or who are not on inotropes but have limiting symptoms at rest, and in whom hemodynamics are stable and end-organ function is preserved or slowly deteriorating. Select patients with acutely unstable hemodynamics and compromised organ function may be better served by a BTB strategy consisting of temporary MCS, followed by placement of a durable MCS device only for those who respond with improvements in hemodynamics and organ function.

FIGURE 29.6 Implantable durable left ventricular assist device—HeartMate 3 (HM3, St. Jude Medical). **A,** The HM3 LVAD is a continuous-flow rotary pump with centrifugal design and complete magnetic levitation of the internal rotor. The blood pump is positioned within the pericardial space, with its integral inflow conduit in the left ventricle and outflow graft (*not shown*) attached to the ascending aorta. The percutaneous power cable is tunneled through the abdominal wall and is attached to the system controller that receives power from two lithium-ion batteries. The implanted components include the inflow cannula, pump housing, motor, control electronics, outflow graft and bend relief, and percutaneous driveline. The HM3 uses a centrifugal flow pump that has a capacity to pump blood up to 10 L/min. LV blood is drawn into the inflow cannula along a central axis and is expelled at right angles by and between the impeller blades of a rotor rotating about the central axis. Blood is angularly accelerated and travels around a volute before it is diffused to a desired pressure and flow rate by being directed tangentially into the outflow graft. The pump rotor is fully supported by magnetic levitation, obviating mechanical or fluid bearings and essentially eliminating mechanical wear as a reliability factor. Both drive (i.e., rotation) and levitation of the rotor is accomplished using a single stator comprising iron pole pieces, a back-iron, copper coils, and position sensors. Measuring the position of a permanent magnet in the rotor and controlling the current in the drive and levitation coils enables active control of the radial position and rotational speed of the rotor. Because the permanent magnet is attracted to the iron pole pieces, the rotor passively resists excursion in the axial direction, whether translating or tilting. The electronics and software necessary to control motor drive and levitation are integrated into the lower housing with the stator; these components plus the rotor comprise the motor. **B,** Cross section of an implantable durable continuous-flow rotary pump with centrifugal design and complete magnetic levitation of the internal rotor. The rotor (*R*) is magnetically levitated by electromagnetic coils (*C*) and rotated by motor drive coils (*D*). The levitated rotor produces wide recirculation passages radially (*P1*) and axially (*P2*). A second axial passage beneath the rotor is hidden in this view. Motor electronics (*E*) are incorporated into the implantable pump. (From Heatley G, Sood P, Goldstein D, et al. Clinical trial design and rationale of the Multicenter Study of MagLev Technology in Patients Undergoing Mechanical Circulatory Support Therapy with HeartMate 3 (MOMENTUM 3) investigational device exemption clinical study protocol. J Heart Lung Transplant 2016;35:528.)

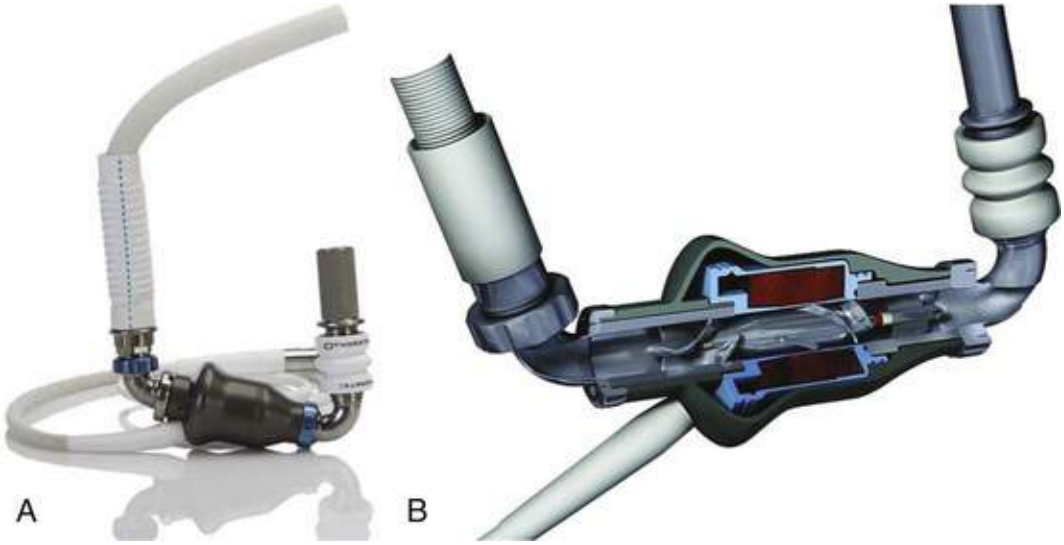

FIGURE 29.7 Implantable durable left ventricular assist device—HeartMate II (St. Jude Medical, Minneapolis, Minn). **A,** The HeartMate II LVAD is a continuous-flow rotary pump with axial design and mechanical support of the internal rotor. The device is positioned outside the pericardial space in a preperitoneal pump pocket. The inlet cannula is inserted into the apex of the left ventricle, and the outflow graft is attached to the ascending aorta. **B,** Internal view of the HeartMate II device demonstrating blood flow path with internal rotor containing a magnet suspended by mechanical pivots (stators) and external wiring (coils), creating a rotating magnetic field that spins the rotor (and internal magnet).

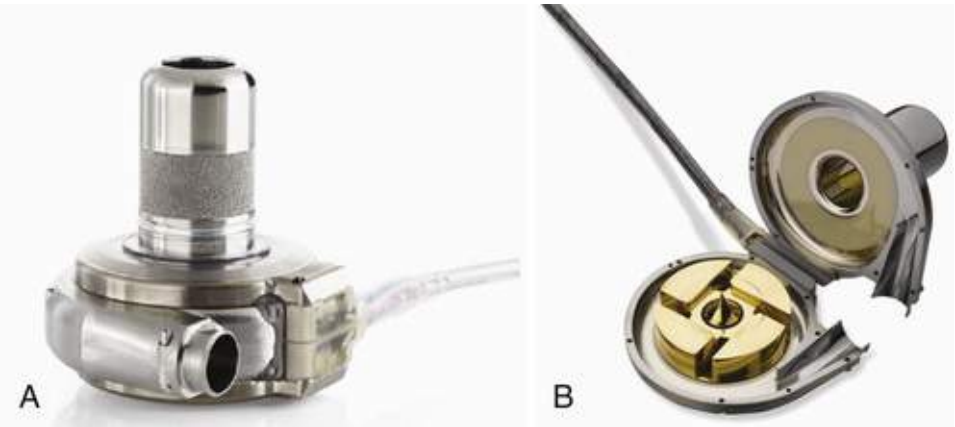

FIGURE 29.8 Implantable durable left ventricular assist device—HVAD (Medtronic, Minneapolis, Minn). **A,** The HVAD LVAD is a continuous-flow rotary pump with centrifugal design and hydrodynamic and magnetic levitation of the internal rotor. The pump is positioned within the pericardial space with the integrated inlet cannula positioned within the apex of the left ventricle and the outflow graft (*not shown*) sewn to the ascending aorta. The percutaneous driveline traverses the skin and attaches to an external controller and power source (batteries). **B,** Internal view of the pump demonstrating internal rotor that is levitated by magnets (passive magnetic field) positioned in the impeller and central post. Hydrodynamic forces generated by the top surface of the impeller stabilize impeller position.

Destination Therapy

The feasibility of durable, implantable MCS devices to provide long-term support demonstrated through the BTT experience prompted further expansion of indications for durable, implantable MCS devices as a permanent alternative to heart transplantation. Destination therapy (DT) is the application of MCS in patients with chronic refractory symptoms of advanced HF that result from irreversible forms of either nonischemic or ischemic cardiomyopathy and who are ineligible for heart transplantation. Use of durable, implantable devices that permit untethered “hands-free” patient mobility at home is appropriate in this

clinical situation. A major operative procedure is required for placement of these implantable pumps, which, as in the setting of BTT, are ideally used in patients with significant symptoms of advanced HF but stable hemodynamics and no manifestations of significant organ injury, frailty, or cachexia. The benefits of MCS for DT, in terms of survival, function, and quality of life, for the treatment of chronic advanced HF were established in a prospective, randomized trial known as REMATCH (Randomized Evaluation of Mechanical Assistance in the Treatment of Congestive Heart Failure).[1] REMATCH evaluated the use of an implantable left ventricular assist device (LVAD) compared with OMM for refractory chronic advanced HF. LVAD therapy halved (relative risk [RR], 0.52; 95% confidence interval [CI] 0.34 to 0.78) the mortality seen in the control population (92% at 2 years) treated with OMM. Despite serious adverse events (e.g., stroke, infection, bleeding, device malfunction) attributable to MCS, LVAD recipients experienced a better quality of life than those in the OMM group.

Patients evaluated for DT must meet specific criteria for reimbursement from CMS that include (1) ineligibility for heart transplantation; (2) significant functional limitations consistent with New York Heart Association (NYHA) Class IIIB or IV symptoms for 45 of the preceding 60 days, despite the use of maximally tolerated doses of drugs outlined in guidelines for heart failure treatment; (3) left ventricular ejection fraction (LVEF) less than 25%; and (4) a peak exercise oxygen consumption (peak VO_2) of 14 mL/kg/min or less, unless the patient is dependent on IV inotropes for 14 days or IABP for 7 days.[2] Although the current reimbursement framework requires determination of DT or BTT status, it is often not possible when assessing VAD candidacy to accurately determine future transplant eligibility. Many patients present with hemodynamic compromise, significant pulmonary hypertension, organ injury, cachexia, or debilitation, all of which represent relative contraindications to heart transplantation but may be reversible with a period of MCS.

The terms *bridge to candidacy* (BTC) and *bridge to decision* (BTD) reflect the unknown efficacy of MCS therapy to reverse the clinical conditions that represent relative barriers to heart transplantation. In a similar vein, patients receiving MCS for BTT indication may experience significant complications after implantation of an MCS device that could adversely affect transplantation candidate status. Although BTC or BTD more accurately reflects the dynamic state of transplant eligibility, BTC and BTD are not recognized by the FDA as an approved indication for use of MCS therapy (nor by CMS as eligible for coverage). Recent clinical trials investigating new devices for durable VAD therapy have attempted to reframe VAD candidacy without reference to transplant candidacy by using patient characteristics and physiologic parameters to define an indication for "long-term support."[3] In the future, this unifying indication of long-term support with coverage determination likely will encompass MCS therapy with durable devices for long-term support independent of transplant eligibility.

The decision to initiate MCS must include an analysis of the intended use and clinical setting, patient variables and conditions, the type of MCS devices available for the selected indication, medical society guidelines for use of the device, and financial considerations.

Design of Ventricular Assist Devices

An MCS pump or pumps may be positioned extracorporeally (outside the body) (**see Figs. 29.1 to 29.5**) or intracorporeally (contained within the body) (**see Figs. 29.6 to 29.8**) as a biventricular assist device

(BiVAD), a right ventricular assist device (RVAD), or more often an LVAD. The pump's flow characteristic further substratifies it as *pulsatile flow* or *continuous flow*. The older-generation, pulsatile-flow, volume-displacement pumps, such as the HeartMate XVE and Novacor LVAS, were large, preload dependent, and associated with decreased durability and are now of only historical interest.[4] Newer-generation continuous-flow pumps are smaller, capable of a similar degree of pumping support (6 to 10 liters per minute [L/min]), more durable, and functionally dependent on both preload and afterload. These include the HeartMate 3 (HM3; **Fig. 29.6**), the HeartMate II (**Fig. 29.7**), and HVAD (**Fig. 29.8**).[5-9] Additional content on this topic is presented in the online supplement for this chapter (Engineering Designs of Ventricular Assist Devices) (**Fig. 29.9**). The improvements in design attributes of the newest continuous-flow pump (HM3) with centrifugal design, including complete magnetic levitation of the internal rotor, decreased mechanical wear, operation at low flow, and perceived improved potential for hemocompatibility, are currently under investigation in the MOMENTUM clinical trial.[8,9]

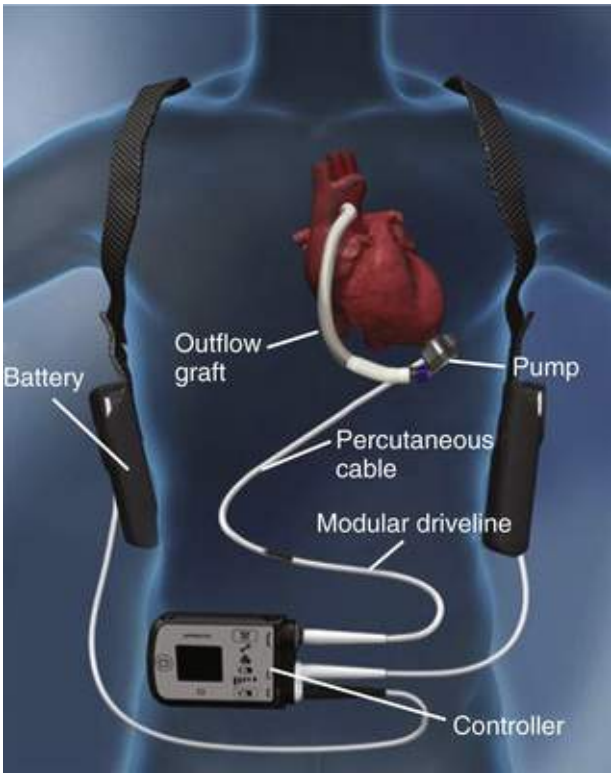

FIGURE 29.9 Typical configuration for a wearable durable LVAD. The pump is attached to the apex of the left ventricle, and the outflow graft is attached to the ascending aorta. The power supply for implantable pumps is delivered through a percutaneous lead (also referred to as driveline) that traverses the skin and connects the external power system (batteries or stationary power unit) with the internal pump. The external components of an implantable system generally consist of a power source (i.e., batteries or an AC power unit) and a small, portable computer (controller) that controls device speed and monitors device function.

Patient Selection, Comorbidity, and Timing of Intervention

Appropriately timing the initiation of MCS is crucial to obtaining good patient outcomes. There are no absolute hemodynamic criteria to meet in order to initiate MCS for any indication. Generally, patients presenting with acute forms of myocardial injury exhibit recognizable changes in hemodynamics. A

cardiac index less than 1.8 to 2.2 L/min/m^2, systolic blood pressure less than 90 mm Hg, pulmonary capillary wedge pressure (PCWP) greater than 20 mm Hg, and evidence of poor tissue perfusion, reflected by oliguria, rising creatinine and liver transaminases, mental status changes, or cool extremities, despite the use of OMM, constitute general guidelines for initiation of MCS.[10] Patient history and overall clinical setting also need to be considered in the decision. When the patient reaches this degree of hemodynamic compromise, the risk of death is substantial, more than 50% at 30 days, despite the availability of OMM, invasive circulatory monitoring, thrombolysis, and IABP support.[11]

More subtle indications to initiate MCS may be present, particularly in patients with chronic advanced HF who are being evaluated for BTT or DT. These indications include resting tachycardia, progressive organ dysfunction, and persistent significant HF symptoms resulting in limited functional capacity and poor quality of life despite OMM, with or without inotrope therapy. In chronic HF patients who had previously maintained good end-organ function and functional performance despite substantially compromised hemodynamics, deterioration in end-organ function or progressive decline in functional performance may occur in the absence of any significant change in hemodynamic parameters. Ambulatory patients with NYHA Class IIIB or IV symptoms who do not tolerate OMM for advanced HF, or who experience renal insufficiency or hypotension with optimal dosages of angiotensin-converting enzyme (ACE) inhibitors or beta blockers, may need evaluation for MCS therapy. Patients who require inotrope therapy or who do not tolerate inotrope therapy as a result of refractory ventricular arrhythmias, or those who have life-threatening coronary anatomy and unstable angina not amenable to revascularization and are at risk of imminent death (hours, days, or weeks), may be considered for MCS without necessarily meeting hemodynamic criteria.

Renal Function

Renal dysfunction has consistently been one of the greatest risks for morbidity and mortality with the use of MCS.[12] Renal dysfunction often is secondary to decreased perfusion of the kidney in cardiogenic shock or advanced HF but also may be caused by nephrotoxic effects of drugs used for HF therapy, intrarenal hemodynamic derangements reflecting overactivity of the renin-angiotensin-aldosterone (RAAS) and sympathetic nervous systems in advanced HF, and immune-mediated nephrotoxicity or complications of noncardiac comorbidity. In patients with shock or advanced HF, it is difficult to assess the reversibility of renal dysfunction. Acute onset of renal failure requiring renal replacement therapy is not necessarily a contraindication to initiate short-term MCS but may be a greater obstacle to successful long-term support with implantable devices for BTT and in particular, DT. In the setting of cardiogenic shock with acute renal failure, establishing normal hemodynamics with MCS may resolve the renal failure in a relatively short period. However, a preimplant creatinine clearance of less than 30 mL/min/m^2 is associated with a 22% 3-month mortality in recipients of a continuous-flow LVAD, and this constitutes a contraindication to durable LVAD implantation at most centers.[12] Thus the degree and duration of cardiogenic shock, along with the patient's baseline renal function, must be considered in estimating the probability of recovery of renal function.

Pulmonary Function

Heart failure may be associated with a restrictive pattern on pulmonary function testing. However, this often improves with removal of interstitial fluid and pleural effusions after placement of an MCS device and resolution of lung congestion. Patients with a long history of smoking or a history of other intrinsic lung disease with significant abnormalities on pulmonary function testing—for example, less than 50% of

predicted normal value for forced vital capacity (FVC), forced expiratory volume at 1 second (FEV_1), or diffusion capacity for carbon monoxide (DL_{CO})—should undergo high-resolution computed tomography (CT). Patients with low oxygen saturation (<92%) on room air also require evaluation with echocardiography to rule out a right-to-left shunt from an atrial septal defect or patent foramen ovale; if results are negative, spiral (helical) CT or radionuclide scanning (in patients without pulmonary abnormalities on chest radiography) is warranted to rule out thromboembolic disease. Patients with severe pulmonary disease may have an elevated pulmonary vascular resistance (PVR) that is fixed (not responsive to pulmonary artery vasodilators). High fixed PVR (thresholds vary from 3 to 6 Wood units) represents a contraindication to heart transplantation and consequently to use of LVAD for BTT indication. Moderate elevations in PVR can be encountered in patients with cardiogenic shock and especially in those with long-established HF and does not preclude successful use of LVAD, if lowering of PVR (reversibility) is achieved with inotropes or pulmonary vasodilators. PVR frequently declines a few months after LVAD implantation, so patients deemed not transplantable because of elevated PVR at the time of implant may later become eligible. Perioperative hypoxia secondary to significant underlying lung disease also may contribute to pulmonary vasoconstriction, leading to right ventricular (RV) failure after institution of VAD support. Sleep apnea is present in a significant number of patients with HF, which may contribute to pulmonary hypertension.

Hepatic Function

Preoperative total bilirubin level and hepatic cellular enzyme levels more than three times normal are independent risk factors for RV failure and reduced survival following LVAD implantation. The etiology of the hyperbilirubinemia may be multifactorial, including congestive hepatopathy, cirrhosis, or a combination of causative disorders. Abnormal liver function often is associated with abnormal coagulation factors, as well as low serum albumin. Attempts should be made to normalize all indices of liver function and the cause(s) of any abnormalities preoperatively. The presence of portal hypertension with liver cirrhosis is a contraindication to initiating MCS support. A history of significant alcohol use should be ruled out in all potential candidates for MCS therapy, especially those with abnormal liver function. Patients also should be tested for previous infection with hepatitis A, B, or C virus or others. Ultrasound visualization of the liver is a good screening test in patients with significant hepatomegaly to rule out infiltrative disease, mass, or other pathologic condition that may warrant biopsy. Decrease in hepatic congestion and recovery of synthetic functions can occur with institution of MCS.

Right Ventricular Function

Patients with advanced HF frequently have coexisting RV failure. This entity may be a major contributor to mortality or morbidity after initiation of MCS.[13-16] RV failure in most patients is a result of LV failure. Patients with a nonischemic etiology often present with significant RV failure and may have a three- to fourfold increased risk of requiring both LV and RV support. Patients who require BiVAD support have significantly higher preoperative creatinine and total bilirubin levels and a greater need for mechanical ventilation before MCS device insertion than patients requiring LVAD support only. The need for BiVAD support is associated with substantially worse survival with both short-term and long-term MCS devices because of a greater degree of compromised preoperative organ function.[13] RV failure is a prominent factor leading to renal dysfunction after LVAD implantation, because significantly elevated right atrial (RA) pressures lead to changes in glomerular filtration from cortical to medullary nephrons, with secondary reduction in urine output and resistance to diuretic therapy. Preoperative optimization of RV function with a goal RA pressure ideally at 10 mm Hg is important in reducing the need for postoperative RV support. The higher the left atrial (LA) pressure or PCWP at device implantation, the greater is the

benefit to the right ventricle and pulmonary artery pressure when the left ventricle is totally unloaded and LA pressure falls. Postoperative recovery of RV function, however, may lag for several days, because total decompression of the left ventricle allows a significant shift of the interventricular septum toward the left ventricle, with further distention and dysfunction of the right ventricle.[16-19]

Coagulation
